ABSTRACT

Short-lived radioactive isotopes (SLRs) with half-lives between 0.1 to 100 Myr can be used to probe the origin of the Solar System. In this work, we examine the core-collapse supernovae production of the 15 SLRs produced: ²⁶Al, ³⁶Cl, ⁴¹Ca, ⁵³Mn, ⁶⁰Fe, ⁹²Nb, ⁹⁷Tc, ⁹⁸Tc, ¹⁰⁷Pd, ¹²⁶Sn, ¹²⁹I, ¹³⁵Cs, ¹⁴⁶Sm, ¹⁸²Hf, and ²⁰⁵Pb. We probe the impact of the uncertainties of the core-collapse explosion mechanism by examining a collection of 62 core-collapse models with initial masses of 15, 20, and 25 M_{\odot} , explosion energies between 3.4×10^{50} and 1.8×10^{52} ergs and compact remnant masses between $1.5 M_{\odot}$ and $4.89 M_{\odot}$. We identify the impact of both explosion energy and remnant mass on the final yields of the SLRs. Isotopes produced within the innermost regions of the star, such as ⁹²Nb and ⁹⁷Tc, are the most affected by the remnant mass, ⁹²Nb varying by five orders of magnitude. Isotopes synthesised primarily in explosive C-burning and explosive He-burning, such as ⁶⁰Fe, are most affected by explosion energies. ⁶⁰Fe increases by two orders of magnitude from the lowest to the highest explosion energy in the 15 M_☉ model. The final yield of each examined SLR is used to compare to literature models.

Key words: Stellar types: Massive stars – Supernovae – Nucleosynthesis

1 INTRODUCTION

Radioactive isotopes are useful tools to determine the age of objects. On Earth, $^{14}\mathrm{C}$ (with a half-life, $\mathrm{t_{\frac{1}{2}}}$, of 5730 yr) is used to measure timescales relative to human history. In the Universe, long lived isotopes ($\mathrm{t_{\frac{1}{2}}}\approx\mathrm{Gyr}$) such as $^{232}\mathrm{Th}$ or $^{238}\mathrm{U}$ are used to measure cosmological timescales like the age of the Galaxy (Dauphas 2005). The process of the formation of the Sun, starting from the formation of its molecular cloud, lasts between 15 years (Hartmann et al. 2001; Murray 2011), therefore, in order to probe this time period we examine isotopes that have comparable decay times. We use radioactive isotopes with half-lives between 0.1 and 100 Myr (short-lived radionuclides: SLRs, henceforth) as chronometers for understanding the birth of the Sun. The abundances

of SLRs in the early Solar System (ESS) are derived from meteoritic analysis.

SLR signatures can be used alongside expected contributions from galactic chemical evolution (GCE) to identify the time elapsed from production to being incorporated into the ESS; this is referred to as the so-called 'isolation time' (Côté et al. 2019a,b; Yagüe López et al. 2021). SLRs with the shortest half-lives completely decay over long timescales (~100 Myr). Therefore, to explain the abundance of the shortest lived isotopes, such as 26 Al, 36 Cl and 41 Ca (half lives of these isotopes can be found in Table 1), we require additional, local sources that are close in both time and space (Huss et al. 2009). These local sources may have polluted either the molecular cloud or the proto-solar disk (see the review by Lugaro et al. 2018).

SLR	Daughter	Reference	$\mathrm{T}_{1/2}~(\mathrm{Myr})$
²⁶ Al	^{26}Mg	²⁷ Al	0.72
$^{36}\mathrm{Cl}$	^{36}S	³⁵ Cl	0.30
^{41}Ca	^{41}K	^{40}Ca	0.099
$^{53}\mathrm{Mn}$	$^{53}\mathrm{Cr}$	^{55}Mn	3.7
60 Fe	⁶⁰ Ni	$^{56}\mathrm{Fe}$	2.6
^{92}Nb	92 Zr	⁹² Mo	34
$^{97}\mathrm{Tc}$	⁹⁷ Mo	98 Ru	4.2
$^{98}\mathrm{Tc}$	98 Ru	98 Ru	4.2
$^{107}\mathrm{Pd}$	^{107}Ag	108 Pd	6.5
^{126}Sn	¹²⁶ Te	^{124}Sn	0.23
¹²⁹ I	129 Xe	^{127}I	15
^{135}Cs	^{135}Ba	^{133}Cs	2.3
$^{146}\mathrm{Sm}$	^{142}Nd	^{144}Sm	68
$^{182}\mathrm{Hf}$	^{182}W	$^{180}\mathrm{Hf}$	8.9
²⁰⁵ Pb	205Tl	²⁰⁴ Pb	17

Table 1. SLRs considered in this work. SLRs are listed with daughter isotopes, reference isotopes and Half-lives $(T_{1/2})$. Data gathered from Lugaro et al. (2018).

Huss et al. (2009) presented a comparison of the potential sources of SLRs into the ESS, concluding that intermediate-mass asymptotic giant branch (AGB) stars and massive stars between 20–60 M_{\odot} provide the most feasible sources. The AGB scenario has been considered (see Wasserburg et al. 2017) and compared to massive stars (Vescovi et al. 2018). The latter find that the contamination of a solar nebula by a single core-collapse supernova (CCSN) event should also pollute stable isotopes to excess. Meyer & Clayton (2000) examines the different SLR yields in the Solar System and the values expected from GCE approaches, including a comparison to the massive star models of Meyer et al. (1995).

A popular ESS pollution scenario is a single CCSN event, which polluted the material that formed the Solar System. A supernova could also explain the formation of the Solar System itself, by shocking the gas cloud that would go on to form the Solar System (as first proposed by Cameron & Truran (1977)). During this shock we can expect the ejecta of this supernova event to enrich the cloud (Gritschneder et al. 2012) or the disk (Portegies Zwart et al. 2018). Boss & Keiser (2014) and Boss (2017) show that a collapse caused by a supernova can explain both $^{60}\mathrm{Fe}$ and 26 Al, but a problem with this is that it can lead to an overenhancement of ⁵³Mn up to three orders of magnitude. The $^{53}\mathrm{Mn}$ over production can be solved by allowing a larger fallback during the CCSN (see Takigawa et al. 2008), where fallback is defined as the inner region of the star that collapses onto the neutron star or black hole remnant. A chemo hydro-dynamical simulation of the entire Milky Way Galaxy by Fujimoto et al. (2018) examined the impact of individual CCSNe to SLR abundances, finding that pollution by CC-SNe provides significant amounts of 26 Al and 60 Fe. However, this work considered only two SLRs.

Previous works that examine CCSN scenario yields have only examined a selection of SLRs. Timmes et al. (1995) examined the GCE component of ²⁶Al and ⁶⁰Fe in the Milky Way using the CCSN yields from Woosley & Weaver (1995). Meyer et al. (1995) examined the yield for the ejecta of a 25 M_{\odot} star, including yields for ²⁶Al, ³⁶Cl, ⁴¹Ca, ⁵³Mn and ⁶⁰Fe. In this work we continue the work done by Jones et al. (2019) and Andrews et al. (2020) to study the production of radioactive isotopes in CCSNe. Our nucleosynthesis simulations cover the full range of explosion parameters as described in Fryer et al. (2018). We aim to study the production of all SLRs presented in Table 1 in CCSNe (Lugaro et al. 2018). In particular, we discuss the impact of the explosion parameters affecting the production of the SLRs in CCSN ejecta.

The paper is organized as follows. In Section 2 we describe the stellar models and the nucleosynthesis code. In Section 3, we present the results for the production and abundances of the SLRs. The discussion about the impact of model parameters on the SLR abundances and the comparison with other models are given in Section 4. In Section 5, we summarize our results.

2 SIMULATIONS

We first describe the CCSN models used in this work, in particular which parameters are altered, as well as the method of pre-explosive and explosive nucleosynthesis. We then give a brief explanation of the nucleosynthesis that has taken place, calling into focus the key explosive nucleosynthesis sites.

2.1 Methods and Models

We use the CCSN models calculated by Fryer et al. (2018) on the basis of three progenitor models with initial masses of 15, 20 and 25 M_{\odot} computed by Heger & Woosley (2010) with the KEPLER code (Weaver et al. 1978; Woosley & Weaver 1995) and with initial metallicity (Z) of 0.02 (Grevesse & Noels 1993). The explosions of each progenitor were calculated using a 1-dimensional Lagrangian hydrodynamic code, to mimic a 3-dimensional convective engine (Fryer et al. 1999; Herant et al. 1994) by injecting energy above the proto-neutron star with three free parameters: the mass at which the energy is injected, the length of time of the energy injection, and the total energy injected. Fryer et al. (2018) use these three parameters to study the uncertainty of the explosive engine, and to determine the uncertainty on the remnant mass and isotopic yield of each explosion model. The compact remnant left after core-collapse and fallback will form either a neutron star or black hole, depending on the final mass of the compact object. The heaviest neutron star known is MSP J0740+6620, with a mass of $2.14^{+0.18}_{-0.20}$ M_{\odot} (Cromartie et al. 2020). In general, we may assume that remnants with masses lower than MSP J0740+6620 form neutron stars, while heavier remnants will form black holes. Theoretical simulations of the critical mass boundary dividing neutron star and black hole formation are affected from several uncertainties, among others from the Equation of State to use for the neutron star interior (e.g., Ozel & Freire 2016). Therefore, at present the observations of the most massive neutron stars provides the best available constraint of such a mass boundary.

From this parameter study we examine 17, 23 and 22 models of progenitor mass 15, 20, and 25 M_{\odot} , respectively. The ranges of the values of the explosion energy and remnant mass are listed in Table 2, with each model's specific resultant explosion energy and remnant mass of the compact

M _{prog}	Model	$\mathop{\rm E_{exp}}\limits_{(\times 10^{51} {\rm ~ergs})}$	M _{rem}
(M _☉)	count		(M _☉)
$15 \\ 20 \\ 25$	17	0.34 - 10.7	1.50 - 1.94
	23	0.53 - 8.86	1.74 - 3.40
	22	0.89 - 9.73	1.83 - 4.89

Table 2. Parameters of CCSN explosion models: M_{prog} is the zero age main sequence mass, E_{exp} is the explosion energy, and M_{rem} is the final mass of the compact object left from the SN explosion (a Neutron Star or a Black Hole).

object listed in Tables A1–A5 (Fryer et al. 2018). As a result of the parameter space explored by Fryer et al. (2018), a large range of explosion energies and remnant masses are given for each stellar progenitor. We note that when describing a model we use the term "mass cut" to define a point in mass below which material falls back back onto the compact remnant. Mass cut is commonly determined by placing it where the ejected yield of 56 Ni is in agreement with CCSN light curves, however in the models examined here mass cut is based on the physical properties of the explosion (See Section 2 of Fryer et al. 2018, for a description).

We perform the nucleosynthesis calculations using Nu-Grid post-processing tools, described in detail in Jones et al. (2019) and Andrews et al. (2020). For the massive star progenitors we use the Multi-zone Post-Processing Network -Parallel (MPPNP) code (Pignatari et al. 2016b; Ritter et al. 2018). This code calculates the nuclear reactions at each time step then performs mixing across the stellar model, separate to calculating the impact of nuclear reactions. The reaction network consists of roughly 1100 isotopes and 14000 reactions. For the core-collapse simulations we used the Tracer particle Post-Processing Network - Parallel (TPPNP) (Jones et al. 2019). TPPNP functions by considering single tracer particles anchored to a mass coordinate, post-processing with no mixing between particles. We use a network of up to 5200 isotopes and 67000 reactions for CCSN nucleosynthesis (for a full description of post-processing techniques see Jones et al. 2019). This network is larger than that in the MPPNP calculations because explosive nucleosynthesis experiences higher temperatures, as well as significantly higher neutron and proton densities. Therefore, more isotopes and reactions are needed. We note that our 26 Al yields are higher than those reported in Jones et al. (2019) and Andrews et al. (2020). In those calculations, the pre-explosive abundance of only the ²⁶Al isomeric state was inadvertently used as initial abundance of ²⁶Al during the supernova nucleosynthesis calculations. In this work this issue with the treatment of the initial abundance of the isomeric and ground states of ²⁶Al is corrected. As a result, higher final ²⁶Al yields are obtained since also the pre-explosive contribution is consistently taken into account when the final integrated yields are calculated from the SN ejecta.

2.2 General nucleosynthesis results

We examine the general nucleosynthesis in the 62 CCSN models described in the previous subsection¹ (Fryer et al. 2018; Andrews et al. 2020). The final yields of SLRs and their reference isotopes, explosive energy and remnant masses are reported in Table A1. Here we focus on three selected models to discuss the nucleosynthesis both pre-explosion and post-explosion. Figures 1, 2, and 3 show selected abundance profiles for pre- and post-CCSN of selected models. These models are selected due to their low mass cut values, allowing the largest range of explosive nucleosynthesis to be observed.

The shaded areas of Figs. 1, 2 and 3 show the location of the pre-CCSN burning ashes, as labeled at the top of the figure. These regions can be identified by the significant reduction of the relevant isotope, due to the previous burning phases. Using the top panel of Fig. 1 as an illustrative example, at mass coordinate 3.21 M_☉ a sharp increase in both ¹²C and ¹⁶O represent the interface between the He-burning ashes and the H-burning ashes. The He-burning ashes extend to 2.57 M_☉, and is split at 2.87 M_☉ into He and He_{inc}, which are the ashes of complete and incomplete He-burning, respectively. During He-burning the triple- α reaction has produced ¹²C, with a further α capture generating ¹⁶O. The ashes of C-burning are identifiable by the significant reduction in the abundance of ¹²C between 1.78 M_☉ and 2.57 M_☉. During C-burning, ¹²C is consumed via the C-fusion main channels ¹²C(¹²C, \alpha)²⁰Ne and ¹²C(¹²C, p)²³Na.

At 1.77 M_☉ the sharp drop in ²⁰Ne and the increase of ¹⁶O (created via the ²⁰Ne(γ, α)¹⁶O reaction) represent the interface between the C-burning and Ne-burning ashes. At 1.71 M_☉ the sharp drop in ¹⁶O and the sharp increase of ²⁸Si define the beginning of the O-burning ashes, whose burning is dominated by the ¹⁶O(¹⁶O, α)²⁸Si reaction. The Si-burning ashes are located below 1.59 M_☉, where there is a sharp drop in ²⁸Si. Silicon burning is characterised by hundreds of reactions, where a significant fraction of forward and backward nuclear reactions balance (Woosley et al. 1973; Chieffi et al. 1998). The main product of Si-burning is ⁵⁶Fe.

The impact of the shock wave on the final yields of a CCSN model can be determined by examining the temperature profiles, as explosive nucleosynthesis processes have a strong temperature dependence. The mass of the remnant, and thus the location of the mass cut, is also key to determining the yields of a CCSN model, as everything above the remnant mass is ejected. In other words, if the mass cut is above a specific explosive nucleosynthesis region, then the products of that region are not ejected, therefore they are not included in the final yields.

As the explosion shock-wave passes through the pre-CCSN material, the temperature and densities rise dramatically (to the peak values shown in Fig. 4) and subsequently cool. These profiles determine the outcome of the explosive nucleosynthesis. During explosive nucleosynthesis (solid lines in Figures 1–3) in the inner stellar ejecta isotopes made in the pre-CCSN phase are mostly destroyed to make new species, due to extreme temperatures and densities (see Fig. 4). Explosive Si-burning mostly feeds the pro-

 1 Full data of these models can be found at: https://ccsweb.lanl.gov/astro/nucleosynthesis/nucleosynthesis_astro.html

Figure 1. Abundance profile (in mass fraction) of selected isotopes for a selected 15 M_{\odot} model with mass cut of 1.50 M_{\odot} (the lowest of the 15 M_{\odot} models) shown as a thick dashed vertical line and explosion energy of 4.79 ×10⁵¹ ergs. The top panel shows isotopes that represent the pre-CCSN structure of the model, with alternating shaded and non-shaded sections showing the different burning ashes. Each burning phase is labelled at the top of the plot. The other panels show the abundance profiles of the SLRs considered in Table 1, all radioactive isotopes including the radiogenic contribution from isotopes with half-lives of less than 10⁵ years. The abundance profiles are plotted at both pre-CCSN (dashed line) and post-CCSN profile (solid line). A thick gray, dashed vertical line shows the mass cut, below which we do not plot the explosive profiles. ⁹²Nb is plotted in both the second from top and the bottom panels, to show its large peak in the innermost region of the ejecta.

Figure 2. Same as Fig. 1 for 20 M_\odot progenitor, with mass cut 1.74 M_\odot and explosion energy $2.85{\times}10^{51}$ ergs.

duction of ⁵⁶Ni and iron-group elements, with some unconsumed ⁴He. This can be seen in Fig. 1, below 1.8 M_{\odot}. The α -rich freeze-out can also trigger the nucleosynthesis of elements heavier than iron by charged particle reactions, up to the mass region of Sr and Zr (e.g., Woosley & Hoffman 1992; Pignatari et al. 2016b).

As the CCSN shock expands , moving outwards in space, the peak temperature decreases (Fig. 4). Note that this temperature peak is not reached in all the structure at the same time, rather only the peak temperature is plotted

Figure 3. Same as Fig. 1 for 25 M_\odot progenitor, with mass cut 1.83 M_\odot and explosion energy 3.07×10^{51} ergs.

per mass coordinate. Between ~1.7 M_{\odot} and ~1.85 M_{\odot} the temperatures decreases to ~5 GK and explosive Si-burning occurs (top panel of Fig. 1) (Woosley & Weaver 1995). This consumes ²⁸Si and produce mostly ⁵⁶Ni and iron-group elements under nuclear statistical equilibrium, possibly leaving some ⁴He unconsumed if the rate of expansion is sufficiently fast (Bodansky et al. 1968; Woosley et al. 1973).

Where the peak temperature of the shock falls to $\sim 3.6 \text{GK}$ (between $\sim 1.85 \text{ M}_{\odot}$ and $\sim 1.95 \text{ M}_{\odot}$ in Fig. 1), explosive O-burning products are mostly obtained

Figure 4. Peak temperature profiles of all the 62 models, constructed by selecting the maximum temperature reached at each mass coordinate as the shock passes through it. The 15 M_{\odot} , 20 M_{\odot} and 25 M_{\odot} models are shown in the upper, middle and lower panels, respectively. Alternating shaded and non-shaded areas highlight pre-CCSN burning ashes as labelled on the top. The profiles marked in red are those of the models shown in Fig.1 – Fig.3.

(Truran & Arnett 1970; Woosley et al. 1973). In the figure, this consumes $\rm ^{16}O$ and produces $\rm ^{28}Si.$

As the peak temperature of the shock falls between ~3.2GK and ~2.5GK (Rapp et al. 2006) also the signature of explosive Ne-burning can be obtained (between ~1.95 M_{\odot} and ~2.1 M_{\odot} in Fig. 1). As in pre-explosive nucleosynthesis ²⁰Ne is consumed by photodisintegration and α -captures

(e.g., Thielemann & Arnett 1985). Heavy isotopes provide successive (γ, n) , (γ, p) , and (γ, α) photodisintegration reactions, allowing for lighter seed nuclei to produce proton rich isotopes such as ⁹²Nb and ¹⁴⁶Sm. This process is the γ -process (e.g. Rauscher et al. 2013; Pignatari et al. 2016a).

As the peak temperature drops to ~2 GK the explosive C-burning signature becomes dominant (between ~2.1 M_☉ and ~2.55 M_☉ in Fig. 1) (Hansen 1971; Truran & Cameron 1978). This consumes ¹²C left in the C-shell ashes, modifying local pre-CCSN abundances of C-burning ashes like Ne, Na and Mg. The neutron density reaches $\sim 10^{18}$ cm⁻³ and the proton density reaches above 10^{20} cm⁻³ (see Fig. 8 of Jones et al. 2019). This allows for the nucleosynthesis of both neutron-rich and proton-rich isotopes. Above ~2.2 M_☉, as temperatures drop to ~2GK, the rate of the 22 Ne(α ,n)²⁵Mg neutron source reaction decreases, as such we see little to no nucleosynthesis between 2.2 M_☉ and 2.55 M_☉.

As the shock expands and peak temperatures drop to ~1 GK, explosive He-burning occurs between ~2.55 M_☉ and ~3.1 M_☉ in the 15 M_☉ model shown in Fig. 1. Here ⁴He is consumed to produce isotopes in the α -capture chain. At mass coordinate 2.77 M_☉ (the peak of ²⁰Ne production), neutrons are significantly made by ²²Ne(α ,n)²⁵Mg. The neutrons made by ¹⁷O(α ,n)²⁰Ne and ²¹Ne(α ,n)²⁴Mg, are recycled from those previously captured by ¹⁶O and ²⁰Ne, respectively (e.g., Raiteri et al. 1991; Pignatari et al. 2010). The peak neutron density here is ~10¹⁸ cm⁻³ and proton density is ~5×10¹⁵ cm⁻³ (see Fig. 8 of Jones et al. 2019). While the neutron density is similar within explosive helium burning and explosive oxygen burning, the production of neutron-rich isotopes is considerably higher in explosive helium burning, as at these lower temperatures photodisintegration reactions are not active for the heavy isotopes beyond iron.

The 20 $\rm M_{\odot}$ and 25 $\rm M_{\odot}$ models (Fig. 2 and Fig. 3 respectively) show some important differences in the CCSN ejecta compared to the 15 $\rm M_{\odot}$ model of Fig. 1. The O and Ne-burning ashes within the pre-CCSN structure of the 20 $\rm M_{\odot}$ and 25 $\rm M_{\odot}$ models cannot be easily distinguished, unlike these ashes in the 15 $\rm M_{\odot}$ models. They are identified only by a reduction in both $^{16}\rm O$ and $^{20}\rm Ne$, while $^{28}\rm Si$ increases considerably more than in Ne-burning (e.g., Chieffi et al. 1998). Both the 20 $\rm M_{\odot}$ and 25 $\rm M_{\odot}$ models as Si_{inc}), characterised by the partial destruction of $^{28}\rm Si$ without significant production of $^{4}\rm He.$ However, these regions will not be ejected by the CCSN explosion.

The steep temperature profile of the 20 M_{\odot} model (see Fig. 4) causes the ignition of explosive Si-, O-, and C-burning to be located in the inner portion of the star. Due to a higher mass cut the contribution of explosive Si-burning is less present in the final yields, with a sharp peak of ⁵⁶Ni reaching 0.46 mass fraction at mass coordinate 1.75 M_{\odot} (0.01 M_{\odot} above the mass cut). Explosive O-burning occurs at ~1.87 M_{\odot} , and explosive C-burning is located at ~2.15 M_{\odot} . As explosive C-burning is within the Ne-burning ashes, there is less ¹²C to be used as fuel, reducing the impact of this explosive nucleosynthesis site on the final yields of isotopes created by these conditions. As the shock reaches ~1 GK, explosive He-burning would normally begin, but as this happens in the upper C-burning ashes there is no ⁴He

Figure 5. An example trajectory of temperature and density. Trajectory generated from mass coordinate 2.77 M_{\odot} in model shown in Fig. 1.

to be consumed, and therefore the nucleosynthesis signature of explosive He-burning is marginal.

The 25 M_{\odot} model shown in Fig. 3 has a structure that resembles the 15 M_{\odot} model, however, as the mass cut is higher, there is no ejected α -rich freeze-out material outside of the mass cut. Figure 4 shows that for all 25 M_{\odot} models, the CCSN peak temperatures is above 1 GK up at the bottom of the former convective He shell, ensuring a strong activation of explosive He-burning.

To examine in detail the specific nucleosynthesis sites of SLRs in the CCSN ejecta we extracted some trajectories from the models, where we took the temperature and density profiles over the course of the CCSN event for a given mass coordinate (an example is given in Fig. 5). We then use these trajectories to examine the flux associated to each reaction and determine which are the most important for production and destruction.

3 RESULTS

For all SLRs we check the impact of radiogenic contributions from the decay of unstable isotopes and we include where significant. In the next section we address the nucleosynthesis of each isotope separately.

We do not consider ⁷Be and ¹⁰Be in this work as they are not produced significantly in supernovae, rather by cosmic ray spallation (Desch et al. 2004). Notice, however, that Banerjee et al. (2016) proposed that low-mass CCSNe could produce ¹⁰Be by neutrino interaction with ejecta. We do not consider ²⁴⁴Pu or ¹⁴⁷Cm as CCSN do not produce r-process isotopes.

3.1 ²⁶Al

In stars the ${}^{25}Mg(p,\gamma){}^{26}Al$ reaction is the main nucleosynthesis channel to produce ${}^{26}Al$. The proton capture on ${}^{25}Mg$ is first activated in the Mg-Al chain during hydrogen burning in the pre-CCSN phase. In more advanced burning stages, ${}^{26}Al$ can be made during C-burning because of the combined presence of abundant ${}^{25}Mg$ and protons, where protons are made directly by C-fusion (via the ${}^{12}C({}^{12}C,p){}^{23}Na$

reaction). During O-fusion ²⁵Mg is destroyed to make heavier elements, and therefore these conditions are not suited for the production of ²⁶Al. Similar considerations can be made for explosive nucleosynthesis triggered by the CCSN shock. The dominant depletion channels for ²⁶Al under explosive conditions are the (n,p) and (n,α) neutron capture reactions. These reactions deplete ²⁶Al in He-burning conditions and mitigate its production during C-burning, where neutrons are released by the 22 Ne $(\alpha, n)^{26}$ Mg reaction. Above approximately 3.2 M_{\odot} the CCSN ejecta are carrying the signature of pre-CCSN H-burning ashes (see Fig. 1). ²⁶Al abundance is of the order of a few 10^{-6} by mass fraction. The He-shell ashes above 2.92 M_{\odot} only show a minor depletion with respect to these quantities. This is due to a marginal activation of the 22 Ne $(\alpha, n)^{26}$ Mg reaction, as also indicated by the negligible depletion of the s-process seed, 56 Fe. In the 15_{\odot} model the explosive H-burning contribution is not relevant for the nucleosynthesis of $^{26}\mathrm{Al},$ rather the bulk of production lies with C-burning (see Fig. 1). Instead, the neutron burst activated in the explosive shell He-burning by the CCSN shock (n-process, e.g., Blake & Schramm 1976; Meyer et al. 2000; Pignatari et al. 2018) depletes 26 Al via the neutron capture channels mentioned above. Interestingly, some production of ²⁶Al also occurs during explosive He-burning. In this case, the source of protons to activate the production channel ${}^{25}Mg(p,\gamma){}^{26}Al$ is a combination of (α,p) and (n,p)reactions.

In the 15 M_{\odot} model the pre-CCSN largest production of ²⁶Al occurs during carbon burning, with protons provided by the ¹²C(¹²C,p)²³Na reaction. Within a region of about 0.8 M_{\odot} in thickness, ²⁶Al reaches values larger than 10⁻⁴ in mass fraction. The CCSN shock will deplete most of the C-burning ashes, but the region between about 2.2 and $2.55M_{\odot}$ is ejected mostly unchanged, including the ²⁶Al reservoir made before the explosion. An explosive C-burning contribution is also present at about 2.15 M_{\odot} , shown by a small increase in ejected ²⁶Al compared to the pre-CCSN abundance. No significant production of ²⁶Al is obtained in CCSN ejecta deeper than the mass coordinates where explosive C-burning is taking place.

The reaction fluxes for these conditions are shown in Fig. 6. As expected, the strongest fluxes are those related to production via ${}^{25}Mg(p,\gamma){}^{26}Al$ and destruction by ${}^{26}Al(n,p){}^{26}Mg$ driven by the high neutron densities. The relevance of the other nuclear reaction channels are at least an order of magnitude smaller. As no radioactive isotopes decaying into ${}^{26}Al$ are produced to a significant level, there is no radiogenic contribution for ${}^{26}Al$.

Comparing the 20 $\rm M_{\odot}$ (Fig. 2) and 25 $\rm M_{\odot}$ (Fig. 3) models with the 15 $\rm M_{\odot}$ model discussed above, the most remarkable difference is the smaller abundance of pre-CCSN $^{26}\rm Al$ in the C-burning ashes (ejecta between 2.2 and 4 $\rm M_{\odot}$, and between 2.9 and 5.9 $\rm M_{\odot}$, respectively for the 20 and 25 $\rm M_{\odot}$ models). This discrepancy is explained by a less efficient or inactive C-burning in the last days of stellar evolution: the $^{26}\rm Al$ previously made decays to $^{26}\rm Mg$ without being produced. Interestingly, in Fig. 3 we can still find $^{26}\rm Al$ abundance of the order of a few 10⁻⁷ in the upper part of the O-Ne ashes, where final pre-explosive O-burning activation is too weak to destroy the isotope. The 25 $\rm M_{\odot}$ star shows a much stronger C-burning explosive nucleosynthesis com-

Figure 6. The distribution of fluxes $(\delta X/\delta t, where X \text{ is mass} fraction)$ for each reaction during explosive carbon burning at mass coordinate 2.16 M_o in the 15 M_o star integrated over the shock time for ²⁶Al. Stellar conditions are extracted at mass coordinate 2.16 M_o in Fig. 1. The ²⁶Al(n,p)²⁶Mg and ²⁶Al(β^{-})²⁶Mg fluxes are both present as two arrows, the smaller arrow denotes the β^{-} decay.

pared to the 20 $\rm M_{\odot}$ star, leading to a higher production of $\rm ^{26}Al$

In the 20 M_{\odot} model shown in Fig. 2, the peak temperature for explosive C-burning (about 2 GK) is reached only at the interface between the O-Ne and C ashes. The same conditions are achieved in the C-ashes for the 25 M_{\odot} model, showing a broad production peak of ²⁶Al.

In summary most of ²⁶Al in the 20 M_{\odot} model (Fig. 2) is made by the pre-CCSN stage, in the 25 M_{\odot} model (Fig. 3) the yields are instead mostly due to explosive nucleosynthesis. In Fig. 1 ²⁶Al is produced by both. From this we may already argue that the relative contribution to the total ejected ²⁶Al from different parts of the ejecta and the fraction of ²⁶Al made by the explosion do not depend solely on the initial mass of the progenitor or on the explosion energy (e.g., Limongi & Chieffi 2006).

We examine the abundance profiles of all 15 M_{\odot} models in Fig. 7. The top panel of Fig. 7 shows the abundance profiles of ²⁶Al, and shows several similarities, with the largest variations obtained in the explosive He-burning. The yields of ²⁶Al for the 15 M_{\odot} and 20 M_{\odot} models show variations by a factor of about 1.5. However, due to broad production peaks during explosive He-burning the 25 M_{\odot} models show a significantly larger variation in yield, of about an order of magnitude (see Table A1).

3.2 ³⁶Cl and ⁴¹Ca

The radioactive isotopes 36 Cl and 41 Ca are both located next to the neutron shell closure at N=20. In the 15 M $_{\odot}$ model shown in Fig. 1, the two isotopes are already efficiently pro-

Figure 7. The isotopic abundances of ²⁶Al, ⁵³Mn and ⁶⁰Fe (upper panel, central panel and lower panel, respectively) are shown with respect to mass coordinate of all 15 M_o models: pre-CCSN abundances are shown by the dashed line, the median of all models is shown by a black solid line, and thin lines show the abundance profiles for single models. Alternating shaded and non-shaded areas highlight pre-CCSN burning ashes, from left to right: Si ashes, O ashes, Ne ashes, C ashes, He ashes and He_{inc} ashes.

duced in the pre-CCSN He-burning and C-burning regions by a neutron capture on ³⁵Cl and ⁴⁰Ca, respectively. Significant variations due to the CCSN explosion are then obtained in the calculations. In explosive nucleosynthesis ³⁶Cl is efficiently made by explosive C-burning, with a peak of production up to one order of magnitude larger than in the pre-CCSN stages. ³⁶Cl is largely destroyed from explosive O-burning and in general for all mass coordinates below 1.9 M_☉. This is not the case for ⁴¹Ca, which can be made even in α -rich freeze-out conditions in the deepest ejecta. The highest production peak is obtained in explosive O-burning conditions (at about 1.9 M_☉), with abundances at least an order of magnitude higher than in the

Figure 8. Same as in Fig. 6, but for ^{36}Cl in explosive carbon burning (at mass coordinate 2.1 M_{\odot} for the 15 M_{\odot} model in Fig. 1).

other ejected stellar layers. The dominant production channel of $^{36}\mathrm{Cl}$ is $^{36}\mathrm{Ar}(\mathrm{n,p})^{36}\mathrm{Cl}$, while it is mostly depleted by the reverse of this reaction, $^{36}\mathrm{Cl}(\mathrm{p,n})^{36}\mathrm{Ar}$. During explosive C-burning, $^{36}\mathrm{Cl}$ is produced by neutron capture on $^{35}\mathrm{Cl}$ and is mostly destroyed by $^{36}\mathrm{Cl}(\mathrm{n,p})^{36}\mathrm{S}$ and $^{36}\mathrm{Cl}(\mathrm{p,n})^{36}\mathrm{Ar}$ (see Fig. 8). $^{41}\mathrm{Ca}$ is largely unaffected by explosive C-burning as the neutron capture reaction that forms $^{41}\mathrm{Ca}$ is balanced by $^{41}\mathrm{Ca}(\mathrm{n,a})^{38}\mathrm{Ar}$. In explosive He-burning both $^{36}\mathrm{Cl}$ and $^{41}\mathrm{Ca}$ are typically destroyed by n-process neutron captures (see Fig. 9 for $^{41}\mathrm{Ca}$).

Comparing all the 15 $\rm M_{\odot}$ models (see Fig. 10) we see that they are all qualitatively consistent for both $^{36}\rm Cl$ and $^{41}\rm Ca$. The largest differences in the yields are due to the amount of depletion in explosive He-burning. The location of the mass cut is another key factor in the final yields of $^{41}\rm Ca$, as a high mass cut prevents the innermost portions of the star from being ejected. Examining the ejected yields from each 15 $\rm M_{\odot}$ model (Table A1), $^{41}\rm Ca$ yield varies by a factor of four $(9.1\times10^{-7}-4.2\times10^{-6}~\rm M_{\odot})$, while $^{36}\rm Cl$ which is not made in the deepest ejecta, varies only by 20% $(8.3\times10^{-7}-1.1\times10^{-6}~\rm M_{\odot})$

The pre-CCSN production of ⁴¹Ca is similar between the 15, 20 and 25 M_{\odot} models. However, the production of ³⁶Cl in pre-CCSN carbon burning is higher in the 15 M_{\odot} model (Fig.1), than in the 20 and 25 M_{\odot} models (Figs. 2 and 3, respectively). Post-CCSN production of ³⁶Cl in the 20 M_{\odot} and 25 M_{\odot} models is close to the position on the mass cut, which causes variance in the ejected yield. For ³⁶Cl the ejected yields vary by two and one order of magnitude, for 20 M_{\odot} and 25 M_{\odot} models respectively. For ⁴¹Ca the ejected yields vary by a factor of two and by one order of magnitude, for 20 M_{\odot} and 25 M_{\odot} models respectively (see Table A1).

Figure 9. Same as in Fig. 6, but for $^{41}\mathrm{Ca}$ in explosive helium burning (at mass coordinate 2.9 M_{\odot} for the 15 M_{\odot} model in Fig. 1).

3.3 ⁵³Mn

 $^{53}\mathrm{Mn}$ is mostly made by explosive nucleosynthesis. In our fiducial 15 M_{\odot} model (presented in Fig. 1), a small pre-CCSN component is present from the C-shell ashes, between about 1.78 M_{\odot} and 2.54 M_{\odot} . During the CCSN explosion, additional nucleosynthesis channels contribute to most of the ejected 53 Mn abundance. At about 2.1 M_{\odot}, a production peak is obtained due to explosive C-burning. The largest contribution is obtained between 1.8 ${\rm M}_{\odot}$ and 1.9 ${\rm M}_{\odot},$ triggered by explosive O-burning and partial Si-burning. Below this point the ⁵³Mn abundance drops by three orders of magnitude in the products of complete Si-burning (between the mass cut and 1.6 M_{\odot}). In the deepest CCSN layers (≤ 1.7 M_{\odot}) the abundance rises again due to production in α -rich freeze-out conditions (e.g., Hoffman et al. 1996). The production peak at $M \approx 1.8 M_{\odot}$ is due to a near equilibrium state between the many forward and reverse reactions that are reached in explosive partial Si-burning. This produces isotopes up to the Fe-group with the largest con-tribution to 53 Mn from the decay of 53 Fe, and its main de-struction reaction being 53 Mn(p, γ) 54 Fe. During explosive Oburning a near equilibrium state is again reached at M≈1.9 M_{\odot} . The main destruction reactions are ${}^{53}Mn(p,\gamma){}^{54}Fe$ and $^{53}Mn(\gamma,p)^{52}Cr$, and the main production reactions are the reverse of these reactions.

The other smaller peak of production is due to explosive C-burning, taking place at $M\approx 2.1 \ M_{\odot}$ (Fig. 1). Here the α -capture reaction $^{24}Mg(\alpha,p)^{27}Al$ produces a large amount of protons, leading to the major production channels of ^{53}Mn : the proton-capture reactions $^{53}Cr(p,n)^{53}Mn$ and $^{52}Cr(p,\gamma)^{53}Mn$. The major destruction channels are the neutron-capture reactions $^{53}Mn(n,p)^{53}Cr$ and $^{53}Mn(n,\gamma)^{54}Mn$ (see Fig. 11).

The middle panel in Fig. 7 shows the 53 Mn abundance

Radioactive nuclei in the early Solar System 9

profiles of all the 15 $\rm M_{\odot}$ models, and demonstrate that the nucleosynthesis behaves consistently across them. The yields of $^{53}\rm Mn$ for the model with the highest mass cut $(1.9~\rm M_{\odot})$ is $5.26 \times 10^{-7}~\rm M_{\odot}$ while it is $5.89 \times 10^{-5}~\rm M_{\odot}$ for the model with the lowest mass cut $(1.5~\rm M_{\odot})$, a variation of the order of two orders of magnitude (see Table A2). This makes $^{53}\rm Mn$ a useful diagnostic of the mass cut, as we discuss further in Section 4.1.

Figs. 2 and 3 for the 20 and 25 M_{\odot} models show a similar production pattern as described above for the 15 M_{\odot} models, although production peaks are closer to the mass cut. This is due to production occurring in the Ne-burning ashes, with no significant production in the C-burning ashes. Examining the yields of ⁵³Mn for the 20 and 25 M_{\odot} models, the abundance of ⁵³Mn varies by four orders of magnitude, from $6.4 \times 10^{-9} M_{\odot}$ for the model with the highest mass cut (4.89 M_{\odot}) to $5.0 \times 10^{-5} M_{\odot}$ with the lowest mass cut (1.7 M_{\odot}) (Table A2). The mass cut impact is even more significant here than for the 15 M_{\odot} model, because the models with the highest mass cut do not even eject any explosive ⁵³Mn contribution. Therefore, within the possible range of progenitor mass and explosion energy, it is indeed possible to have CCNSNe with no substantial ⁵³Mn ejected.

3.4 ⁶⁰Fe

Prior to core-collapse, 60 Fe is produced in C-burning and also marginally in He-burning (see the second panel from top in Fig. 1, for the reference 15 M_{\odot} model). 60 Fe is destroyed in O-burning when the temperature rises above about ~2GK. During explosive nucleosynthesis all the pre-CCSN 60 Fe exposed to conditions more extreme than explo-

Figure 11. The same as in Fig. 6, but for $^{53}{\rm Mn}$ from mass coordinate 2.1 ${\rm M}_{\odot}$ in Fig. 1.

sive carbon burning is depleted. Instead, ⁶⁰Fe is significantly produced during explosive He-burning, as neutron densities reach $\geq 10^{18}$ cm⁻³ and neutron captures are very efficient during the n-process activation (e.g., Pignatari et al. 2018). Here, ⁶⁰Fe is mostly created via the double neutron-capture chain ⁵⁸Fe(n, γ)⁵⁹Fe(n, γ)⁶⁰Fe, and marginally via the β^- decay of ⁶⁰Mn (see Fig. 12), made by a sequence of neutron captures starting from stable ⁵⁵Mn. The main destruction channel of 60 Fe is the (n, γ) neutron capture forming 61 Fe. The 60 Fe production peak due to C-burning at about 2.15. M_{\odot} in Fig. 1 is around one order of magnitude lower than the peak in explosive He-burning. This result may potentially be affected by parameters like the progenitor mass and the explosion energy, which we will discuss below. However, another important parameter to consider is the amount of 22 Ne left to produce neutrons in the C shell during the CCSN shock. Indeed, a weaker s-process activation in the progenitor would cause a larger remaining amount of ²²Ne to produce neutrons during the explosion, a lower pre-CCSN abundance of 60 Fe, but also a higher amount of iron seeds to feed the explosive $^{60}\mathrm{Fe}$ production. Therefore, the relative relevance of explosive He burning and explosive C burning in producing ${}^{6\bar{0}}$ Fe could potentially vary between different sets of stellar models.

Comparing the ^{60}Fe abundance profile of the 15 M_{\odot} model (Fig. 1) to that of the 20 M_{\odot} (Fig. 2) and 25 M_{\odot} (Fig. 3) models, the production sites for the radioactive isotope do not change. However, in the 25 M_{\odot} model the relevance of explosive carbon burning is higher than for the other two masses (see peak at 3.8 M_{\odot} in Fig. 3). In the same model, a significant pre-CCSN ^{60}Fe production is obtained in the most internal convective He shell, between about 6.4 M_{\odot} and 7.1 M_{\odot} . The explosion will boost further the isotope at the bottom of the shell. In the 20 M_{\odot} model, there is no significant explosive production peak in the He-burning ashes compared to the other stellar masses considered. The

Figure 12. The same as in Fig. 6, but for 60 Fe from mass coordinate 3.0 M_{\odot} in Fig. 1, respectively.

reason is that in this model the temperature peak associated the CCSN shock is too low at the bottom of the former He shell to trigger the n-process within the short explosive timescales.

The bottom panel of Fig. 7 shows the abundance profile of $^{60}\mathrm{Fe}$ in all the 15 M_{\odot} models. The qualitative behaviour is the same for all the models, with almost complete depletion for mass coordinates below explosive carbon burning and a large production in explosive He-burning. However, the amount of ⁶⁰Fe made by explosive He-burning changes greatly by varying the CCSN explosion parameters used in this work, with the final yield varying by two orders of magnitude for the 15 M_{\odot} models (Table A2). This is due to the temperature variation in the He-shell material during the CCSN shock, which falls below 10^9 K in the models with lower explosion energy. Due to the lack of contribution from explosive He-burning in the 20 M_{\odot} models, the ⁶⁰Fe yield is lower by up to one order of magnitude relative to the 15 M_{\odot} model. The 25 M_{\odot} models show an increase in yield of $^{60}\mathrm{Fe}$ when compared to the 15 M_{\odot} model, mainly due to higher contribution from the pre-CCSN stage (see also, e.g., Timmes et al. 1995; Limongi & Chieffi 2006).

We note that there is little contribution from radiogenic decay in the final yields of 60 Fe. For a more extended description of the production of 60 Fe in massive stars, we refer to Jones et al. (2019) for the same models that we use here.

3.5 107Pd and 205Pb

Beyond iron, $^{107}\mathrm{Pd}$ and $^{205}\mathrm{Pb}$ are SLRs located in-between stable isotopes ($^{106}\mathrm{Pd}$ and $^{108}\mathrm{Pd}$, and $^{204}\mathrm{Pb}$ and $^{206}\mathrm{Pb}$, respectively). Both SLRs areÂğ produced by a neutron capture on $^{106}\mathrm{Pd}$ and $^{204}\mathrm{Pb}$, respectively, and they are also destroyed by neutron captures. Charged particle reactions are not relevant for the nucleosynthesis of such a heavy nuclei. the $\gamma\text{-}\mathrm{process}$ does not contribute to the production of these

Figure 13. Same as Fig. 7. Isotopes shown are ¹⁰⁷Pd and ²⁰⁵Pb.

isotopes either: there are no seeds for making ^{205}Pb via photodisintegration, and ^{107}Pd is shielded from any $\gamma\text{-process}$ contribution by its stable isobar ^{107}Ag .

In Fig. 1 (third panel from top), ¹⁰⁷Pd and ²⁰⁵Pb show a relevant production by neutron captures in the pre-CCSN phase during He- and C-burning, while they are destroyed in more advanced evolutionary stages. In stellar conditions the weak decay rates of both the two isotopes depend on temperature and density. However, electron captures on ²⁰⁵Pb starts to affect its half-life at much lower temperatures than ¹⁰⁷Pd. For instance, at typical conditions at the onset of Heburning, the half-life of ²⁰⁵Pb is reduced to a value of the order of a few decades, while the ¹⁰⁷Pd β -decay half-life is still of the order of a Myr. Such a difference may also introduce significant variations in the abundance profiles of the two isotopes, as can be seen for example in the drop in abundance above 3.2 M_☉ in Fig. 1.

During the CCSN explosion both ¹⁰⁷Pd and ²⁰⁵Pb are destroyed below the explosive C-burning peak, at about 2.15 M_☉. In explosive He-burning, the n-process neutron burst produces ¹⁰⁷Pd by radiogenic contribution from β^- decay of the neutron-rich isotopes ¹⁰⁷Rh and ¹⁰⁷Ru. The pre-CCSN ²⁰⁵Pb is destroyed by neutron captures and cannot be formed by the β^- decay of unstable isotopes because it is shielded by the stable isobar ²⁰⁵Tl.

In the 20 M_{\odot} model shown in Fig. 2, there is no effect of the explosion on the abundance profiles, as we have seen for other isotopes, due to the steep temperature gradient (Fig. 4). Comparing the 15 M_{\odot} model (Fig. 1) with the 25 M_{\odot} model shown in Fig. 3, the nucleosynthesis profiles are similar, with a more limited depletion of ²⁰⁵Pb in the 25 M_{\odot} model during explosive He-burning.

Radioactive nuclei in the early Solar System 11

As a general trend, we can see from Tables A3 and A5 that the yields of 107 Pd and 205 Pb decrease as the explosion energy increases, varying only by as much as a factor of two. This is due to the fact that by increasing the explosion energy more of the CCSN ejecta are exposed to conditions where both the two SLRs are depleted, and the explosive C-burning peak is moved outward in mass coordinate.

3.6 ¹²⁶Sn

The nucleosynthesis of $^{126}\mathrm{Sn}$ requires neutron-rich conditions to drive a double neutron capture via the reaction chain 124 Sn (n,γ) 125 Sn (n,γ) 126 Sn. The efficiency of this channel depends on the temperature dependent β -decay at ¹²⁵Sn, whose half-life becomes less than a day in typical He-burning conditions and of the order of an hour or less in C-burning conditions (e.g., Takahashi & Yokoi 1987). Therefore, high neutron densities are required to accumulate a significant amount of $^{126}{\rm Sn.}$ Figure 1 shows that in the 15 ${\rm M}_{\odot}$ model 126 Sn is marginally produced in the pre-CCSN phase in the C-burning ashes. During explosive nucleosynthesis, ¹²⁶Sn is produced in sites of high neutron density, specifically in explosive C burning (around 2.16 M_o) and much more significantly (by three orders of magnitude in this model) in explosive He burning $(2.75 - 3.2 M_{\odot})$. Thanks to the high neutron densities reached by the n-process, we notice also a small additional radiogenic contribution to ¹²⁶Sn by ¹²⁶In.

In the fiducial 20 M_{\odot} model (shown in Fig. 2) explosive C- and He-burning are not significantly activated, resulting in a lack of a neutron source and no production of ¹²⁶Sn. Furthermore, the pre-CCSN production of ¹²⁶Sn is even lower than in the 15 M_{\odot} model, by almost two orders of magnitude. Finally, also in the 25 M_{\odot} model in Fig. 3, ¹²⁶Sn production occurs during the explosion, in both the C-burning (with similar abundance as in the 15 M_{\odot} model) and He-burning ashes (but an order of magnitude lower than in the 15 M_{\odot} model).

The final yields of the all 15, 20 and 25 M_{\odot} models are given in Table A4. In general, the models with high explosion energies produce more ¹²⁶Sn. This is due to an increase in neutron density in explosive C-burning, and to a broader range of ejecta affected by the n-process during explosive He-burning. We obtain the largest variation of ¹²⁶Sn yields for the 20 M_{\odot} models, increasing from 8.9×10^{-14} M_{\odot} in the model with the lowest explosion energy (0.5×10^{51} ergs) to 5×10^{-10} M_{\odot} in the model with the highest explosion energy (8.9×10^{51} ergs).

3.7 ¹²⁹I and ¹³⁵Cs

The neutron-rich SLRs ¹²⁹I and ¹³⁵Cs are also separated from the β^- -valley of stability by one unstable isotope. The radiogenic contribution from their respective neutron-rich unstable isobars can be very significant in explosive conditions, or even dominate the total CCSN ejecta.

Using the 15 M_{\odot} model shown in Fig. 1 as an example, during the pre-CCSN stages the s-process makes both ¹²⁹I and ¹³⁵Cs by neutron capture through the branching points of ¹²⁸I and ¹³⁴Cs in the He-burning shell and the C-burning shell, while they are depleted in more advanced stages. In the CCSN explosion, the pre-CCSN abundances

are only partially modified in the explosive C-burning peak at about 2.1 M_☉. While, they are depleted by photodisintegration in the deeper parts of the former convective C shell. The n-process triggered by explosive He burning generates a complex pattern of production peaks. ¹²⁹I and ¹³⁵Cs are produced directly only in he mildest n-process ejecta, the highest peaks of production are given by radiogenic contribution from higher neutron-rich isotopes. For the models considered in this work, the ejected isotopes ¹²⁹Te, ¹²⁹Sb, ¹²⁹Sn and ¹²⁹In will eventually decay into ¹²⁹I. The radioactive isotopes ¹³⁵Xe, ¹³⁵I and ¹³⁵Te may instead contribute to the ejecta of ¹³⁵Cs.

In the 20 ${\rm M}_{\odot}$ model shown in Fig. 2, the explosive contribution to ¹²⁹I and ¹³⁵Cs is more limited compared to the 15 M_{\odot} model, while a significant fraction of the pre-CCSN yields are ejected mostly unchanged from pre-CCSN abundances for material above $2.2 \ M_{\odot}$ mass coordinate. A relevant production peak is still obtained with explosive Heburning, in particular for ¹²⁹I. As we discussed for other SLRs before, this is due to the final n-process burst of neutrons from 22 Ne $(\alpha, n)^{25}$ Mg. The 25 M $_{\odot}$ model in Fig. 3 shows a similar pre-CCSN production as in the 15 M_{\odot} model. However, during explosive nucleosynthesis we see a more complex production in explosive C burning at mass coordinates between 3.3 M_{\odot} and 4.6 M_{\odot} , due to the diverse radiogenic contribution to both 129 I and 135 Cs. Comparing the final yields within each 15, 20 and 25 M_{\odot} sets of models, there are no significant changes (Table A4). The largest variation is obtained between the 15 $\rm M_{\odot},$ 20 $\rm M_{\odot}$ and 25 $\rm M_{\odot}$ models, within the yields of $^{129}\rm I$ or $^{135}\rm Cs$ increasing by factors of two, three and two, respectively.

3.8 ¹⁸²**Hf**

 182 Hf is produce by neutron capture, similar to 129 I and 135 Cs. It may be directly produced from two neutron captures from 180 Hf through the unstable 181 Hf, or as a result of radiogenic contribution via β^- decay from its more neutron-rich unstable isobars. However, for the stellar calculations presented in this work we have used the 181 Hf β^- decay rate by Goriely (1999), which does not take into account of experimental data by Bondarenko et al. (2002). Therefore, we underestimated the half-life of 181 Hf. Lugaro et al. (2014) showed that the different half-life leads to an increase of 182 Hf in CCSN by 7% in their 15 Mo model and a factor of 2.6 for their 25 Mo model.

In the 15 M_{\odot} model shown in Fig. 1, during the pre-CCSN phase ¹⁸²Hf is directly produced via neutron capture in C-burning, and some late production is also visible in the deepest He-burning regions between mass coordinates 2.6 M_{\odot} and 2.8 M_{\odot} . As for other neutron-rich SLRs seen in previous sections, the C-burning ashes are the deepest CCSN ejecta carrying some ¹⁸²Hf. However, unlike these other SLRs, in this case there is no direct or radiogenic contribution from explosive C-burning feeding ¹⁸²Hf. In explosive He-burning the production of ¹⁸²Hf is instead more complex, where the direct production is supplemented by radiogenic contributions to ¹⁸²Hf. Within the models considered in this work, we can identify the contribution of ¹⁸²Lu, ¹⁸²Yb, ¹⁸²Tm and ¹⁸²Er.

Compared to the 15 $\rm M_{\odot}$ model, the 20 $\rm M_{\odot}$ model shown in Fig. 2 has a lower contribution from explosive nucleosyn-

thesis, and therefore its yields are expected to be more affected by the ¹⁸¹Hf β^- decay rate used in the simulations. Within this model, ¹⁸²Hf is produced during the CCSN explosion only in the He-burning regions. On the other hand, the total ejecta are dominated by the pre-CCSN production in the C shell ashes, between about 2.2 M_{\odot} and 4 M_{\odot} . Also the $^{182}\mathrm{Hf}$ ejecta from the 25 M_{\odot} model are dominated by the pre-CCSN production. Comparing the final yields of the 15 M_{\odot} set of models, there are variations of an order of magnitude (Table A5). This is due to the distribution of the CCSN peak temperatures reached within the stellar progenitor structure, where the more extreme explosion energy models reach the He burning ashes with higher temperatures (see Fig. 4), thus producing more neutrons and more radiogenic contributions to ¹⁸²Hf. Variations in the yields of $^{182}\mathrm{Hf}$ for the 20 M_{\odot} models set is similar to that of the 15 M_{\odot} models, varying by roughly one order of magnitude. Variations in the yields of 182 Hf for the 25 M_{\odot} models are more limited, of a factor of two (Table A5).

3.9 Heavy SLR isotopes accessible via the γ-process: ⁹²Nb, ⁹⁷Tc, ⁹⁸Tc, and ¹⁴⁶Sm

The four SLRs isotopes $^{92}\rm Nb,\,^{97}Tc,\,^{98}Tc$ and $^{146}\rm Sm$ are all potential products of the γ process in CCSNe, where the nucleosynthesis is mostly driven by the photodisintegration of heavier isotopes (e.g., Woosley & Howard 1978; Arnould & Goriely 2003; Rauscher et al. 2013; Pignatari et al. 2016b). In some of the CCSN ejecta exposed to the highest temperatures and densities, also charged particle reactions and in particular direct proton captures can be expected to be relevant for the production of ⁹²Nb, ⁹⁷Tc and ⁹⁸Tc (e.g., Hoffman et al. 1996; Lugaro et al. 2016; Travaglio et al. 2018). Moreover, both Te SLRs may receive a small neutron capture contribution fed from the available abundance of the stable isotope 96 Ru, via the 96 Ru (n,γ) 97 Ru (β^+) 97 Tc (n,γ) 98 Tc chain. A small amount of ¹⁴⁶Sm can also be made by neutron capture, starting from the stable isotope ¹⁴⁴Sm. ⁹²Nb is shielded from any radiogenic contribution from the proton-rich side of the valley of β stability by its stable isobar ⁹²Mo. The same applies for ⁹⁸Tc and its stable isobar ⁹⁸Ru. A radiogenic contribution to ¹⁴⁶Sm can be made by the respective proton-rich unstable isobars, but also by the α -decay channel ¹⁵⁴Dy $(\alpha)^{150}$ Gd $(\alpha)^{146}$ Sm after the β -decay radiogenic contributions to the single radioactive ¹⁵⁴Dy and ¹⁵⁰Gd.

For the 15 M_{\odot} model in Figure 1, all the proton-rich SLRs except for 98 Tc are present in the pre-CCSN ashes of Ne-burning and partial O-burning. In these regions, between about 1.65 M_{\odot} and 1.8 M_{\odot} , the γ -process is activated (e.g., Arnould 1976). Some 92 Nb and 146 Sm can also be found in the pre-CCSN C-burning ashes up to a mass coordinate 2.55 M_{\odot} , due to the interaction between the former convective O-burning shell and C-burning shell (e.g., Meakin & Arnett 2006; Ritter et al. 2018; Andrassy et al. 2020). 97 Tc, 98 Tc, and 146 Sm are also produced in the top layers of the Heburning ashes (above 2.8 M_{\odot} in the figure), due to their neutron capture channels activated by the s-process in these regions.

During explosive nucleosynthesis, proton captures are active in the deepest region of the ejecta by α -rich freeze-

Figure 14. Same as in Fig. 6, but for 97 Tc (Z=43, top panel) and 146 Sm (Z=62, bottom panel) in explosive Ne burning (mass coordinate 2.1 M_{\odot} from the 15 M_{\odot} model, Fig. 1).

out (e.g., Hoffman et al. 1996; Pignatari et al. 2016b), producing 92 Nb, 97 Tc and small traces of 98 Tc (see in Figure 1 the region between the mass cut and 1.6 M_☉). Note that, the abundance of 92 Nb is so high in this deep region that this isotope is plotted both in the second and the forth panels from the top in Figure 1. The γ -process driven by the CCSN explosion is active at a typical CCSN temperature peak between about 2.5 GK and 3.2 GK (e.g., Rapp et al. 2006). This temperature range is reached in the explosive Ne-burning and partial O-burning regions, where the isotopes discussed in this section are efficiently produced (bottom panel of Fig. 1). The production flux of 97 Tc and 146 Sm during explosive Ne-burning is shown in Fig. 14. In

Radioactive nuclei in the early Solar System 13

the figure we can see that together with the nucleosynthesis flow triggered by photodisintegration reactions, for $^{97}\mathrm{Tc}$ also some proton capture reactions happen: namely, $^{96}\mathrm{Mo}(\mathrm{p},\gamma)^{97}\mathrm{Tc}$. Not included in the figure, $^{91}\mathrm{Zr}(\mathrm{p},\gamma)^{92}\mathrm{Nb}$ and $^{98}\mathrm{Mo}(\mathrm{p},\mathrm{n})^{98}\mathrm{Tc}$ drives the relevant production flow for $^{92}\mathrm{Nb}$ and $^{98}\mathrm{Tc}$, respectively. Instead, in this same mass region $^{146}\mathrm{Sm}$ is mostly driven by (γ,n) and (γ,α) photodisintegration. During the explosion most of the pre-CCSN $^{97}\mathrm{Tc}$, $^{98}\mathrm{Tc}$ and $^{146}\mathrm{Sm}$ made in the He ashes are destroyed by neutron captures. However, some of these isotopes are made again in the milder n-process components between 3.1 M_{\odot} and 3.3 M_{\odot}, during the neutron burst.

Figure 15 shows the abundance profiles of $^{92}\mathrm{Nb},\,^{97}\mathrm{Te},$ $^{98}\mathrm{Tc}$ and $^{146}\mathrm{Sm}$ for all the 15 M_{\odot} models. Qualitatively, the behaviour is consistent between the models. Except for ⁹²Nb, significant variations in the abundances are seen in explosive He-burning, due to the n-process efficiency varying between the models. The yield of 92 Nb is mostly sensitive to the amount of CCSN fallback of the model, due to production via α -rich freeze-out in the innermost regions. For instance, by comparing the yields of 92 Nb from the 15 M $_{\odot}$ models with a low and high amount of CCSN fallback, the ⁹²Nb abundance changes by five orders of magnitude (see Table A3). The yield of 97 Tc is less affected by the position of the mass cut compared to 92 Nb, as 97 Tc is produced in both the α -rich freeze-out and by neutron capture in He-burning conditions. According to Table A3, the ⁹⁷Tc ejected yield varies by an order of magnitude, depending on the position of the mass cut.

From comparing the 20 ${\rm M}_{\odot}$ (Fig. 2) and 25 ${\rm M}_{\odot}$ (Fig. 3) models with the 15 M_{\odot} model (Fig. 1), the first relevant difference is that the higher mass progenitors do not eject any material exposed to α -rich freeze-out conditions. In the 20 M_{\odot} model, the γ -process production is limited to between mass coordinates 2 M_{\odot} and 2.2 M_{\odot} . The milder explosive He-burning experienced in this model with respect to the 15 M_{\odot} model, causes a weaker efficiency of the n-process. These conditions favour the production of 98 Tc and 146 Sm in the ejecta between 4.8 M_{\odot} and 5.2 M_{\odot} . The s-process component of ⁹⁷Tc made during the pre-CCSN phase appears to be more relevant than the γ -process in the ejecta of this model. In the 25 M_{\odot} star shown in Fig. 3, the γ -process production becomes extremely important for all the SLR isotopes considered here. For instance, in this model ⁹⁷Tc is mostly made in these conditions (around 3.4 ${\rm M}_{\odot}).$ For $^{146}{\rm Sm},$ there is also a clear contribution from explosive C-burning made by neutron captures, above mass coordinate 3.6 M_{\odot} . ⁹⁸Tc shows a comparable production due to photodisintegration and by neutron captures.

The yields of all 15, 20 and 25 M_{\odot} models are listed in Tables A2 (⁹²Nb), A3 (⁹⁷Tc and ⁹⁸Tc) and A5(¹⁴⁶Sm). As mentioned, ⁹²Nb shows the largest difference in yields, depending on the location of the mass cut, varying from 2.8×10^{-12} M_{\odot} to 5.2×10^{-7} M_{\odot} in the 15 M_{\odot} models. The 20 M_{\odot} models have no inclusion of the α -rich freeze-out in ejecta, and some of these models do not eject the results of explosive carbon burning either. This causes the ejected yield to also vary considerably, from 2.8×10^{-15} M_{\odot} to 1.8×10^{-7} M_{\odot}. The final yields of ⁹⁷Tc and ⁹⁸Tc also change with the mass cut by about an order of magnitude, as there is production in the α -rich freeze-out that is not included in models with more CCSN fallback. As ⁹⁷Tc is more impacted

Figure 15. Abundance plots of 92 Nb, 97 Tc, 98 Tc and 146 Sm for all 15 M_{\odot} models, as in Fig. 7. It should be noted at 92 Nb abundances reach peaks of about 1×10^{-5} mass fraction in α -rich freeze-out conditions, for mass coordinates M<1.6 M_{\odot}.

by *a*-rich freeze-out its ejected yield varies by an order of magnitude in the 15 $\rm M_{\odot}$ models and by a factor of two in the 20 $\rm M_{\odot}$. As $^{98}\rm Tc$ is less impacted it has a similar variation between models across the 15 $\rm M_{\odot}$, 20 $\rm M_{\odot}$ and 25 $\rm M_{\odot}$ models, of around a factor of two. $^{146}\rm Sm$ shows more limited variation in the yield across the 15 $\rm M_{\odot}$ and 25 $\rm M_{\odot}$ models, up to a factor of 20%. The 20 $\rm M_{\odot}$ and 25 $\rm M_{\odot}$ models with the mass cut above the location of explosive C-burning have reduced yields, from $8.3 \times 10^{-11} \rm M_{\odot}$ in the 20 $\rm M_{\odot}$ model with the lowest mass cut to $1.0 \times 10^{-13} \rm M_{\odot}$ in the 20 $\rm M_{\odot}$ model with the highest mass cut.

4 DISCUSSION

Starting from the analysis provided in the previous section, we discuss here the possibility of using SLRs abundances to track the contribution of the different components in the CCSN ejecta. We then compare our results with other stellar yield sets available in the literature.

4.1 Abundances of SLR isotopes: a diagnostic for CCSN nucleosynthesis?

In Section 3, we have described in detail the nucleosynthesis of SLRs in the different components of CCSN ejecta and have shown that the same SLR can be found in different parts of the ejecta. In some cases (e.g., 36 Cl and 41 Ca) the nucleosynthesis production paths change from one region to the other, with different nuclear reactions relevant for the production in the different regions. In other cases,

the important nuclear reactions are the same (e.g., 60 Fe), but they are triggered at different temperature and density conditions. Furthermore, the stellar half-life of most of SLRs is long enough to have a significant amount of their pre-CCSN production still present in the final ejecta (e.g., 26 Al and 182 Hf). Overall six main nucleosynthesis components in CCSN ejecta can be identified from our analysis for the SLRs: (1) α -rich freeze-out; (2) explosive Si-burning; (3) explosive O-burning; (4) explosive Ne-burning with partial O-burning; (5) explosive C-burning together with pre-CCSN C-burning ashes; and (6) the most external ejecta with He-burning and H-burning products, from both pre-CCSN and explosive nucleosynthesis. The production of isotopes in H-burning and He-burning conditions differ from each other, although, depending on the evolution history of the progenitor star, it is possible to find significant overlap between the ejecta of these two components. Additionally, a precise discussion of the SLR production in the He-burning region requires the He-burning ejecta to be split into subcomponents. Therefore, for the sake of simplicity we consider these most external components together.

In Fig. 16, as a summary, we show the 15 M_{\odot} CCSN ejecta, highlighting the main nucleosynthesis components for the different SLRs. Using the simplified scheme of the six components mentioned above, the components can be roughly divided as described in the caption of Fig. 16.

The α -rich freeze-out component (1) is present in most of the 15 M_{\odot} CCSN models of our set, and in one model of the 20 M_{\odot} star, as the inner most regions of most models are swallowed by the mass cut. Although our models tend to have the α -rich freeze-out component in smaller progenitor

Radioactive nuclei in the early Solar System 15

Figure 16. As a summary, we highlight the main production layers in the CCSN ejecta for the each SLR. We use as a background structure the 15 M_{\odot} model (shown in the top panel of Fig. 1). Each colour defines a specific explosive nucleosynthesis regime: pink is α -rich freeze-out (1.5 M_{\odot} (location of the mass cut) $\lesssim M_{\odot} \lesssim 1.67 M_{\odot}$), light green explosive Si-burning (1.67 $M_{\odot} \lesssim M_{\odot} \lesssim 1.82 M_{\odot}$), blue explosive O-burning (1.82 $M_{\odot} \lesssim M_{\odot} \lesssim 1.95 M_{\odot}$), dark green explosive Ne-burning (1.95 $M_{\odot} \lesssim M_{\odot} \lesssim 2.1 M_{\odot}$), yellow explosive C-burning (2.1 $M_{\odot} \lesssim M_{\odot} \lesssim 2.55 M_{\odot}$), and red explosive He-burning ($M_{\odot} \gtrsim 2.55 M_{\odot}$). The position of each box does not depict the exact mass range of nucleosynthesis, rather it is indicative of the rough position.

masses, there is no clear correlation with the progenitor mass or linear dependence with explosion energy. In the following section, we will see that in other stellar sets this component is not ejected from any stellar masses. We have seen that the SLR isotopes 92 Nb and 97 Tc are efficiently made by component (1), together with a contribution from the explosive Ne-burning, component (4), among others. Our 97 To abundances are not particularly enhanced compared to other stellar sets without α -rich freeze-out in 15 M $_{\odot}$ stars (see following section). This is because the 97 Tc production by component (1) is less than an order of magnitude larger than by produced component (4), with additional contributions from explosive C-burning (5) and He-burning (6), respectively. Therefore, only the 92 Nb abundance can be used as a diagnostic of component (1) contribution, as it dominates its production by component (4) by up to several orders of magnitudes. An important caveat to keep in mind is that one-dimensional CCSN models tend to under-produce the γ -process production in the ⁹²Nb region by about an order of magnitude, when compared to the abundances of stable Mo and Ru proton-rich isotopes in the Solar System. This puzzle is still a matter of debate (e.g., Travaglio et al. 2018). However, the production of 92 Nb is so high in zone (1) of our models, that the diagnostic power of the SLR for this component can be safely derived.

The SLRs ²⁶Al, ³⁶Cl, ⁴¹Ca, ⁶⁰Fe, ¹⁰⁷Pd and ²⁰⁵Pb are made by multiple components (see Figure 16), both from pre-CCSN and explosive nucleosynthesis. This makes them unsuited as a diagnostic of the CCSN properties, as the impact of real physics properties, stellar uncertainties, and nuclear physics uncertainties are difficult to disentangle. ¹³⁵Cs may also be included in this list of SLRs as the explosive contribution during explosive He-burning causes the contribution from component (6) to match that of component (5). This impact is dependent on the explosive energy of the model in question.

We also include ¹⁸²Hf in this category of SLRs with limited diagnostic capability. In our models, we have seen that the CCSN production of this isotope dominates the pre-CCSN production due to neutron captures in (5) and (6). However, as we mentioned in Section 3.8, our models are calculated using an older stellar half-life of the branching point ¹⁸¹Hf, which reduces the s-process production of ¹⁸²Hf in pre-CCSN conditions (Lugaro et al. 2014). In practice, by using the updated nuclear reaction rates the pre-CCSN production will increase, while the CCSN production will not be affected by such a modification and its effective contribution to the ejected yields will be reduced. New simulations are needed using the updated nuclear reaction to establish whether ¹⁸²Hf can be used a diagnostic of CCSN properties.

 $^{53}\mathrm{Mn}$ is produced by the deepest components (1) - (4). Therefore, an efficient production is obtained for different progenitor masses and over a wide range of explosion energies. Faint supernova models with high fall-back mass will not eject these internal zones (e.g., Takigawa et al. 2008; Nomoto et al. 2013), and therefore will be $^{53}\mathrm{Mn}$ -poor. In our stellar sample this is the case for three 25 M_{\odot} models.

As we discussed in Section 3.9, the typical γ -process SLRs 97 Tc, 98 Tc and 146 Sm (by component 4) can also be made by neutron captures within component (6). Additionally, 146 Sm is also made by component (5). In our models, for all progenitor masses and explosion setups, the γ -process

production by component (4) is by far the most efficient for 146 Sm. Therefore, we can consider 146 Sm as the only safe diagnostic to track the contribution from the γ -process and this region of the ejecta.

Finally, according to our models, ¹²⁶Sn is a convincing diagnostic of the high neutron densities reached during the CCSN explosion by the ${}^{22}Ne(\alpha,n){}^{25}Mg$ activation within component (5) and (6). The production associated to the final neutron density is orders of magnitude larger than the pre-CCSN production, and the 126 Sn abundance is extremely low in models with the weakest CCSN explosion energies. This is the case for all the progenitor masses. It is less clear that the same is true for ¹²⁹I. While for instance we can derive similar conclusions for the 25 M_{\odot} models (Figure 3), this is less clear for the 15 M_{\odot} and 20 M_{\odot} models (Figures 1 and 2, respectively), where a significant pre-CCSN production is obtained in zone (5). A more detailed analysis of the ¹²⁹I production and a careful handling of present nuclear uncertainties may be useful to clarify the diagnostic potential of this SLR isotope.

4.2 Comparison with other studies

We compare our yields to other sets of CCSN models found in literature: Rauscher et al. (2002, R02), Limongi & Chieffi (2018, L18), Sieverding et al. (2018, S18), and Curtis et al. (2019, C19). The models described in R02 are calculated using Kepler for both progenitor and explosion calculations, with an initial composition based on Anders & Grevesse (1989) at Z=0.02. The models described in L18 are calculated using the FRANEC code with initial composition also based on Anders & Grevesse (1989) at Z=0.02. The models described in S18 are calculated using the Kepler code (Weaver et al. 1978) with an initial composition based on Lodders (2003). The explosion is simulated with a piston as described in Woosley & Weaver (1995). The models described in C19 are calculated using the Kepler code for the progenitor (Woosley & Heger 2007) and the PUSH model for the explosion (Perego et al. 2015). These models have an initial composition as described in Lodders (2003), at Z=0.013. We note that the C19 study considers only the innermost regions of the star when calculating the explosive nucleosynthesis. S18 includes all SLRs found in Table 1, while R02, L18 and C19 do not, in particular: R02 does not include 98 Tc; L18 does not include 97 Tc, 98 Tc, 107 Pd, 126 Sn, $^{129}\mathrm{I},\,^{146}\mathrm{Sm}$ and $^{182}\mathrm{Hf};$ and C19 does not include $^{36}\mathrm{Cl},\,^{92}\mathrm{Nb},$ $^{107}\mathrm{Pd},~^{126}\mathrm{Sn},~^{129}\mathrm{I},~^{135}\mathrm{Cs},~^{146}\mathrm{Sm},~^{182}\mathrm{Hf},~\mathrm{and}~^{205}\mathrm{Pb}.$ In Figure 17 we compare the yields of the SLRs listed in

In Figure 17 we compare the yields of the SLRs listed in Table 1 to the literature yields mentioned above. For each yield data set (R02, L18, S18, and C19) we compare the yields from the same initial mass. For completion we include the yields that include radiogenic contributions.

We first examine the 15 M_{\odot} models (upper panel of Figure 17). In our calculations, ⁵³Mn, ⁹⁷Tc, ¹²⁹I, ¹³⁵Cs, ¹⁴⁶Sm and ¹⁸²Hf show a relevant or dominant radiogenic production, as already described in Section 3. While, the other SLRs are mostly present already in the CCSN ejecta. The interquartile range (i.e., the range between the 25th and 75th percentiles) is limited within a factor of two for most of the isotopes. Exceptions are ⁹²Nb, ⁹⁷Tc and ¹²⁶Sn. In particular, the largest interquartile range is obtained for ⁹²Nb, varying by of a factor of around two orders of magnitude. The lower

Figure 17. Comparison of all yield sets for each SLR isotope. Literature models plotted here are: Rauscher et al. (2002, R02), Limongi & Chieffi (2018, L18), Sieverding et al. (2018, S18), and Curtis et al. (2019, C19). The upper panel shows the 15 M_{\odot} models, the middle panel the 20 M_{\odot} models and the lower panel the 25 M_{\odot} models. Yields presented in this work are shown as a two boxplots, in red (yields including their respective radiogenic contributions) and in dashed black (vields not including radiogenic contributions). As by the definition of a *boxplot* the box size shows the range of values between the 25th and the 75th percentile of all the models in the dataset. The error bar on the boxplot denote the lower (upper) quartiles, and are given by subtracting (adding) to the position of the 25^{th} (75th) percentile 1.5 times the interquartile range (i.e., the box size). All values above (below) these thresholds are plotted as outliers. Outlying models outside the outer quartiles are shown as small circles for both decayed and undecayed results, using the same color scheme as the boxes.

quartile range can be very large towards lower abundances, where the full range of outlying models are considered within this range (see figure caption for details). ⁹²Nb is again the most remarkable case in the figure, with an effective lower quartile range of about six orders of magnitude. ⁹²Nb is effectively produced only in the innermost region of the explosion ejecta. Therefore, the models that do not include this region will have drastically lower final yields. In the figure, ²⁶Al, ³⁶Cl, ⁴¹Ca, ⁹⁷Tc, ¹⁰⁷Pd, ¹²⁹I and ¹⁸²Hf show remarkable similarities by comparing our results with different yield sets from the literature. For other isotopes large discrepancies can be obtained.

All literature models that include ⁹²Nb show yields that lie within the lower quartile of our models, indicating a higher mass cut than many of our 15 M_{\odot} models. Our ⁵³Mn yields lie in between the high production obtained by R02 and L18, and the lower abundances by S18 and C19. However, S18 and C19 would still be well within the production range of some of our outlying models. The 60 Fe yields are consistent for all models, except for L18 whose abundances are roughly one order of magnitude lower than all others. The lower ⁶⁰Fe abundance in L18 compared to those found in our models is likely due to a reduced neutron burst. Our 98 Tc yields are about factor of 20 smaller than S18 and C19. Our models also tend to produce less ¹²⁶Sn compared to R02 and S18, although outlying models show similar (or even higher) production. The ¹⁴⁶Sm yields vary by two orders of magnitude between R02 and S18. Our decayed yields are in between these values, but with low variances between models. Similarly, we obtain small variations between our models for ²⁰⁵Pb, while considering all the models plotted the range of predictions shown is about one order of magnitude. Nuclear and stellar physics uncertainties of different origin can be the source of these discrepancies, in particular for cases where we see little variations in our set of CCSN models.

The 20 M_{\odot} models are shown in the central panel of Figure 17. Only for ¹⁴⁶Sm do we obtain a relevant radiogenic contribution, while this was the case for six SLRs in the 15 M_{\odot} models above. Boxes larger than a factor of two are obtained for ³⁶Cl, ⁴¹Ca, ⁵³Mn, ⁹²Nb, ⁹⁸Tc, and ¹⁴⁶Sm. A large lower quartile range is also obtained for ⁵³Mn, due to the contribution of outlying models with low concentrations of this isotope.

When we compare all the model sets we find that 26 Al, 41 Ca, 60 Fe, 97 Tc, 98 Tc, 107 Pd, 129 I, 135 Cs, 182 Hf, and 205 Pb show a total range smaller than an order of magnitude. Instead, for 36 Cl our results are consistent with L18 and S18, but they are much smaller than R02. R02 also provided much higher yields for 41 Ca and 92 Nb, although for 92 Nb there are outlying models in our sample with much larger values and covering the full abundance range. Our upper interquartile limit for 92 Nb is one order of magnitude smaller than L18 and up to three order of magnitude smaller than R02. As for the 15 M $_{\odot}$ models in the upper panel of the figure, most of our models show a smaller production of 98 Tc and 126 Sn by about an order of magnitude compared to S18 and C19. Finally, once the radiogenic contribution is taken into account, our 146 Sm median is consistent with S18, but it is almost two orders of magnitude smaller than R02.

The 25 M_{\odot} models are shown in the lower panel of Figure 17. We obtain relevant radiogenic contribution for ¹²⁹I, ¹³⁵Cs and ¹⁴⁶Sm, and we derived interquartile ranges larger

than a factor of two only for ⁵³Mn, ⁹²Nb, ¹²⁶Sn and ¹⁴⁶Sm. Large lower quartile ranges are also obtained for the same SLRs and for 92 Nb. This is due to the efficient fallback of the 25 M_{\odot} models in our stellar sample, where the products of e.g., explosive O-burning is often not ejected. This explanation, however, would not apply to ¹²⁶Sn. Indeed, this SLR is produced primarily in explosive He-burning (see Section 3.6). In this case, the large variance in the ejected yield can be explained by the position of the ignition point of this burning phase. Comparing our $25 M_{\odot}$ models to those in literature, we find overall a good consistency up to ⁹⁷Tc, with some significant variation for ⁵³Mn. We tend to produce less ⁹⁸Tc, ¹²⁹I and ¹³⁵Cs compared to other stellar sets, while for $^{146}\mathrm{Sm}$ most of our data are in between R02 and S18 (with about two order of magnitude of variation between the two models).

In general, for SLRs lighter than ⁶⁰Fe there is agreement within an order of magnitude between different $15 M_{\odot}$ and 25 ${\rm M}_{\odot}$ models. The 20 ${\rm M}_{\odot}$ models show a much larger variation, with up to three orders of magnitude difference for $^{41}\mathrm{Ca}.$ For SLRs heavier than $^{60}\mathrm{Fe},~^{146}\mathrm{Sm}$ shows the largest variation of about two orders of magnitude, varying from S18 up to R02 yields. Other isotope yields are consistent within an order of magnitude. There are three exceptions: ⁹²Nb, $^{98}\mathrm{Tc},$ and $^{126}\mathrm{Sn}.$ For all the progenitor masses considered, in our calculations we produce about an order of magnitude less $^{98}\mathrm{Tc}$ compared to other stellar sets. The same applies for $^{126}\mathrm{Sn}$ if we only consider the 15 M_{\odot} and 20 M_{\odot} stars, although in this case we have outlying models consistent or even exceeding other published results. $^{92}\mathrm{Nb}$ abundances show the most variance in ejected yields, due to the extreme sensitivity to mass cut. If we use our median yield as a reference, the 15 M_{\odot} models overproduce the SLR isotope by at least three orders of magnitude (even if we have outlying models with low 92 Nb abundance). The median of the 20 M_{\odot} models is instead about an order of magnitude lower than the closest set (L18), while the 25 M_{\odot} models median and other sets are in good agreement.

5 CONCLUSIONS

We presented the CCSN yields of 62 one-dimensional models for three progenitors with initial masses of 15, 20 and 25 M_{\odot} and of solar metallicity (Z=0.02, Grevesse & Noels 1993). The impact on the nucleosynthesis of different explosion parameters is explored for each progenitor mass. This work is part of a set of studies focused on the production of radioactive isotopes in the same set of CCSNe models: Jones et al. (2019) analyzed the nucleosynthesis of 60 Fe and Andrews et al. (2020) focused on the production of radioisotopes that are relevant for the next generation of γ -ray astronomical observations. In this work, we study the production of short-lived radioactive isotopes (SLRs) that have been detected in the early Solar System (ESS), with half lives between 0.1 and 100 Myr. Note that compared to Jones et al. (2019) and Andrews et al. (2020), calculations have been redone to correctly take into account the ²⁶Al isomer during the explosion, resulting in an increase of the ²⁶Al yields compared to these previous data sets.

Using the CCSN models presented in this work, we explore for the first time in detail the nucleosynthesis for the

fifteen SLRs both in the progenitor and during the CCSN explosion. In particular, we examine the main production and destruction sites for each isotope individually in the CCSN ejecta. We have identified the most favourable stellar conditions to produce each SLR for the CCSN models considered in this work. In particular, several SLRs are co-produced under the same explosive nucleosynthesis conditions in the CCSN ejecta, as summarised in Fig. 16.

We compared our results with different sets of CCSN models available in the literature and find the following:

• SLRs lighter than and including ⁶⁰Fe are in agreement within an order of magnitude across all masses.

 \bullet SLRs heavier than $^{60}{\rm Fe}$ are generally consistent within an order of magnitude, excluding $^{92}{\rm Nb},~^{98}{\rm Tc},~^{126}{\rm Sn},$ and $^{146}{\rm Sm}.$

• Regarding $^{92}\rm Nb$, the 15 $\rm M_{\odot}$ models overproduce the SLR isotope by three orders of magnitude in the 15 $\rm M_{\odot}$ models and by an order of magnitude in the 20 $\rm M_{\odot}$ models.

 \bullet We produce an order of magnitude less $^{98}\mathrm{Tc}$ than in other stellar sets.

 $\bullet\,$ We produce an order of magnitude less $^{126}{\rm Sn}$ relative to other 15 and 20 ${\rm M}_{\odot}$ models.

• Rauscher et al. (2002) produces more ¹⁴⁶Sm than our models (up to two orders of magnitude) and Sieverding et al. (2018) produces less than our models (up to an order of magnitude).

Such variations in the production of SLRs in onedimensional CCSN models can be understood for nuclei like 92 Nb and 53 Mn due to their creation in the inner regions of the CCSN ejecta, and the impact of assumptions made in the models and stellar uncertainties. Also, typical γ -process products like ¹⁴⁶Sm and neutron-capture products like ¹²⁶Sn show variations well above an order of magnitude. Because our set of CCSN explosions cover a large parameter space, we were able to provide a first assessment of the impact of these differences. More detailed works are required in the future in order to understand and disentangle the source of these changes. In particular, for a number of SLRs (⁴¹Ca, ⁹²Nb, ⁹⁸Tc, ¹²⁶Sn, and ¹⁴⁶Sm) other stellar sets show yields higher than our range of ejected abundances. Other sources of variations need to be carefully taken into account in future works, like e.g., nuclear reaction rate uncertainties and the use of different stellar progenitors. Future work will apply this broad nucleosynthesis analysis to observed ESS abundances, in order to determine if a single CCSN could populate the SLRs found in meteorites.
