Abstract: The aim of the present study is to summarize new results concerning the capacity of the Roman aqueduct of Brigetio (Komárom/Szöny). Hydrological *formulae* used for calculations on the capacity of aqueducts are described and used to determine the daily discharge of the Roman aqueduct of Brigetio. The results presented are hypothetical, but it is hoped that they reflect the performance of the aqueduct. Calculations on *per capita* daily water supply and related problems are also addressed.

Keywords: Brigetio (Komárom/Szöny), aqueduct, capacity of aqueducts, *per capita* water supply

Introduction

The aim of the present study is to summarize new scientific results about the Brigetio (Komárom/Szöny) aqueduct. Literary sources, maps, scientific references, and the archaeological material regarding the Brigetio aqueduct have already been examined in detail and published in a previous study.¹ Thus, the present study will treat these sources only to the extent required by the aims of the new examination.

This paper presents the hydrological methods and *formulae* which enable us to determine the capacity of the aqueducts, and according to them the hypothetical capacity of the Brigetio aqueduct. So far, no section of the Brigetio aqueduct has been observed or excavated by modern archaeological methods. For this reason, the fact that the results presented are hypothetical is emphasized. Besides the capacity of the aqueduct of Brigetio, problems of ancient Roman water usage will be discussed, including the presentation of scientific approaches to the quantity of water supplied to several Roman cities and the difficulties of determining the *per capita* water supply or usage in ancient Roman times.

Calculation of the capacity of aqueducts

The capacity of aqueducts that is, the quantity or discharge of water carried by the conduit can be calculated by the following formula: $Q=VA$. In this formula, Q stands for the capacity that can be calculated by multiplying the average velocity of flow (V , measured in m/s) by the cross-sectional area of the wetted perimeter (A , measured in m^2). It is noteworthy that we calculate with the cross-sectional area of wetted perimeter, thus with the cross-sectional area where the water in fact

1 BENES 2018.

flows and not the whole cross-sectional area of the conduit.² To calculate the average velocity of flow, we can use either the *Chézy formula* or the *Manning formula*. The *Chézy formula* is expressed as follows: $V=C\sqrt{R}\times S$. According to this formula, to calculate the velocity of flow we need to know the hydraulic radius of the conduit (R), the slope or the aqueduct gradient (S) and the factor of flow resistance, the so-called *Chézy's coefficient* (C). The hydraulic radius (R) is defined as the quotient of the cross-sectional area (A) and the wetted perimeter (P) expressed as follows: A/P . The slope (S) of the conduit is defined by the head loss (H) per length (L) of the conduit (H/L), which can be expressed in ‰. Regarding the factor of flow, the so-called *Chézy's coefficient* (C), Antoine Chézy considered it a constant, but the value of the coefficient is defined by the roughness of the surface of the conduit, thus by the degree of friction that the surface of the conduit causes.³

For the determination of *Chézy's coefficient*, several *formulae* have been created. The *Gangillet–Kutter formula* was created by two Swiss engineers in 1869. According to this *formula*, to express Chézy's resistance factor we need to know the slope (S), the hydraulic radius (R) and the coefficient of roughness (n):

$$C = \frac{23 + \frac{0.00155}{S} + \frac{1}{n}}{1 + \left(23 + \frac{0.00155}{S}\right) \frac{n}{\sqrt{R}}}$$

The coefficient of roughness (n) refers to Kutter's n and the formula itself is based on flow-measurement data concerning various types of channels.⁴

In 1897, a new formula was introduced by Emile Bazin to determine *Chézy's coefficient* (C), which is expressed as follows:

$$C = \frac{87}{1 + \frac{m}{\sqrt{R}}}$$

In the *Bazin formula*, m is a coefficient of roughness which is defined in a table (*Table 1*) and R is the hydraulic radius. According to this formula, the slope (S) does not play a part in determining the factor of flow, i.e., *Chézy's coefficient* (C). The value of the coefficient of roughness (m) depends on the material and quality of the channel. In order to define the value of m , Emile Bazin used data based on small experimental channels. According to later studies, the *Gangillet–Kutter formula* is more precise than the *Bazin formula*.⁵

In 1889, Robert Manning created a new formula to determine the factor of flow (C), which is expressed as $C=KR^{1/6}$. In this formula, K refers to a coefficient that determines the roughness of a certain channel. In order to determine the K coefficient, we need the reciprocal value of Manning's n coefficient of roughness, which is expressed as $K=1/n$. The value of n is determined by the quality of the surface (Table 2): as the surface gets rougher the value of n increases and the value of K decreases.⁶

In the case of Roman aqueducts, which were lined with smooth plastered concrete (*terrazzo*), the factor of flow, i.e., the C coefficient is always between the values of 60 and 80. The smoother and newer the work, the higher the value of the C coefficient.⁷ Based on the formulae described above, we can calculate the capacity of Roman aqueducts if we know the slope of the aqueduct, the size of the channel, the height of the water carried in the channel, and the factor of flow, i.e., the C coefficient.

The capacity of the Roman aqueduct of Brigetio

Due to the fact that, unfortunately, no section of the aqueduct channel has been studied by modern archaeological methods, for the Roman aqueduct of Brigetio, only a hypothesis can be built on its capacity. Regarding the route and the length of the aqueduct and the size of the channel, we have to rely on maps and literary sources that mention the aqueduct. Thanks to the literary sources, we can formulate an idea of its structure, construction, and size.⁸

8 See BENES 2018 for maps and literary sources concerning the Roman aqueduct of Brigetio.

Based on literary sources, maps, and studies concerning the structure and construction of the aqueduct, we conclude that it consisted partly of a vaulted channel running near the surface, partly in a ramp, therefore it was a surface channel,⁹ and partly the aqueduct channel was built on arcades above the level of the surface. The construction consisted of bricks, stone, and tuff stuffed with lime.¹⁰ The size of the vaulted surface channel running in a ramp at least at the intact section near BÉlapusztá observed by Rudolf Gyulai was one meter high, and 0.8 m wide. The length of the aqueduct according to the available literary sources was between 15.2 and 15.75 km. To determine the slope of the aqueduct, we need the levels of the starting point and the endpoint. As the endpoint of the aqueduct, we can assign the foreground of the south gate of the legionary camp,¹¹ which is located 107 m above sea level. It is more difficult to define the starting point of the aqueduct, in other words, to determine the location of the spring that supplied it.

According to literary sources, maps, and studies, the following locations are the possible options: the spring of Kőkút Köz,¹² the spring of the Eszterházy Hospital,¹³ the springs in the area of the Old Lake,¹⁴ and the Fényes Springs.¹⁵ I used the daily discharge values estimated by Henrik Horusitzky in 1919.¹⁶

According to the discharge values described above, the Romans must have used the abundant sources of either the Fényes Springs or the Great Spring under the Castle to supply the Brigetio aqueduct. The Great Spring under the Castle is located 118 m above sea level. The Fényes Springs are located 118–119 m above sea level. If we assign the foreground of the south gate of the legionary camp as the endpoint of the aqueduct, which is located 107 m above sea level, and we count with a 15.75 km long route,¹⁷ the difference between the level of the starting point and that of the endpoint of the aqueduct is 11 m in the case of the Great Spring under the Castle. This means the slope of the aqueduct would be 0.69%. In the case of the Fényes Springs, the difference between the levels

9 Following the terminology of HODGE 1992, 93: *surface channel* – ‘a conduit that closely followed the surface of the land, instead of being raised on arches or sunk deep beneath it in a tunnel’.

10 MARSIGLI 1726, 3; BÉL 1989, 80, 93, 96; National Archives of Hungary Fasc. 39, Nr. 63; GYULAI 1885; GYULAI 1886.

11 I assigned the foreground of the south gate of the legionary camp as the endpoint of the aqueduct based on the maps of Sámuel Mikoviny (National Archives of Hungary S. 11 No. 290), Rudolf Gyulai (GYULAI 1886, 333.), and Milos Berkovics-Borota (BERKOVICS-BOROTA 1886, 393).

12 Based on Sámuel Mikoviny’s map, Bence Simon and László Rupnik suppose that the spring of Kőkút Köz supplied the aqueduct. The estimated daily discharge of the spring of Kőkút Köz in 1919 was 32.4 l/min, which means the daily discharge of the spring was 46.656 m³. If we suppose the aqueduct collected the water of the springs of Komárom Street, the daily discharge increases by 1,800 l/min, which equals 2,592 m³/day. Overall, the total daily discharge of the springs of Komárom Street and Kőkút Köz is 2,638.656 m³.

13 GYULAI 1885. In the case of the spring of the Eszterházy Hospital (recently called the springs of the Castle Garden), which is located 135.3 m above sea level, the daily discharge was 60 l/min, which amounts to 86.4 m³/day according to the estimations made in 1919.

14 GYULAI 1886; BERKOVICS-BOROTA 1886, 393. Regarding the area of the Old Lake, the Great Spring under the Castle located at 118 m above sea level had considerable discharge. According to the data given by Henrik Horusitzky, its discharge was 10,998 l/min, thus we can count with a daily discharge of 15,837.12 m³.

15 PAULOVICS 1941, 145–151; Of the above options, the Fényes Springs had the highest discharge. The springs are located 118–119 m above sea level and their discharge was 81,000 l/min, which means a daily discharge of 116,640 m³ according to the estimated data from 1919.

16 HORUSITZKY 1923. For a detailed description of the springs of Tata and the possible sources of the aqueduct of Brigetio, see: BENES 2018, 425–428, Tab. 1, Fig. 7.

17 I count with a 15.75 km long aqueduct route, according to data given by Milos Berkovics-Borota (BERKOVICS-BOROTA 1886, 393.).

is 11–12 m, thus the slope of the aqueduct would be 0.69‰ to 0.76‰. These values differ from the values suggested by Vitruvius (5‰) (VITRUVIUS: *De Arch.* 8. 6. 1.) and Plinius (0,2‰) (PLINIUS: *Nat. Hist.* 31. 57). However, aqueducts with similar slopes are common in the Roman Empire.¹⁸

To determine the capacity of the aqueduct (Q), as described above, we need to know the average velocity of the flow (V) of the water in the channel and the cross-sectional area of the wetted perimeter (A), as the capacity is calculated by multiplying these values: $Q=VA$. For the calculation of the size of the cross-sectional area of the wetted perimeter, we need to know the height of the water in the aqueduct channel and the width of the channel. Based on the description of Rudolf Gyulai, the vaulted channel of the Brigetio aqueduct was one meter high and 0.8 m wide.¹⁹ Considering the ancient Roman practice, we can assume that the aqueduct channel was only half to two thirds full of water.²⁰ In the case of a channel half full, we can calculate the cross-sectional area of the wetted perimeter as follows: $A=0.8\text{ m}\times 0.5\text{ m}$, which equals 0.4 m^2 . To calculate the average flow of water in the channel, we can use the *Chézy formula*: $V=C\sqrt{R\times S}$. The size of the hydraulic radius R equals the quotient of the cross-sectional area of the wetted perimeter (A) and the wetted perimeter (P): $R=A/P$. Thus, in the case of the Brigetio aqueduct, we can calculate with $0.4\text{ m}^2/1.8\text{ m}$, which equals 0.222 m .

The slope (S) of the aqueduct is defined by the head loss (H) per length (L) of the channel (H/L), which can be expressed in ‰. As noted above, based on the discharge of springs in Tata, the Great Spring under the Castle (118 m above sea level) and the Fényes Springs (118–119 m above sea level) must have been able to supply the aqueduct. As the endpoint of the aqueduct probably we can assign the foreground of the south gate of the legionary camp (107 m above sea level). Calculating with these options, the difference between the levels of the starting point and the endpoint, i.e., the head loss of the aqueduct is 11 m in the case of the Great Spring under the Castle, and 11–12 m in the case of the Fényes Springs. Regarding the length of the route of the aqueduct, I have opted for using the length given by Milos Berkovics-Borota,²¹ as he also located the source of the aqueduct in the vicinity of the Castle. Therefore, the slope of the aqueduct in the case of the Great Spring under the Castle is $11\text{ m}/15.750\text{ m}=0.00069841$, which means 0.69‰. For the Fényes Springs, this value is $11\text{ m}/15.750\text{ m}=0.00069841$ or $12\text{ m}/15.750\text{ m}=0.00076190$, which means 0.69‰ or 0.76‰. As both options are possible, I have calculated the capacity of the aqueduct for both.

Besides the values listed above, we need the factor of flow, the so-called *Chézy's coefficient* (C) in the calculation of the capacity of the aqueduct. In the case of ancient Roman aqueducts which were lined with smooth plastered concrete (*terrazzo*), the C coefficient is always between the values of 60 and 80. The smoother and newer the construction, the higher the value of the C coefficient.²² Considering the fact that no section of the aqueduct has been studied by modern archaeological methods, I decided to calculate with both the lowest and the highest value of the C coefficient.

Using the *Chézy formula*, the average velocity of the water flow in the channel is 0.75 m/s if the slope is 0.69‰, and the C coefficient is 60; thus in an older or less elaborated, rougher channel. If the slope is the same, but the C coefficient is 80, therefore in the case of a smoother and newer channel, the average velocity is 1 m/s. If the slope is 0.76‰ and the C coefficient is 60, the average velocity of the water flow in the channel is 0.78 m/s, if the C coefficient is 80; thus, for a smoother channel, this value is 1.04 m/s.

18 BENES 2018, 428; HODGE 1992, 347–348.

19 GYULAI 1885.

20 HODGE 1992, 94–95, 225, Fig. 157.

21 BERKOVICS-BOROTA 1886, 393.

22 HODGE 1992, 354.

According to the calculations above, we may suppose that the average velocity of the water flow in the channel was between 0.75 m/s and 1.04 m/s. Calculations for capacity have been made with both values of the average velocity of the water flow in the channel. In order to calculate the capacity of the aqueduct, as noted above, the average value of the velocity of the water flow in the channel has to be multiplied by the size of the cross-sectional area of the wetted perimeter. In the case of the Brigetio aqueduct, calculating with an 0.40 m² cross-sectional area of the wetted perimeter and the lower value of the velocity of water flow in the channel, thus with 0.75 m/s, the capacity is: $0.40 \times 0.75 = 0.3$ m³/s. This means 18 m³/min, 1,080 m³/h, and 25,920 m³/day. Calculating with the higher value of average velocity of water flow in the channel, thus with 1.04 m/s, the capacity of the aqueduct is $0.40 \times 1.04 = 0.416$ m³/s, which means 24.96 m³/min, 1,497.6 m³/h, and 35,942.4 m³/day. Rounding these values of capacity, we may suppose the daily discharge of the Roman aqueduct of Brigetio was between 26,000 m³ and 36,000 m³. It is important to note that the results are hypothetical because of several reasons: the size of the aqueduct channel might have been different in certain sections,²³ the slope of the aqueduct might differ in sections of the channel, and the height of the water in the channel could also vary. All these factors had an impact on the capacity of the aqueduct, and the results are based on the limited data available, thus are to be handled with caution. However, these hypothetical results represent the efficiency of the Roman aqueduct of Brigetio. Even calculating with the lowest values, we have a daily discharge of 26,000 m³, which might seem very high, but for Roman aqueducts this capacity is average (*Table 3*).

The best-known Roman aqueduct in Pannonia from an archaeological point of view is that of Savaria (Szombathely). Thanks to modern archaeological excavations on different sections of the aqueduct channel, we are able to study its hydrology. Regarding the capacity of the Roman aqueduct of Savaria, Krisztián Anderkó has recently published his results. On the basis of two Austrian sections of the aqueduct channel with average permeability, he has calculated the capacity of the aqueduct in the case of maximal utilization of the channel and has obtained the results of 76,000 m³/day and 163,200 m³/day. Due to the slope between the starting point and the endpoint, which is 9.1‰, the capacity of the aqueduct is very high. Based on the wear and scaling process observed on a section of the channel in Bucsú, he assumes that only 50 to 60% of the channel was in fact filled with water.²⁴ This means we should count with half of the above discharge values to estimate the actual daily discharge of the aqueduct, which in this case is between 38,000 m³/day and 81,600 m³/day. These values are significantly higher than the hypothetical results regarding the capacity of the Brigetio aqueduct.

The hypothetical results regarding the capacity of the Brigetio aqueduct confirm the former assumption that the source of the aqueduct might have been either the Great Spring under the Castle or the Fényes Springs. According to the hypothetical capacity calculated, the aqueduct could easily transport the 15,837.12 m³ daily discharge of the Great Spring under the Castle. Regarding the enormous discharge of the Fényes Springs, the aqueduct would have been unable to transport the entire 116,640 m³ daily discharge of all the springs, but if the source of the aqueduct was located here, we can consider that it was not necessary to use all the springs to supply the aqueduct.

23 The aqueduct of Savaria can be given as an example, which shows different cross-sections. For further details, see: ANDERKÓ 2006, 37, Fig. 6, Fig. 8.

24 ANDERKÓ 2006, 36–39.

Ancient Roman *per capita* water supply

The problem of ancient Roman *per capita* water usage and *per capita* water supply is an unresolved historical problem. Neither the literary sources nor the archaeological evidence provide enough and appropriate data regarding the determination of *per capita* water usage or *per capita* water supply in Roman times. Although it is possible to calculate the capacity of certain aqueducts, in most cases the extent of utilization of the channel remains unknown. Another problem is that we are unable to capture temporal changes in the utilization of the aqueducts.²⁵ However, it can be established that the size of an aqueduct channel was determined not only by the amount of water it had to carry, but ample space had to be provided for maintenance and cleaning work as well.²⁶ It also has to be noted that aqueduct channels were never running full: they were normally filled half to two thirds.²⁷

Another uncertainty is the population of ancient Roman settlements. We do not have reliable data even for the population of Imperial Rome in any period. The generally accepted assumption regarding Rome's Frontinus era population is approximately one million.²⁸ The estimated values regarding the total daily discharge of Rome's aqueducts are also different, therefore the estimated *per capita* daily supply also varies on a wide range. According to Pietrantonio Pace, the total daily discharge of Rome's aqueducts was 1,010,000 m³,²⁹ while the estimate of Trevor A. Hodge on the total daily discharge gives a value between 700,000 and a million cubic meters.³⁰ Henning Fahlbusch assumes it was between 520,000 and 635,000 m³,³¹ while according to Deane Blackman, the total daily discharge was approximately 560,000 to 620,000 m³.³² Another problem is the daily *per capita* water supply, as it is usually calculated simply by the division of the above listed estimated total discharge values by the estimated population numbers. However, the resulting figure might be misleading because this method does not yield actual and useful results. One reason is that the water distribution between inhabitants was unequal. For example, the higher classes of society had their private water supply. In addition, a significant proportion of the water supplied was used by baths, latrines, and fountains.

These issues are highlighted in a study by Christer Bruun regarding the daily *per capita* water supply in Imperial Rome. According to Bruun, the total daily discharge of Rome's aqueducts was approximately 600,000 m³. Calculating with a population of one million, the *per capita* daily water supply was 0.6 m³. This figure might be misleading because water was not distributed equally between the public and the private spheres. According to Frontinus, the aqueducts of Rome served 591 major delivery points, so-called *laci*.³³ Bruun estimated each *lacus* could supply 60 m³ of water on a daily basis, and each *lacus* served 900 inhabitants, thus the daily *per capita* water supply was 0.067 m³. This amount might seem low but it reflects only the *laci*. In addition, Rome's inhabitants could also use the water supplied by public fountains, baths and latrines, as well as the water of the Tiberis and rainwater collected in cisterns.³⁴ Roger D. Hansen has found the daily 0.067 m³ amount

per capita supplied by the *laci* satisfactory. Moreover, in comparison, he notes that the average daily water consumption *per capita* in the U.S.A. in the 1990s was 0.25 m³. He also mentions that Roman water supply was fundamentally different compared to modern water supply. Modern water supply is of the 'on-demand' type, while the ancient Roman water supply was constant, because the water was running all the time in conduits, channels, latrines, and fountains. Therefore, it might lead to false conclusions if we compared the *per capita* water use of Rome with contemporary figures.³⁵ According to Bruun, for the Romans the constant day and night flow of water was a symbol of wealth. On the other hand, they highly valued water. Although Frontinus does not refer to saving water, archaeological excavations have unearthed taps³⁶ used in the water distribution system that provide evidence for the 'on-demand' type of water usage. Furthermore, the different types and sizes of cisterns also refer to saving water.³⁷

To sum up, concerning the discharge of Roman aqueducts and the *per capita* daily water supply, unfortunately, we do not have enough scholarly and archaeological evidence. Nevertheless, based on available estimations, Imperial Rome was able to adequately supply approximately one million people, which must have been a great achievement.

Hans Eschebach estimates the water usage and supply of the city of Pompeii. Based on the fact that a total of 40 public fountains have been discovered in the excavated area, i.e., in about two-thirds of the entire city, he puts the total number of public fountains at 50. With an estimated population of 8,000, this means each public fountain served 160 inhabitants. The fountains were located approximately 100 meters apart, thus there was one available for every single inhabitant within 50 meters. The estimated daily discharge of the aqueduct is 6,480 m³. Calculating with 0.5 m³ daily *per capita* water usage, a total of 4,000 m³ of water was used by the inhabitants, and 2,480 m³ was left for other public and industrial use.³⁸ Regarding the estimated figures of the daily *per capita* consumption, Hodge notes calculating with a consumption of a daily 0.5 m³ *per capita* is excessively generous, especially compared to a person's minimal daily need of about 0.01 m³. The estimations of Eschebach do not take account of inhabitants who had their own private water supply and probably did not use the public fountains. Besides, there were further supplies of water thanks to the wells and cisterns available. Overall, the aqueduct seems to have carried sufficient amounts of water to supply the estimated 8,000 inhabitants of Pompeii.³⁹

For the population of Brigetio, unfortunately, we do not have any estimates. Taking into account the city's importance, we can calculate with approximately 20,000 to 25,000 inhabitants concerning the whole population of the legionary camp, the *canabae* and the *municipium*, as only the legionary camp was made up of at least 10,000 persons.⁴⁰ According to the above calculations on the hypothetical capacity of the Brigetio aqueduct, it seems that it managed to supply the entire city with fresh water. It appears that the earlier defined hypothetical 26,000 to 36,000 m³ daily discharge was needed for the city. The recently discovered Roman bath on the territory of the *canabae*, which has so far been excavated in an area of some 900 m², but whose full size is unknown,⁴¹ also needed

36 Taps were not uncommon in the Roman water network system. They served two functions: they were either moulded over a sink or bath, or they were inserted where pipes branched off to shut off the supply when needed. For further details, see: HODGE 1992, 322–326.

significant amounts of water. As described above, to calculate the daily *per capita* water supply, we can devise the daily discharge of the aqueduct, but we have to remember that, because of the reasons given above, the value is only a hypothetical 'guiding' figure, not reflecting the actual situation. However, based on the available data, this is the only way to calculate the daily *per capita* water supply. For Brigetio, I have calculated the daily *per capita* consumption using both the minimal and the maximal results on the daily discharge of the aqueduct, and have also made calculations with both the minimal and the maximal estimated numbers of inhabitants. Calculating with the minimal values in both cases, that is with 26,00 m³ and 20,000 inhabitants, the daily *per capita* water consumption or supply is 1.3 m³. Calculating with the minimal daily discharge of the aqueduct and the maximal number of inhabitants, that is with 26,000 m³ and 25,000 inhabitants, the daily *per capita* water supply is 1.04 m³. If counting with the maximal daily discharge of the aqueduct and the minimal number of inhabitants, that is with 36,000 m³ and 20,000 inhabitants, the daily *per capita* water supply is 1.8 m³. Calculating with both the maximal discharge and the maximal number of inhabitants, that is with 36,000 m³ and 25,000 inhabitants, the result on the daily *per capita* water supply is 1.44 m³.

To sum up, according to the calculations based on hypothetical and estimated data of the capacity of the aqueduct and the number of inhabitants, the daily *per capita* water supply was between 1.04 and 1.8 m³. This might seem very high but it has to be remembered that this is a 'guiding' figure, and due to the lack of information, more accurate estimation seems impossible.

In conclusion, concerning Roman water usage and supply, there are several unknown factors. Although the capacity of the aqueducts can be estimated, the estimation of the daily *per capita* water supply is more difficult because the water was not distributed equally among the inhabitants. Furthermore, we know that cisterns, wells, rivers, and lakes also provided water, but unfortunately, we have no methods to measure the amounts they provided.

Summary

The aim of the present study is to introduce new data on the Roman aqueduct of Brigetio and on the daily *per capita* water supply in the city. Based on the available information, calculations have been made to gauge the capacity of the aqueduct. Unfortunately, no section of the aqueduct has been studied by modern archaeological methods, therefore the results presented in the study are hypothetical and based on indirect sources. Consequently, results should be interpreted with caution. The size of the channel, the slope of certain sections, and also the height of the water in the channel could vary, which had an effect on the capacity of the aqueduct. In addition, the results are based on the limited data available.

It is calculated that the estimated daily discharge of the aqueduct was between 26,000 m³ and 36,000 m³. Based on this figure and a population of 20,000 to 25,000, in Brigetio the estimated daily *per capita* water supply was between 1.04 and 1.8 m³.
