16. Abstract

One of the important environmental issues raised recently in regard to coal ash reuse for highway construction purposes (e.g., embankment development) is that of worker, and public, exposure to radiation which might possibly be emitted by these types of residuals. Radiation emission is, in fact, a natural phenomenon for most materials, both natural and man-made, but in the case of coal ash residuals the process of combustion produces an inevitable concentration of radionuclides from the original virgin coal. INDOT's corresponding environmental concern consequently focuses on the following basic question: *does this magnification of radionuclides found within these coal ash residuals cause sufficiently high levels of radiation to impose harmful effects due to exposure?*

This research project subsequently addressed the associated issue of radiation emission by coal ash residuals generated within the State of Indiana, covering both fly ash and bottom ash materials. Samples were obtained at sixteen (16) different coal-fired power generating facilities within Indiana and subjected to a quantitative analysis of their associated gamma-ray emission levels. After identifying the responsible radionuclides, a conservative approximation was then developed for the worst-case potential occupational exposure with construction employees working on this type of high-volume, coal ash embankment. In turn, these potential emission levels were compared to those of other traditional construction materials and other common sources.

The observed results indicated that these coal ash residuals did contain levels of gamma-ray emitters that were, in fact, higher than those of traditional construction materials (i.e., clay, sand, brick, and limestone). However, these levels of gamma-ray emission were not excessively high, and considerably below the limits respectively promulgated for public exposure and occupational exposure by the Environmental Protection Agency (100 mrem/yr for a single man-made source) and the Nuclear Regulatory Commission (5 rem/yr).

ACKNOWLEDGMENTS

During the course of this project, the following individuals and organizations provided considerable, and enthusiastic, support to the development and completion of the research effort detailed within this report:

- **Barry Partridge**, INDOT, Chief of Research Division,
- **David Ward**, INDOT Section Manager,
  [*INDOT Applied and Environmental Research, Electrical Engineering and Technical Support*]
  ...for their technical assistance, professional insight, and financial support

- **Participating Indiana Power Generators,**
  - ***AEP***
  - ***Hoosier Energy***
  - ***IPL***
  - ***NIPSCO***
  - ***PSI***
  - ***Purdue University***

  ...without their cooperation and understanding, the gathering of samples would have been much more difficult, and this project would not have been as comprehensive

- **Brandon Ogilvie,**
  [*M.S. Candidate, Environmental and Hydraulic Engineering Area, Purdue University]*
  ...for writing a computer code that saved several hours of sorting data

K	Potassium	Tl	Thallium
Pa	Palladium	U	Uranium

IMPLEMENTATION REPORT

Coal combustion by-products (i.e., coal ash) have been considered as a alternative material for use in the construction of large embankments for highways. One of the concerns raised with using these coal ash residuals, though, is the potential for exposure to the public by radiation resulting from naturally occurring radionuclides that are concentrated in ash during the burning of coal. However, the findings presented within this report indicate that this concern is unwarranted since the levels of exposure observed with residuals taken at sixteen different facilities have been found to be consistently low. While the dose equivalent of coal ash (i.e., due to the emission of gamma radiation) is higher than that of several other traditional construction materials, it is comparable to, and often lower than, a number of other radiation exposures that are present in everyday life.

Pursuant to these findings, therefore, the following suggestions are being provided as a means of implementing and extending this research effort:

- **Continued Full-Scale Implementation Projects**

  During the recent few years, INDOT has conducted three 'proof-of-concept' full-scale embankment projects using coal ash materials. The findings of this report strongly support further INDOT efforts to extend the scale of this reuse activity, working in consort with similarly motivated coal-fired power plants to develop mutually favorable arrangements for material preparation, stockpiling, and conveyance.

- **Development of Pro-Active INDOT Reuse Perspective for Indiana Residents**

  The fact that environmental groups within the State of Indiana have openly raised concerns about coal ash radiation levels is a circumstance which underlies the importance and direction of public sentiment relative to their perception of environmentally sensitive technical matters. Backed by real data which negates the associated level of concern stemming from coal ash radiation levels, a constructive dialogue with these types of groups would appear to be beneficial to the long-term success of INDOT's reuse policies for coal ash materials.

CHAPTER 1

Introduction

Given the fact that one of the largest problems facing the coal-fired electric power industry is that of the massive buildup of coal combustion by-products (i.e. coal ash), there is a significant on-going search to find acceptable uses for these residuals. While several beneficial reuse applications have been considered (e.g., concrete and asphalt additives, roofing material preparation, etc.), the high-volume use of these coal ash residuals with embankments for highways and bridge overpasses appears to represent one of the most promising management options.

Indeed, the Indiana Department of Transportation (INDOT) currently lists coal ash as a qualified material for road construction and has arrangements with several power companies to obtain coal ash for this purpose. Within recent years, INDOT has conducted three such full-scale, '*proof-of-concept*' road construction projects, including:

- US Highway-50 near Vincinnes, IN,
- US Highway-12 in Gary, IN, and the
- 56th Street overpass across Interstate Highway-465 in Indianapolis, IN.

Using coal ash in this type of application, however, may present a number of concerns for public safety and environmental protection. Although chemical-specific issues (e.g., relative to leachate elements such as arsenic, selenium, etc.) are typically cited in this respect, additional concerns have also been expressed in the technical literature regarding radiation emission levels and their potential impact on human health (e.g., Myrick, *et al.*, 1983; Tadmor, 1986; and Roeck, *et al.*, 1987).

On the one hand, radiation is usually perceived as a problem because of its perceived potential for harming humans, and the corresponding anxiety over unknown and misunderstood facts. However, this perception is normally unwarranted, especially at the low levels of radiation experienced in the natural environment.

In the case of coal ash residuals, though, radiation levels found within virgin coals will inevitably be concentrated during the course of firing. While there may well be some loss of radionuclides through the stack during firing, the expected magnification level for these radionuclides (increasing from virgin coal to fired ash levels) could well estimated to be a factor a ten, and possibly

higher (i.e., based on the fact that raw coal typically has an inert, non-volatile ash content of approximately 10%).

INDOT's corresponding environmental concern consequently focuses on the following basic question: *does the magnification of radionuclides found within these coal ash residuals reach levels sufficiently high to impose harmful risks of exposure?*

This research project subsequently addressed the associated issue of radiation emission by coal ash residuals within the State of Indiana, covering both fly ash and bottom ash. Samples were obtained at sixteen (16) different coal-fired power generating facilities within Indiana and subjected to a quantitative analysis of their gamma-ray emission levels.

After identifying the responsible radionuclides, a conservative approximation was then developed for the worst-case potential occupational exposure to construction employees working on this type of high-volume, coal ash embankment. In turn, these potential emission levels were compared to those of other traditional construction materials and other common sources.

CHAPTER 2

Objectives

This project was developed to experimentally quantify the level of radiation hazard (or lack thereof) associated with the projected use of coal ash residuals for highway-related embankment construction. Overall, the project had seven (7) sequential objectives, as follows:

- **First**, to develop and secure technical contacts at each of Indiana's principal coal-fired power plant facilities who, in turn, would be able to provide authorization and access for subsequent sampling visits,
- **Second,** to secure a representative set of real-world samples from a range of coal-fired power plants within the State of Indiana, including both residual (i.e., fly ash and bottom ash) and virgin coal specimens,
- **Third,** to obtain another group of natural materials (e.g., clays, sands, limestone, granite, etc.) to serve as testing benchmarks for comparative purposes against which the coal ash residuals could be compared,
- **Fourth,** to analytically quantify the gamma-ray emission spectrums for each of the aforementioned coal, coal ash, and natural materials,
- **Fifth,** to develop a corresponding, conservative analysis of the projected radiation emission levels which could be experienced by occupational workers using these coal ash residuals during the construction of embankments,
- **Sixth,** to compare these latter coal ash emission levels against radiation dose equivalents commonly associated with other natural and commonplace sources routinely linked to our workplace and home environments, and
- **Seventh,** to compile and disseminate these findings within this technical report.

CHAPTER 3

Basic Concepts in Radiochemistry and Nuclear Physics

3.1 Technical Definitions Associated with Radiation Testing and Analysis

The technical vernacular used with the science and engineering of radiation testing and emission analysis tends to be rather unfamiliar to most individuals. As a result, a special *'Key Definitions Listing'* has been provided in Appendix F in order to provide a quick guide to many of the terms used throughout this report (i.e., supplementing the *'Acronyms, Symbols, and Abbreviations'* list given earlier on pg. vii).

3.2 Radionuclides in Natural Materials

Coal and coal ash, as well as any other solid material that is naturally derived from the earth's crust, contain trace elements that undergo radioactive decay. Most radionuclides that are naturally common in raw materials are derived from a few long-lived isotopes. Three of these isotopes, Uranium-238 (^{238}U), Uranium-235 (^{235}U), and Thorium-232 (^{232}Th), are the parents of a series of alpha and beta decays called decay chains. These decay chains are shown in Figure 1. After the emission of alpha and beta particles, gamma rays are frequently emitted to release extra decay energy. Table 1 shows the half-lives and significant gamma-rays of each isotope. Each of these chains results in a stable isotope of lead.

The ^{235}U and ^{232}Th decay chains exhibit a phenomenon called branching. Branching occurs when a radionuclide has two options of decay. The percentages shown next to the decay modes, alpha or beta, of Francium-223 and Actinium-227 are the branching ratios for those modes.

$$^{238}U \xrightarrow{\alpha} {}^{234}Th \xrightarrow{\beta^-} {}^{234}Pa \xrightarrow{\beta^-} {}^{234}U \xrightarrow{\alpha} {}^{230}Th \xrightarrow{\alpha} {}^{226}Ra \xrightarrow{\alpha} {}^{222}Rn \xrightarrow{\alpha} {}^{218}Po$$

$$^{218}Po \xrightarrow{\alpha} {}^{214}Pb \xrightarrow{\beta^-} {}^{234}Bi \xrightarrow{\beta^-} {}^{214}Po \xrightarrow{\alpha} {}^{210}Pb \xrightarrow{\beta^-} {}^{210}Bi \xrightarrow{\beta^-} {}^{210}Po \xrightarrow{\alpha} {}^{206}Pb$$

One isotope that is naturally occurring but not a daughter or parent of a decay chain is Potassium-40 (^{40}K), whose decay is shown in Figure 2a. The beta decay of ^{40}K results in Calcium-40.

Other radioactive isotopes that are present in many natural materials that are located near the surface of the earth (in top few meters) result from fallout of nuclear tests. One major isotope of this type is Cesium-137 (^{137}Cs). The beta decay of ^{137}Cs results in Barium-137, shown in Figure 2b. Half-lives and gamma rays for ^{137}Cs and ^{40}K are in Table 2.

Cs-137	30.17 yr	662

3.3 Gamma Radiation

Along with the alpha and beta particles that are emitted, there are many gamma rays released from each decay. In most situations outside of the body, it is gamma radiation that presents the greatest potential for harm to human health. This is because photons are much more difficult to attenuate than alpha or beta particles. For example, alpha particles can be effectively shielded by a sheet of paper or a layer of dead skin cells on the human body, beta particles by several millimeters of concrete or a layer of skin, and gamma rays by several centimeters of lead. Of course, shielding is only necessary when large amounts of radiation is being produced.

Although radioisotopes emit a total sum of hundreds of gamma rays, many of these gamma rays are undetectable because they rarely occur or have a low energy. In fact, some of the radionuclides above actually emit twenty or more gamma rays during a decay, but many of them are undetectable and present no significant risk to humans. Some gamma rays are undetectable because their energies are too low. Other gamma rays are rarely emitted but can be detected in concentrated samples of the source radionuclide. Ten radionuclides that emit significant numbers of high-energy gamma rays are singled-out for this study.

Despite the amount of shielding required to stop each type of radiation and lack of significant gamma rays, it should be noted that beta and alpha radiation can be problematic. If particles are inhaled that have radionuclides attached to them, alpha and beta radiation could be quite hazardous, because no shielding exists inside the body to protect internal organs. For this reason some of the radionuclides in

the decays shown above, that do not have significant gamma rays, could still cause some damage when inhaled.

The detectable gamma rays can be represented on an energy spectrum. An energy spectrum is used to quantify the energy and frequency of gamma-ray emission. This information can be used to identify which radionuclides are present in an unknown sample. Since each radionuclide emits a specific energy and number of gamma rays that can be counted, the presence of a radionuclide can be determined by collecting data in the form of an energy spectrum and analyzing the spectrum for specific patterns of gamma rays.

CHAPTER 4

Materials and Methods

4.1 Coal and Coal Ash Sample Collection

Five power companies, encompassing fifteen power stations, along with the Purdue University power plant, were visited to collect samples of coal, bottom ash, various types of fly ash, and commingled ash, a mixture of bottom and fly ash. Table 3 lists the types of samples acquired from each plant (**NOTE**: *a map depicting the location of the sixteen plants sampled during this project is given in Appendix G*).

Table 3: Evaluated Power Plants and Sample Types

Plant Name	Output (MWe)	Sample Type
IPL		
Stout	900	BA, ESP, Coal

AEP		
Breed	N/A	AP
Rockport	1300	BA, ESP, Coal
Purdue University	50	BA, BH, MC, LS, HA, Coal

Key: BA=bottom ash, BH=baghouse fly ash, LS=limestone, AP=ash pile, APHA=air preheat fly ash, ESP=electrostatic precipitator fly ash, HA=hopper ash, MC=mechanical collector, EA=economizer fly ash, IA=intermediate ash

In most cases the coal and bottom and fly ashes comprise a "complete set" of freshly-produced samples. At some power plants other samples of bottom and fly ash were collected along with the "complete sets." Coal was sampled from bunkers or pulverizers just before being burned. Bottom and fly ash samples, that correspond to the coal were taken from ash hoppers. Representative commingled ash specimens were taken from ash piles, ponds, or silos.

4.2 Comparison of Ash to Natural Materials

The activities and exposures of ash samples were compared to those of several traditional building materials and other common materials. Granite, limestone, clay, brick, marble, and medium-grained sand were among the building materials included in the comparison, and diatomaceous earth, dried bananas, and potassium chloride were among the other materials tested.

4.3 Sample Analysis

Before analysis each sample was oven dried, to determine the dry density of material and to remove the effects of water during radiation detection, and ground into fine particles, in the case of bottom-ash clinkers, if required.

Each sample was tested for photon emissions in a one-liter Marinelli beaker using a Germanium-crystal detector system, as schematically depicted in Figure 3.

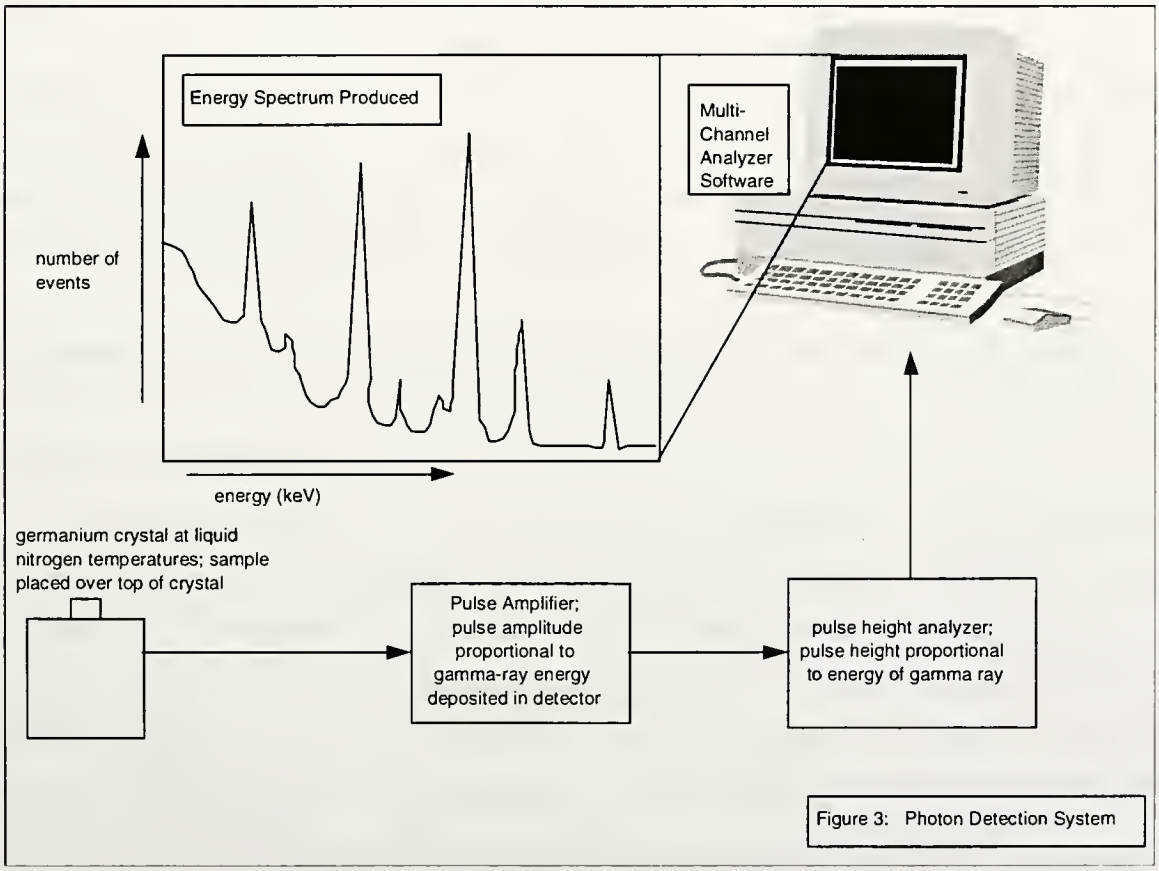

Figure 3: Photon Detection System

The Germanium crystal within this device was sensitive to incident photons at temperatures below 100°K. Through a series of conversions these incident photons were represented by electronic impulses which were recorded on an energy spectrum.

Each test produced a gamma-ray spectrum that was used to identify and quantify the radionuclides present in each sample. Sample spectrums for the fly ash, bottom ash, and coal of plant number 4 are shown in Figures 4, 5, and 6.

The spectral data obtained from testing was analyzed using a gamma ray analysis program, GANAAS, to determine which radioactive species were present in the samples and to calculate the isotopic activities of each species, based on the energy and intensity of the gamma rays listed in Tables 1 and 2.

The pattern of gamma-ray energies in the energy spectrum of each sample was compared to a standard library of gamma rays to determine which radionuclides were present. In turn, the activities provided by GANAAS were used to calculate exposure levels from gamma radiation.

It should be noted that some gamma-ray energies are emitted by two or more isotopes, as is the case with ^{235}U and ^{226}Ra (E=186 keV). In these cases special attention is required to determine the contributions of each isotope to the spectral peak of interest. By using the activities of ^{210}Bi and ^{210}Pb and the emission probabilities of the 186 keV gamma ray for ^{235}U and ^{226}Ra, the contribution to the 186 keV peak of each of the two isotopes can be determined.

4.4 Modeling Methods to Characterize Coal Ash Embankment Radionuclide Emission and Exposure

4.4.1 Basis of Physical Model

Figure 7 and 8 show the physical condition of an embankment of coal ash and the scenario for exposure, respectively. The embankment can be from several centimeters to several meters thick. It is assumed to be comprised of incremental volumes of silicon (coal ash composition can be best approximated by silicon for gamma-ray attenuation purposes) that isotropically emit gamma rays. The gamma rays, that can "escape" an embankment, are those that travel in the positive z-direction. Each volume also has the ability to attenuate gamma rays, removing them or, at least, reducing their energy.

It is also assumed that no soil, asphalt, or concrete is covering the surface of the coal ash. This assumption provides a worst-case scenario, since anything covering the coal ash would have the ability to attenuate gamma rays.

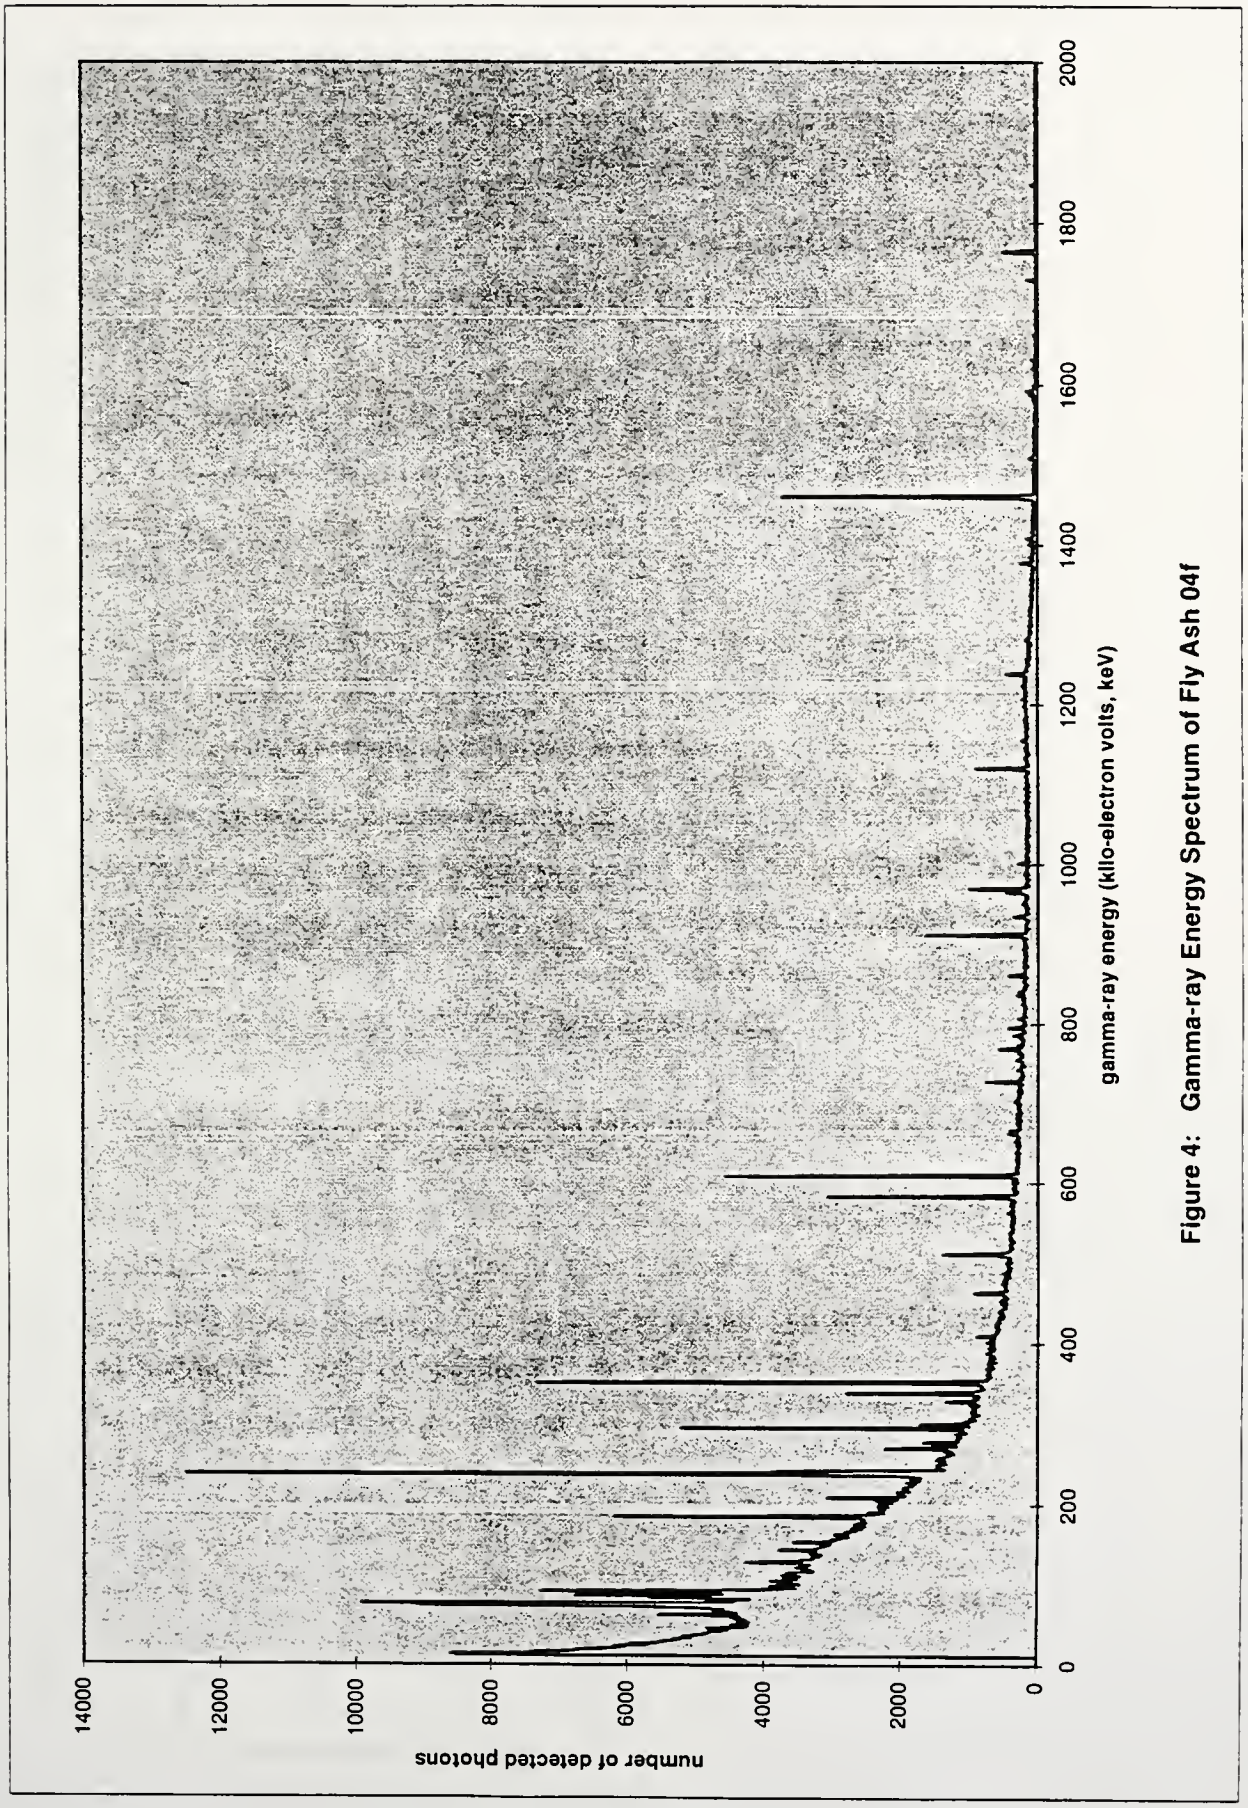

Figure 4: Gamma-ray Energy Spectrum of Fly Ash 04f

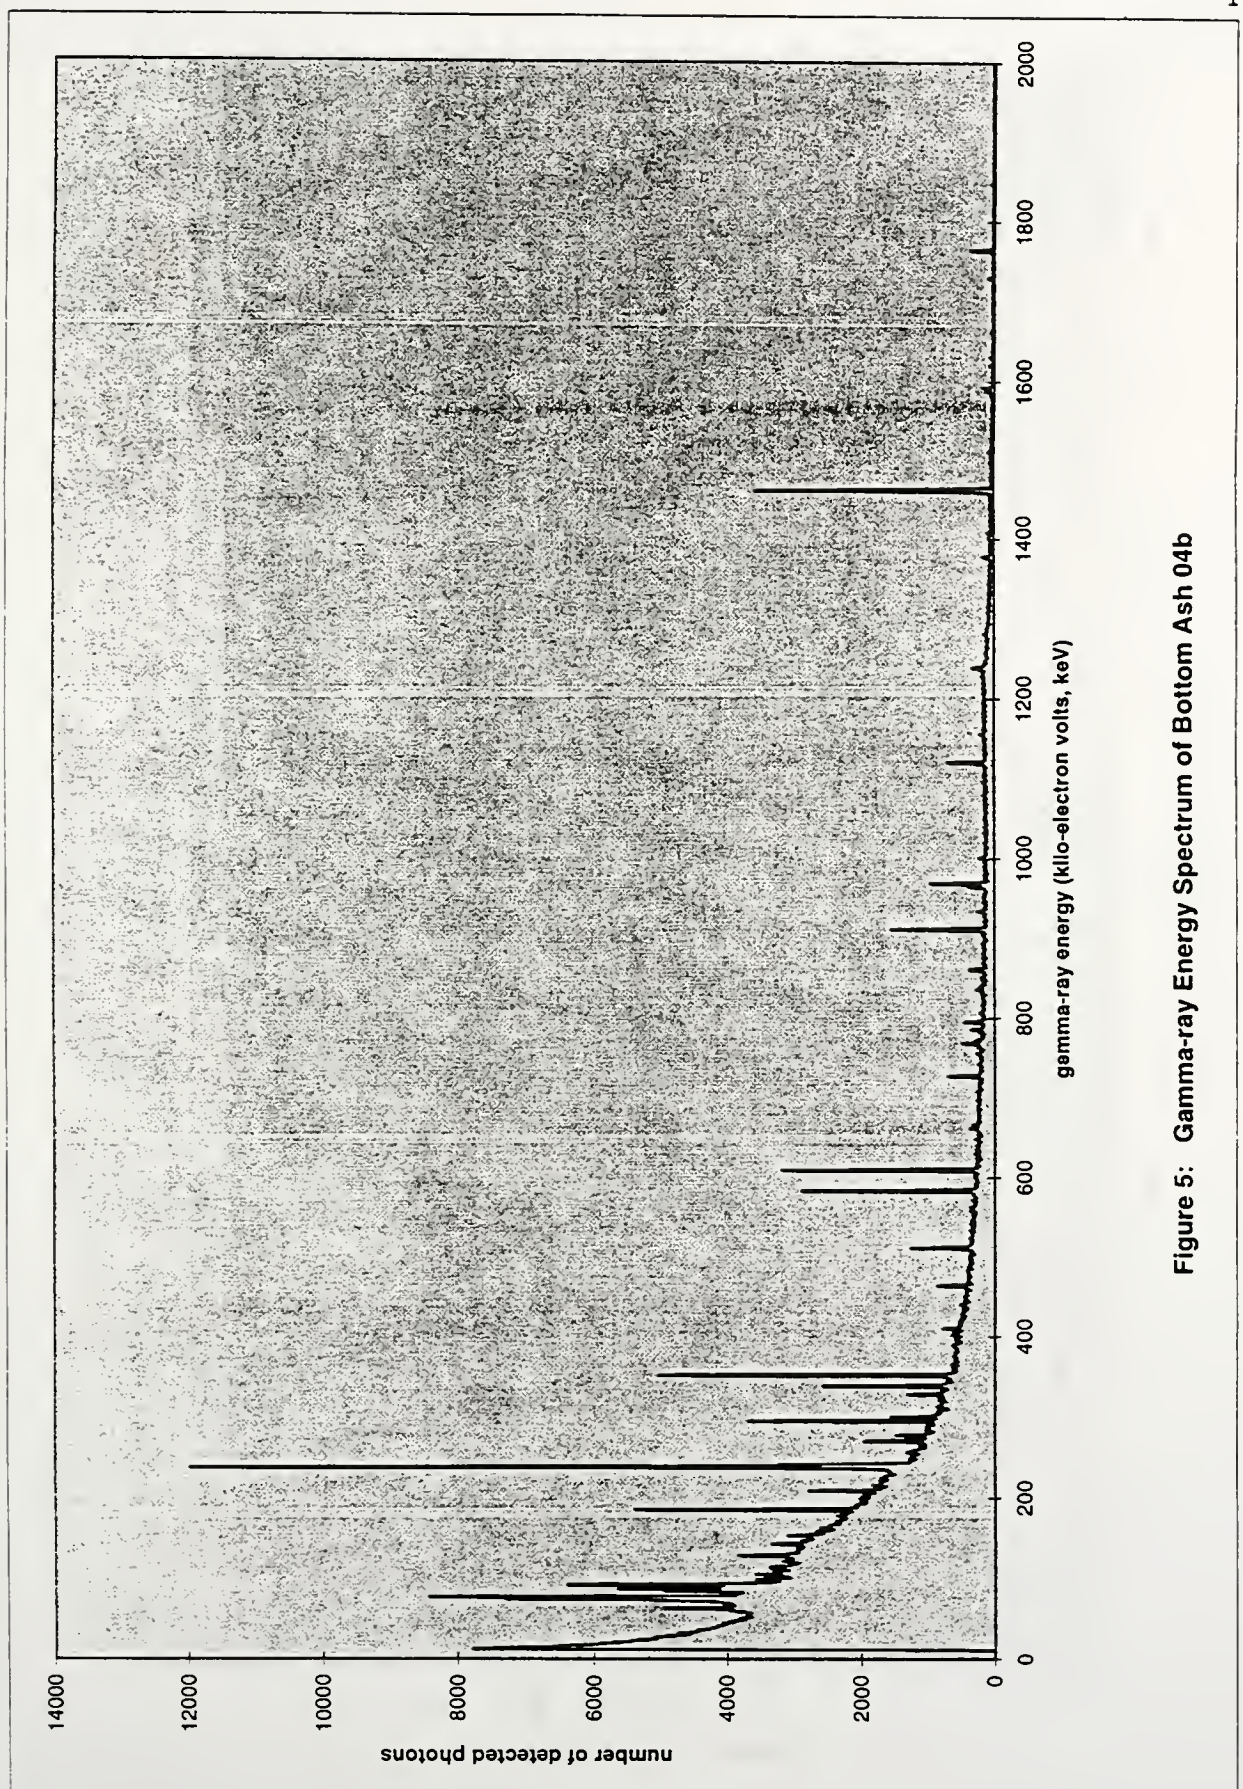

Figure 5: Gamma-ray Energy Spectrum of Bottom Ash 04b

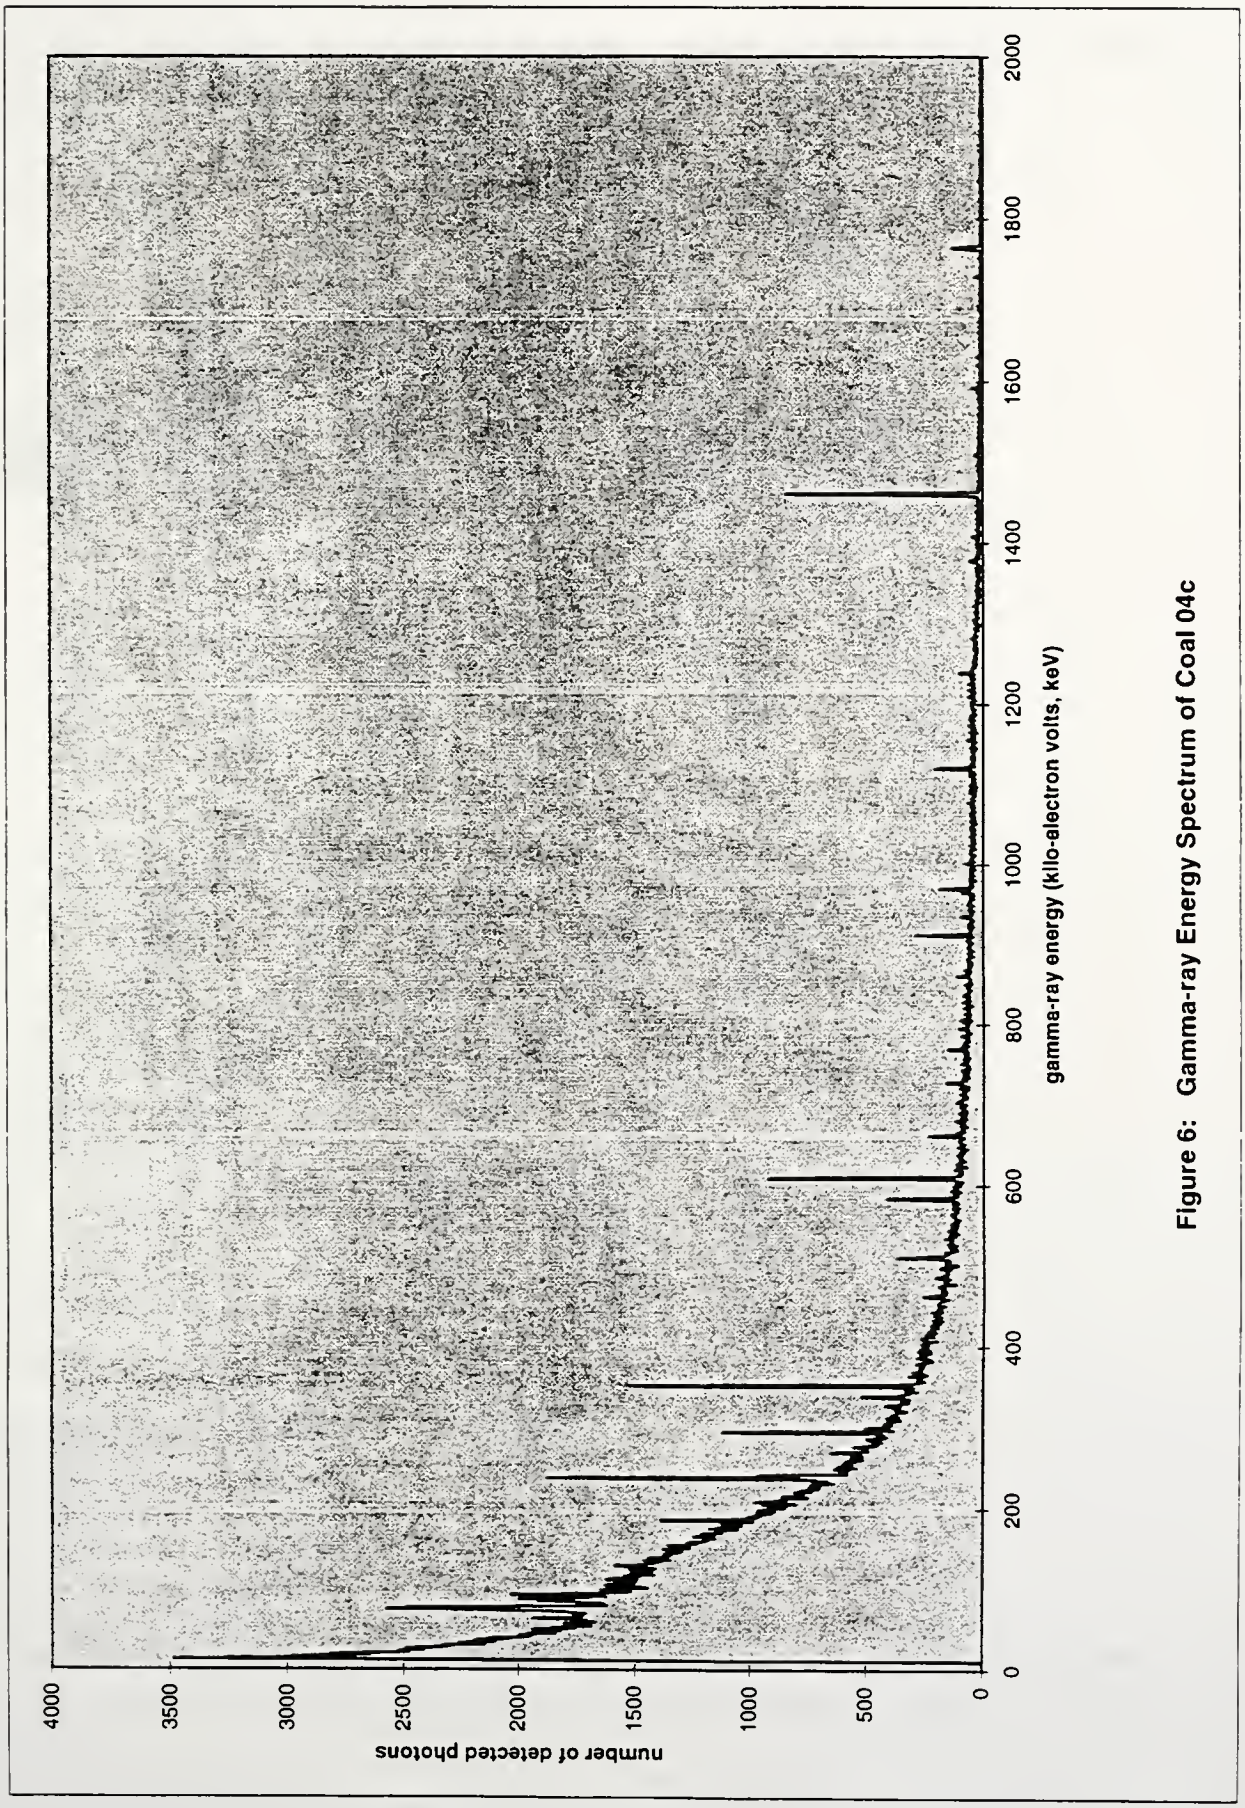

Figure 6: Gamma-ray Energy Spectrum of Coal 04c

The air surrounding the embankment also attenuates some gamma rays, but attenuation in the air is much smaller than attenuation in the ash.

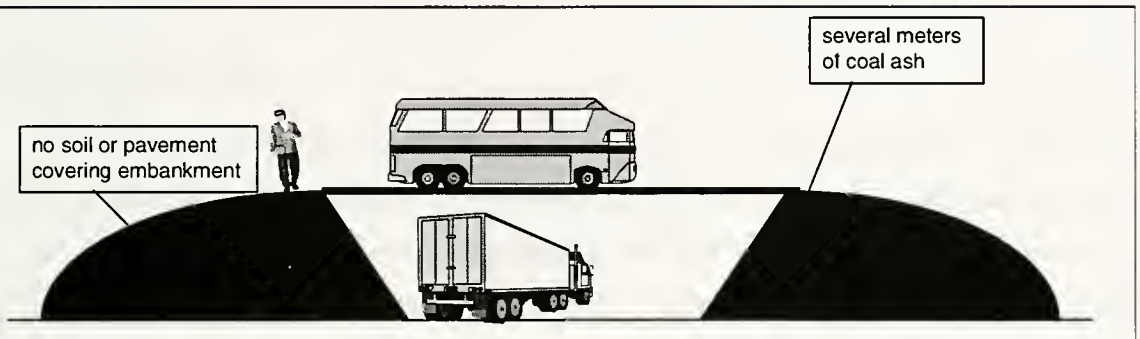

Figure 7: Physical Representation of a Coal Ash Embankment (overpass)

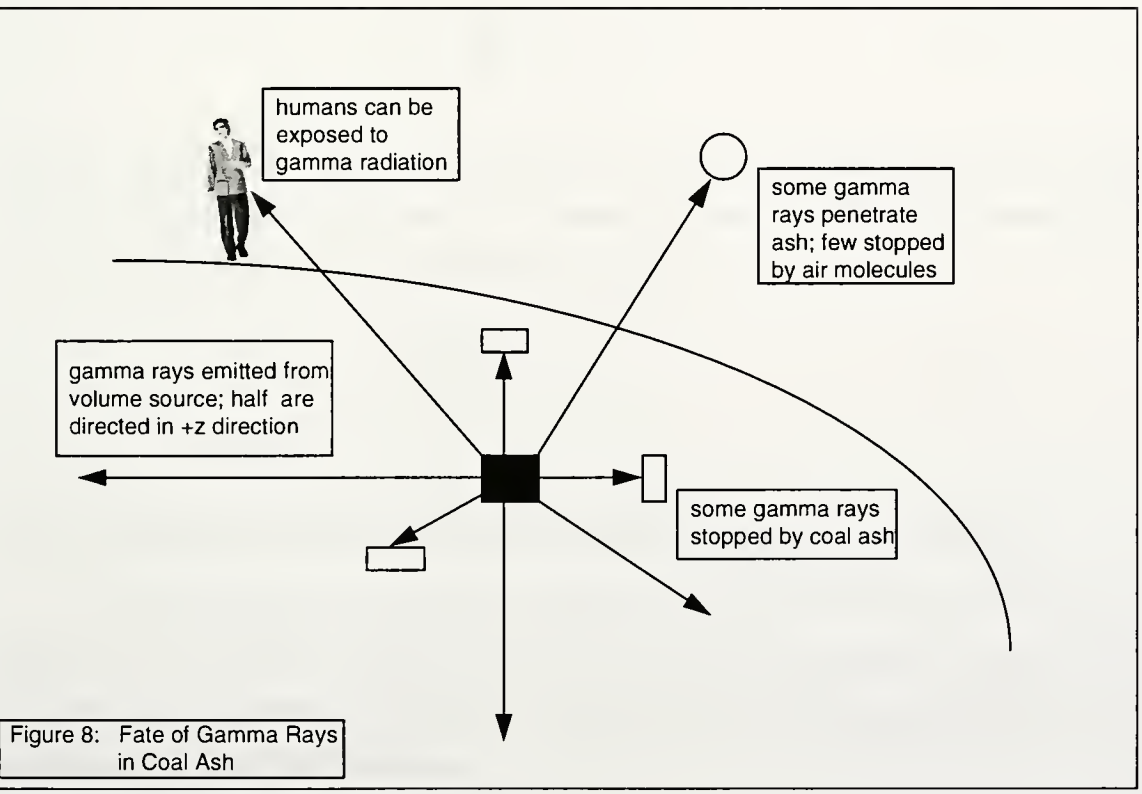

Figure 8: Fate of Gamma Rays in Coal Ash

4.4.2 Basis of Mathematical Model

The numerical output of GANAAS is the isotopic activity given in the metric unit of Bequerels (Bq), or decays per second, of a one-liter sample of material. The activity of an isotope is the rate at

which a radionuclide decays or the rate at which alpha or beta particles are emitted from a source. Activity is not the rate of exposure or the dose from gamma rays. The following is the method used to relate the activity to the dose equivalent experienced by the public from an embankment of coal ash.

4.4.2.1 Specific Activity

For purposes of this report the term "activity" is used to refer to the activity of those radionuclides that emit gamma rays. The inclusion of the other isotopes, i.e. all alpha and beta emitters, in the decay chains described would dramatically increase the actual activity of each sample. For analysis of gamma-ray emission and exposure, the activity of those radionuclides that emit gamma-rays is used.

The specific activity is the isotopic activity of a material per unit mass of material. It is given by:

$$A_i = \frac{A_{meas,i}}{M}, \qquad (1)$$

where A_i (Bq/g) is the specific activity of isotope, i, $A_{meas,i}$ (Bq) is the measured activity of isotope, i, and M is the mass of the one-liter test sample. The sum of the contributions of n gamma-emitting isotopes is the composite specific activity of gamma-emitting isotopes, A, of the sample:

$$A = \sum_{i=1}^{n} A_i. \qquad (2)$$

4.4.2.2 Gamma-ray Flux at the Surface of a Volume-distributed, Self-attenuating Source

An embankment of coal ash can be modeled as a volume-distributed, self-attenuating source of gamma rays. The volume is comprised of point sources that each contribute a small part of the gamma-ray emissions from the entire embankment. The integration of all of these point sources results in the total gamma-ray flux of the embankment.

The gamma-ray flux at the ash/air interface is the rate of gamma-ray emission per unit surface area. The surface flux of a gamma ray with energy, j, $\phi_{ash,j}$ (gamma rays/cm^2*sec), as a function of ash depth, b (cm), and gamma-ray energy, E (keV) is:

$$\phi_{ash,j}(b,E_j)=\frac{A_i*\rho*\varepsilon_j}{2*\mu(E_j)}\left[1-E_2(\mu(E_j)*b)\right],\ \text{(Glasstone/Sesonske, 1981)} \qquad (3)$$

where A_i is the specific isotopic activity, ρ (g/cm^3) is the uncompacted density of the test sample, E_j is the energy of gamma ray, j, μ_j (cm^{-1}) is the linear attenuation coefficient that corresponds to E_j, ε_j (gamma rays/decay) is the probability of emission of gamma ray, j, and E_2 is the second-order exponential integral function.

E_2 is the result of the mathematical integration of the contribution of point sources to the gamma-ray flux of a volume source. $E_n(x)$ is given by:

$$E_n(x)=x^{n-1}\int_x^{\infty}\frac{e^{-p}}{p^n}dp. \qquad \text{(Glasstone/Sesonske, 1981)} \qquad (4)$$

E_2 can be approximated by:

$$E_2(x)=\frac{e^{-x}(x+3)}{(x)^2+5x+4}. \qquad \text{(Glasstone/Sesonske, 1981)} \qquad (5)$$

As the argument of E_2 becomes large, E_2 quickly approaches zero, and equation (3) simplifies to:

$$\phi_{ash,j}(b,E_j)=\frac{A_i*\rho*\varepsilon_j}{2*\mu(E_j)}. \qquad \text{(Glasstone/Sesonske, 1981)} \qquad (6)$$

As mentioned, μ is the linear attenuation coefficient. The value of $e^{-\mu x}$ is the probability that a gamma ray will pass through an absorber with thickness x without interaction. Dividing μ by the absorber density, ρ, results in the mass attenuation coefficient (cm^2/g). Both coefficients are a function of gamma-ray energy. Table 4 contains the mass attenuation coefficients of silicon at relevant energies.

Table 4 also contains the gamma-ray emission probabilities for relevant gamma rays.

Table 4: Nuclear Data for Relevant Isotopes and Energies

Isotope	Energy (keV)	Probability of gamma-ray emission	Mass absorption coefficients for tissue (cm^2/g)	Mass attenuation coefficients for silicon (cm^2/g)	Mass attenuation coefficients for air (cm^2/g)

4.4.2.3 Gamma-ray Flux at a Distance above the Ash

The gamma-ray flux is slightly attenuated by air. It can be considered to be the flux at a point above an infinite plane source, i.e. the ash embankment. The flux, $\phi_{air,j}$ (gamma rays/cm^2*s), for gamma ray, j, at a point that is a distance, z (cm), above the ash/air interface is:

$$\phi_{air,j}(z, E_j) = \phi_{ash,j}(z, E_j) * e^{-z\mu(E_j)}, \qquad (7)$$

where μ (cm^{-1}) is the linear attenuation coefficient for air. Mass attenuation coefficients for air are analogous to those of ash and are listed in Table 4.

4.4.2.4 Dose Rate to the Human Body

The dose rate, $\dot{D}$, is the rate at which radiation deposits energy into an absorbing material, which, in the case of this study, is human tissue. It is a function of photon flux and energy and is given by:

$$\dot{D}_j(E_j) = 5.76*10^{-5}\,\frac{\phi_{air,j}(z,E_j)*E_j*\mu_a(E_j)}{\rho}. \text{ (Glasstone/Sesonske 1981)} \quad (8)$$

μ_a is the linear energy absorption coefficient (cm^{-1}). It is analogous to the linear attenuation coefficient except it represents the rate of energy deposition, not the rate of particle interaction. Table 3 lists the mass energy adsorption coefficients, μ_a/ρ, for soft human tissue. E_j is the gamma-ray energy in keV. Dose rate, $\dot{D}_j(E_j)$, is expressed in units of mrads, or 10^{-3} rads (radiation absorbed dose), per hour. The dose rates of each gamma-ray energy, E_j, of a single source may be summed to obtain the total dose rate of the source.

4.4.2.5 Dose Equivalent

The dose equivalent rate, $\dot{D}$, of radiation is a measure of the amount of energy the body absorbs per gram of tissue, not the biological effect of the absorbed radiation. Since the biological effect depends on the type of radiation and other factors, the dose equivalent is used to quantify the biological effect. The unit of dose equivalent is the rem (radiation equivalent in mammal). The dose equivalent rate, $\dot{H}$, is:

$$H(E) = D(E)*QF. \text{ (Glasstone/Sesonske 1981)} \quad (9)$$

QF is the quality factor. It represents the potential for a specific type of radiation to deposit energy over a short distance in tissue. For gamma rays of interest to this study, QF ≈ 1, and for alpha

particles, QF ≈ 10. The dose equivalent rates for all energies of a single source may be summed to obtain the total dose equivalent rate of the source.

4.5 Significant Qualifications and Assumptions Associated with the Applied Model

4.5.1 Model Assumptions

There were three important assumptions used during the course of this modeling effort, as follows:

1. For calculating dose levels, a 2000 hour work year was assumed for occupational exposures (i.e., project workers with the highest possible exposure levels). In contrast, public exposure stemming from infrequent contact with these types of embankments (measured in time increments of seconds or, at most, minutes) would be much less than the occupational exposure levels.

2. For calculation of doses the embankment of coal ash was represented as a self-attenuating volumetric source with a finite thickness without any clay, topsoil, or asphalt covering. This represents a conservative assessment, however, given the fact that this type of attenuating cover will almost certainly be employed (e.g., as an erosion control measure).

3. The vital (i.e., critical organ location) zone of the human body was assumed to be one meter above ground level when in the standing position.

4.5.2 Model Qualifications

The applied modeling approach was based on 'single sample' results obtained at random from ash piles, steam generators, and coal piles. It should be noted, however, that the observed activities might well change from location to location in a single coal mine, depending on geologic history and deposit formation. Since the location inside a coal seam and, in many cases, the specific coal mine is unknown, the values presented in this report would be somewhat representative of each specific coalmine and its by-product ash. If a sampling scheme were to be developed and exact sampling information (i.e. location in the mine), a "radiation map" could be constructed showing larger activities and lower activities within each seam of coal.

It is also possible that burning processes and steam generator types change the activities of the ash. For example, if the exact same coal were burned in a stoker boiler and a tangential boiler, the activities of the resulting ashes could be different.

In many cases, the measured activities appear to be large in comparison to other materials, but in reality the activities are very minuscule in comparison to doses experienced from many other sources of radiation. (see, for example, the KCl salt substitute activities, as well as the 'background radiation' information)

Finally, these exposures and doses were calculated using uncompacted densities determined in the laboratory. Under actual conditions the ash would be compacted to about 1.5 times the uncompacted density. Exposures generally decrease as densities increase.

CHAPTER 5

Results and Discussion

5. 1 Activities of Coal, Bottom Ash, Fly Ash, and Commingled Ash

Figures 9, 10, and 11 show the isotopic activities of the ten radionuclides that emit significant numbers of gamma rays for samples of coal, bottom ash, and ESP fly ash which belong to "complete sets." Figure 12 shows the isotopic activities of commingled ash samples. The labeling scheme used to establish sample ID's in these figures was as follows:

1) the first number of the sample ID identifies the respective power plant being tested,

2) the following letter (f, b, or c) establishes the form of the material, respectively including 'fly ash,' 'bottom ash,' or 'coal,' and

3) a concluding number was then added, if necessary, when multiple samples of the same type were obtained and tested at each location. For example, sample ID '10c2' corresponds to the second of two 'coal' samples tested from power plant #10.

By comparing the vertical scale of the four plots, it can be seen that the activities of coal were much less than those of any type of ash. This was expected because the burning of coal removed all of the carbon and volatiles, leaving the impurities, including radionuclides, in the ash. The combustion of coal concentrated the activity by an order of magnitude or more, since the ash content of coal was about 10%. In most samples there were four gamma-ray emitting isotopes, ^{214}Pb, ^{214}Bi, ^{226}Ra, and ^{40}K, that regularly appeared as significant contributions to the activity of the sample. ^{214}Pb and ^{214}Bi appeared because they emitted many significant gamma rays. They will always have similar activities because they were part of the same decay chain, ^{238}U, and have relatively equal half-lives. The appearance of ^{226}Ra coincided with ^{214}Pb and ^{214}Bi since it was also part of the ^{238}U decay chain. ^{40}K was present in the greatest quantities because it was much more abundant in nature than almost any other radionuclide.

When looking at these plots, it is tempting to draw conclusions that a certain coal, that may or may not have a high activity when compared to other coals, produces an ash with a high activity. Caution should be taken because these sets of samples do not represent a perfect conversion from coal to ash.

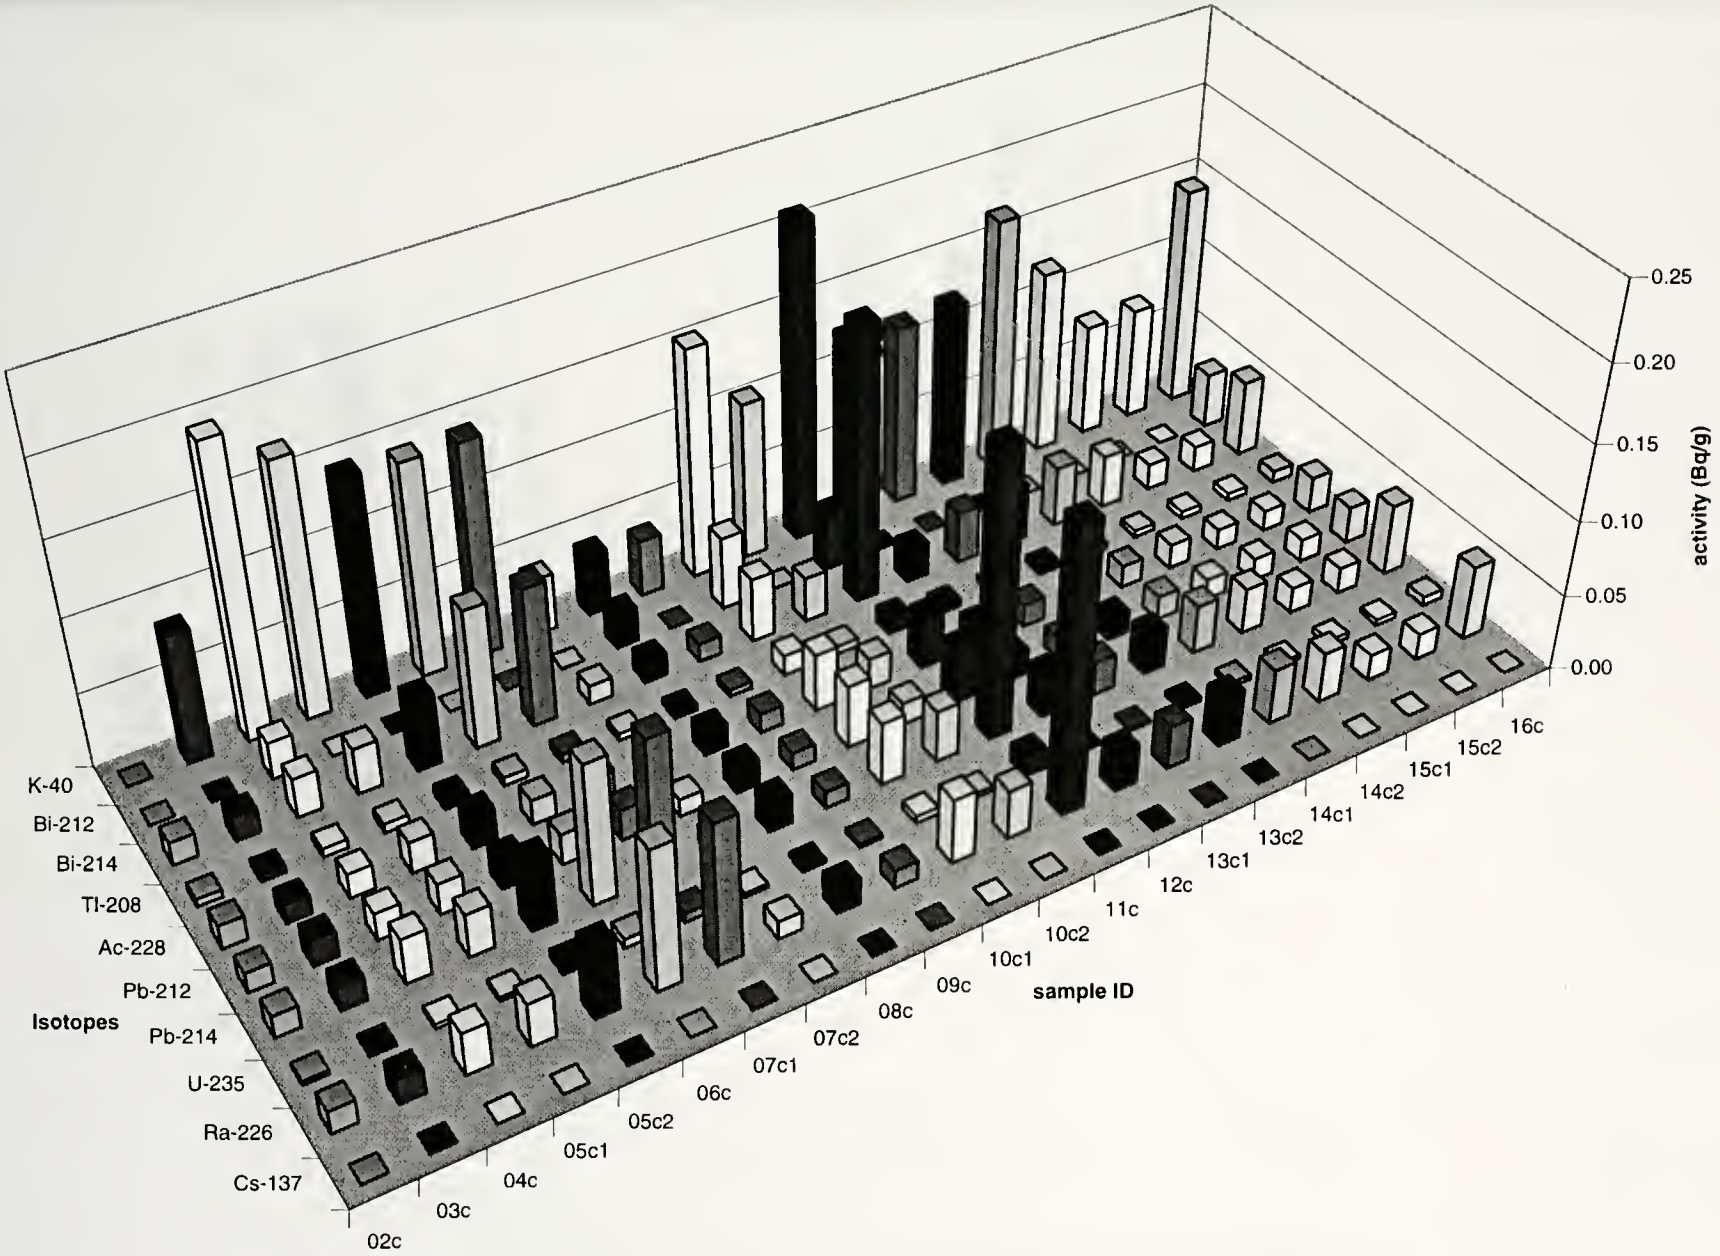

Figure 9: Isotopic Activities of Gamma-Ray Emitters in Coal

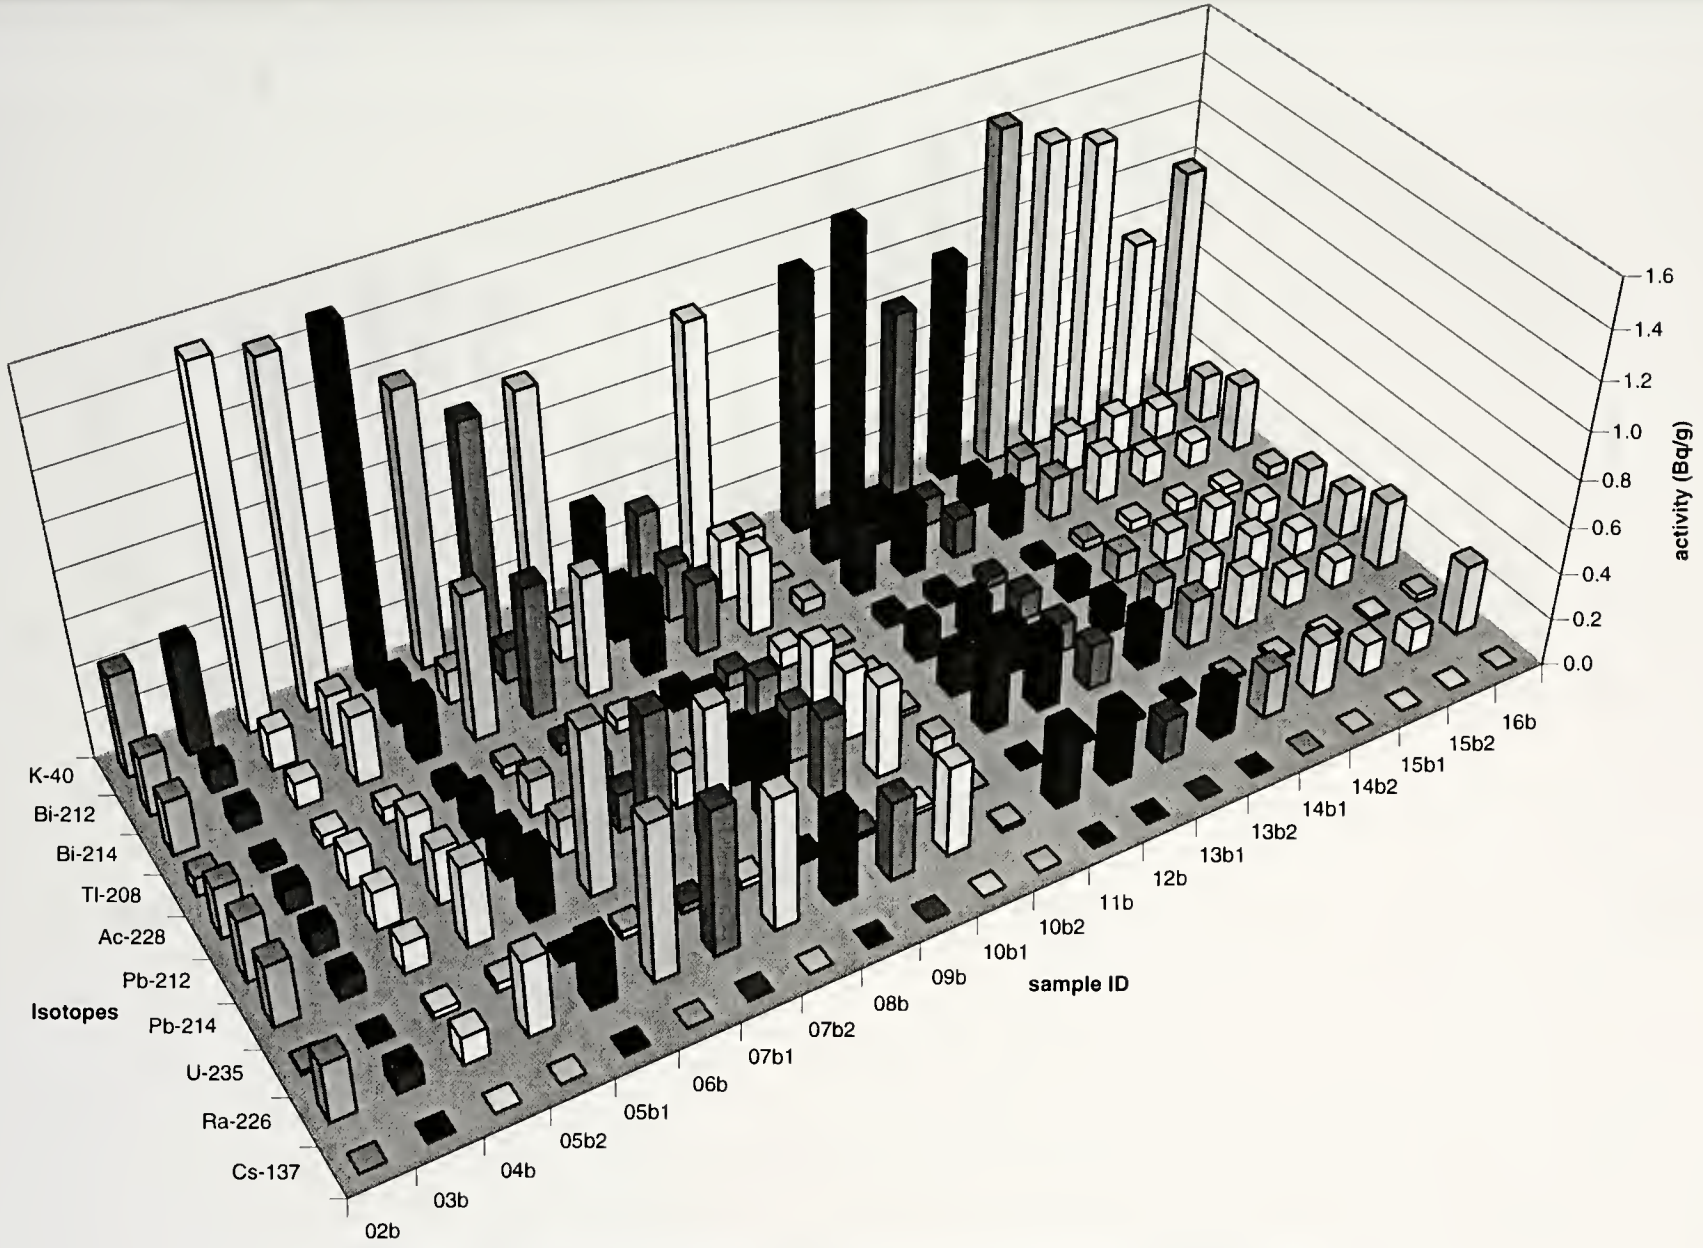

Figure 10: Isotopic Activities of Gamma-Ray Emitters in Bottom Ash

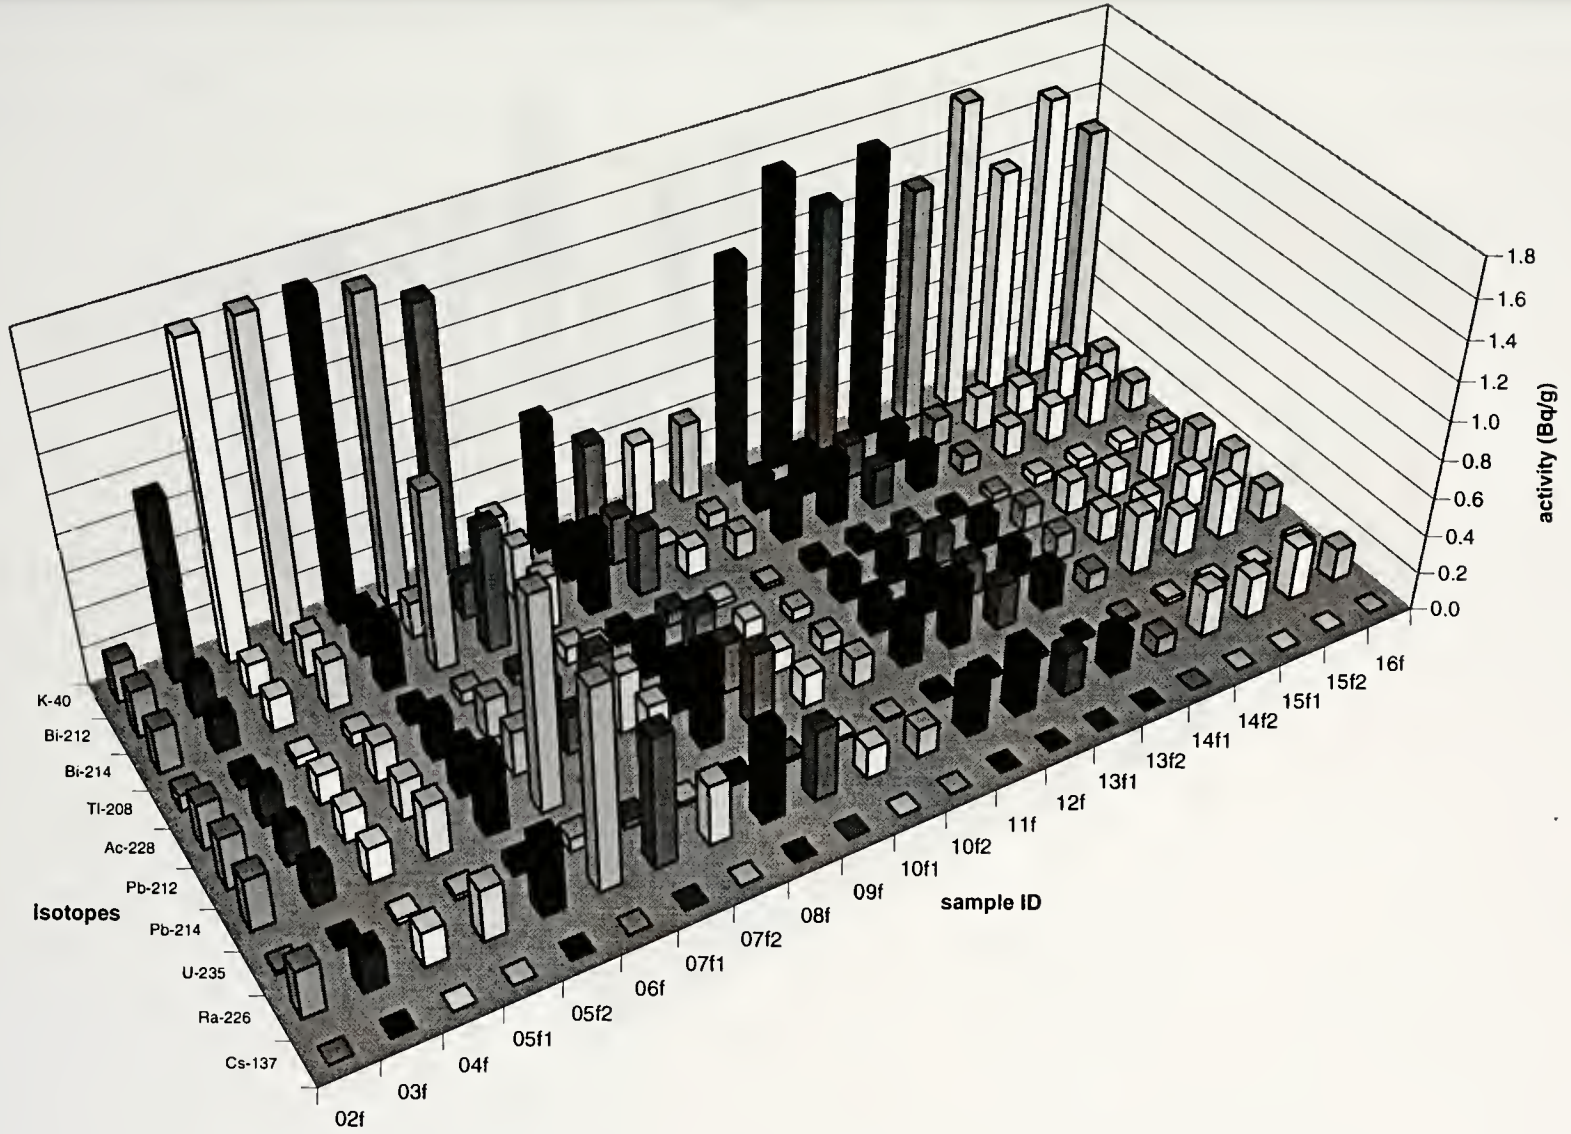

Figure 11: Isotopic Activities of Gamma-Ray Emitters in Fly Ash

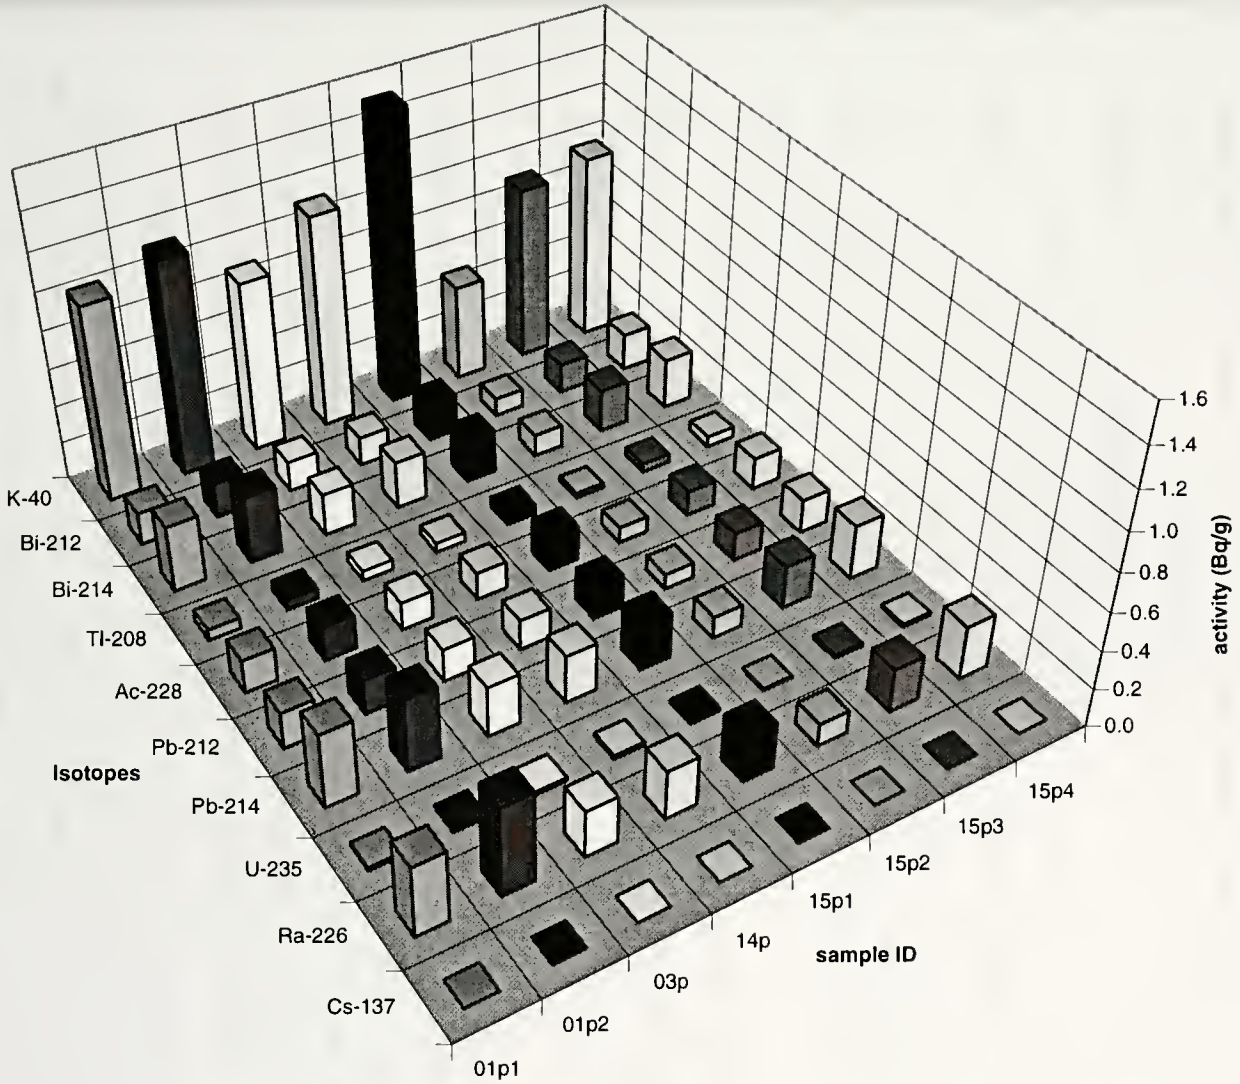

Figure 12: Isotopic Activities of Gamma-Ray Emitters in Commingled Ash

Different burning processes or steam generators have the potential of altering the isotopic composition of the ash. Many removal mechanisms such as isotopic exchange at high temperatures, volatilization of gaseous radon or other nuclides, and electrostatic forces and Brownian motion in airstreams, may have an effect on radionuclide composition. The ability of a radionuclide to sorb to the surfaces of different types of ash also affects the relative magnitudes of activities. Changes in the nuclide composition have an effect on the nuclide conversion between coal and ash. Consequently, if the same coal were to be burned in two different power-generation units, two ashes that were isotopically and radiogenically different could be produced.

Another point to consider is the origin of coal. Many factors contribute to the distribution of radionuclides in the earth's crust, including coal deposits. Different deposits of coal will have different isotopic compositions. In fact, isotopic compositions in the same coal mine will vary. Sampling for this study was done in a somewhat random fashion. In some cases the coal collected from different power stations originated from the same mine, but those samples have different activities. In general, a single coal sample was not necessarily representative of an entire coal mine.

In addition to the properties of combustion and coal, radiation measurements are associated with large amounts of uncertainty, especially when only one sample of a material is available for analysis. Uncertainty in nuclear measurements can be as high as twenty percent. This uncertainty applies throughout the course of this study.

Despite these qualifiers, patterns of isotopic activities can be seen that coincide between some coals and the resultant ashes. For example, set 05-1 (coal 05c1, bottom ash 05b1, and fly ash 05f1) shows the same pattern of isotopic activities. The activities have different absolute magnitudes but similar relative magnitudes, which suggests that 05b1 and 05f1 originated from 05c1, and the burning process did not change the ratios of the radioisotopes. Although the ash of other sets actually originated from the parent coal, the activity patterns do not necessarily indicate a "matched set."

More obvious matches can be seen between bottom ashes and fly ashes of each set of samples than between coal and ash. The isotopic activities of fly ash and bottom ash are compared in Figure 13. With some exceptions (02f/02b, 16f/16b, 15f1/15b1, 14f1/14b1) the same pattern appeared in all sets of fly and bottom ashes. The activity of ^{214}Bi was larger than ^{212}Bi, ^{214}Pb is larger than ^{212}Pb, and, in most cases, the ^{40}K activity was much larger than all other isotopic activities.

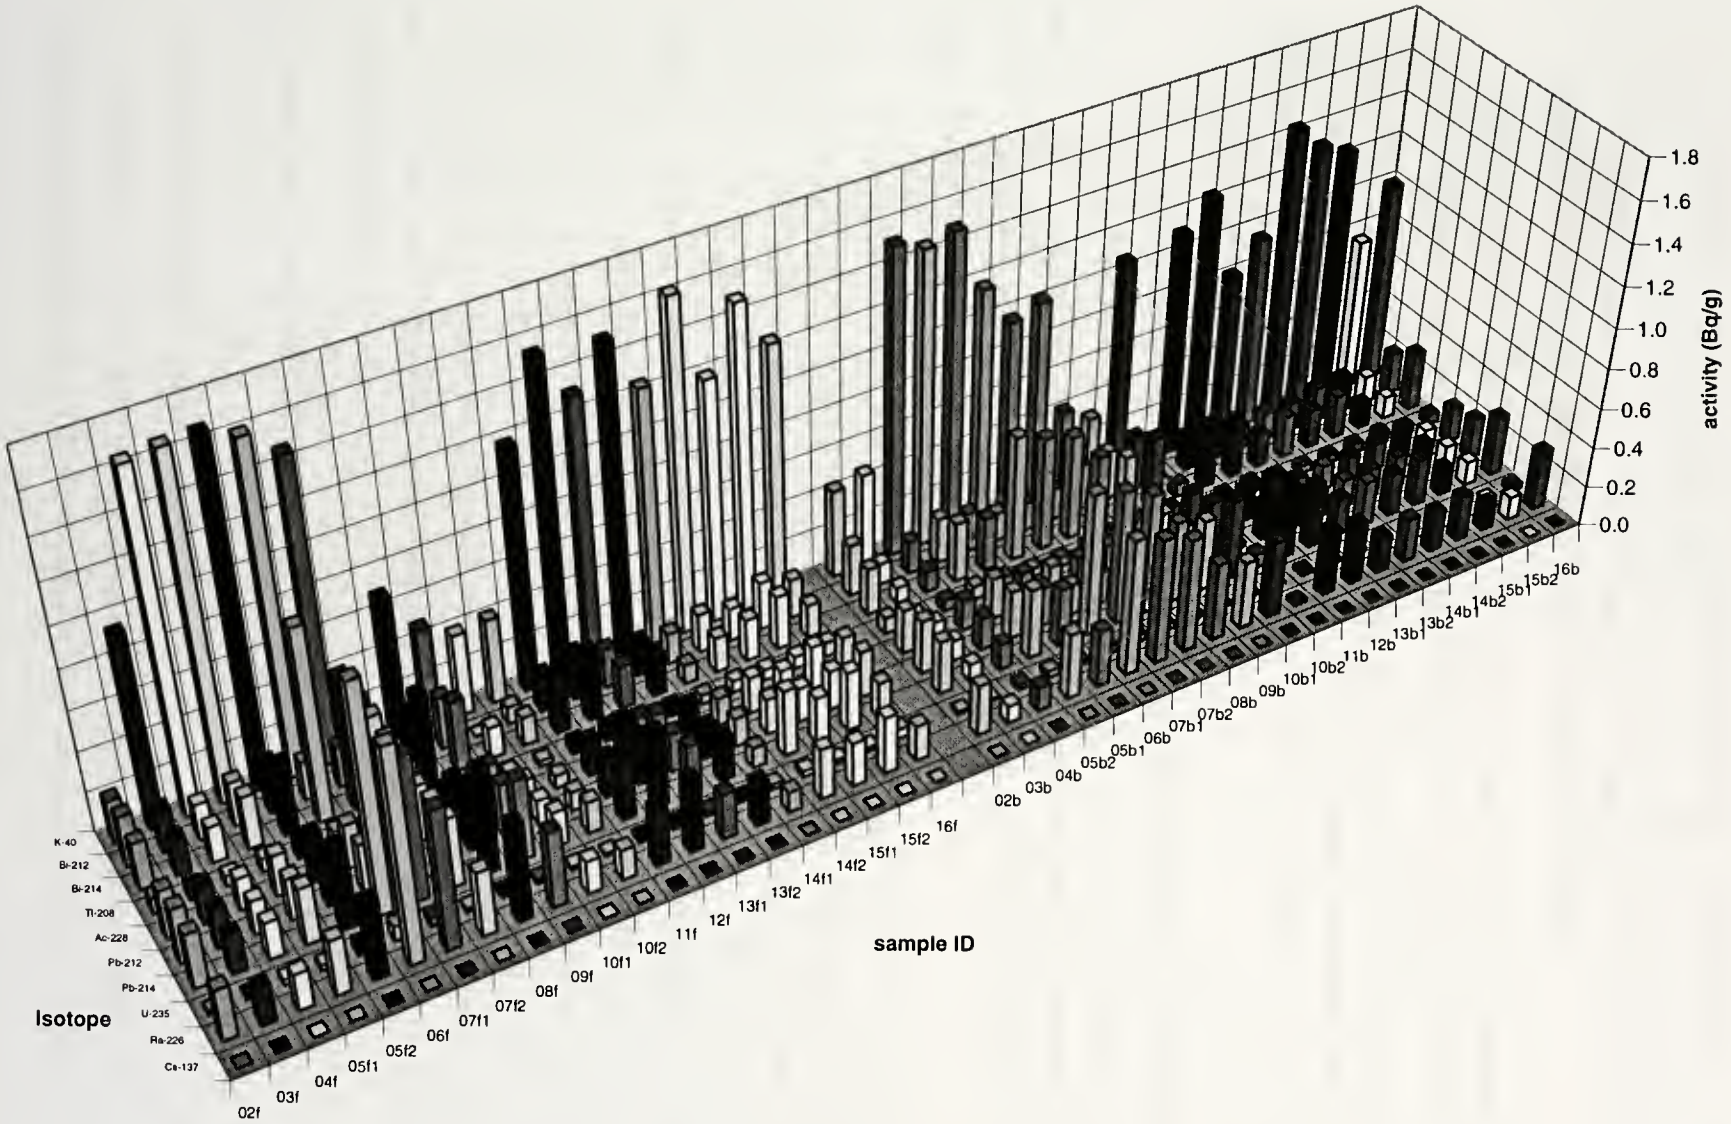

Figure 13: Comparison of Isotopic Activities of Gamma Emitters in Fly Ash and Bottom Ash

Looking at the set 06f1/06b1, the ^{40}K activity was larger than all other activities in both types of ash, and the ^{214}Bi and ^{214}Pb activities were also large in comparison to other activities. ^{226}Ra activity was also relatively large. Other activities have the same relative magnitudes in the bottom and fly ash of power plant number six. These similar patterns suggest "matching" ash samples.

Figures 14, 15, 16, and 17 depict the total specific activities of significant gamma-ray producing isotopes in coal, bottom ash, fly ash, and commingled ash, respectively. These plots include all samples of fly ash involved in the study. Earlier plots included only ESP samples. The observed activities of coal ranged from 0.081 Bq/g to 0.902 Bq/g, and averaged 0.292 Bq/g. Bottom ash ranged from 0.281 to 3.71 Bq/g, fly ash from 1.12 to 5.50 Bq/g, and commingled from 1.13 to 2.99 Bq/g. The ash averages were 2.39 Bq/g, 2.65 Bq/g, and 2.34 Bq/g, respectively.

Total specific activities do not indicate the same matches between coal, fly ash, and bottom ash as the isotopic activities because the relative patterns were lost after combining isotopic activities into absolute sums. In general, the total activities of fly ash were larger than those of bottom ash (Figure 18). This was most likely due to higher surface areas on fly ash particles that provide more sites for radionuclides to sorb, producing a higher activity on fly ash.

It was mentioned above that coals with high activities, when compared to other coals, did not necessarily produce ash with high activity, when compared to other ash. This point can be illustrated by comparing the total activities of the coal/ash sets from plants 06, 11, and 12. As mentioned, coal 11c has the highest activity among coals, coal 12c has a lower activity, and coal 06c has an activity that is roughly the average of 12c and 11c. Comparing the total activities of the resultant ash of each coal yields different results. The activity of bottom ash 12b was greater than that of 11b, which was the opposite of the relationship between the two coals, and the activity of 6b was the largest of all bottom ash samples. The activities of the corresponding fly ash samples followed the same pattern as the bottom ash. By comparing the total activities to the isotopic activities, it can be seen that in most cases the activity of Potassium-40 was the controlling contributor to the total. As the ^{40}K activity varied, the total activity varied in the same manner.

5.2 Comparison of Activities of Coal and Coal Ash to Other Materials

5.2.1 Specific Isotopic Activities of Other Samples

Figures 19, a and b, show the specific isotopic activities of several other materials. Natural construction materials included red brick, two types of clay from central Indiana, two types

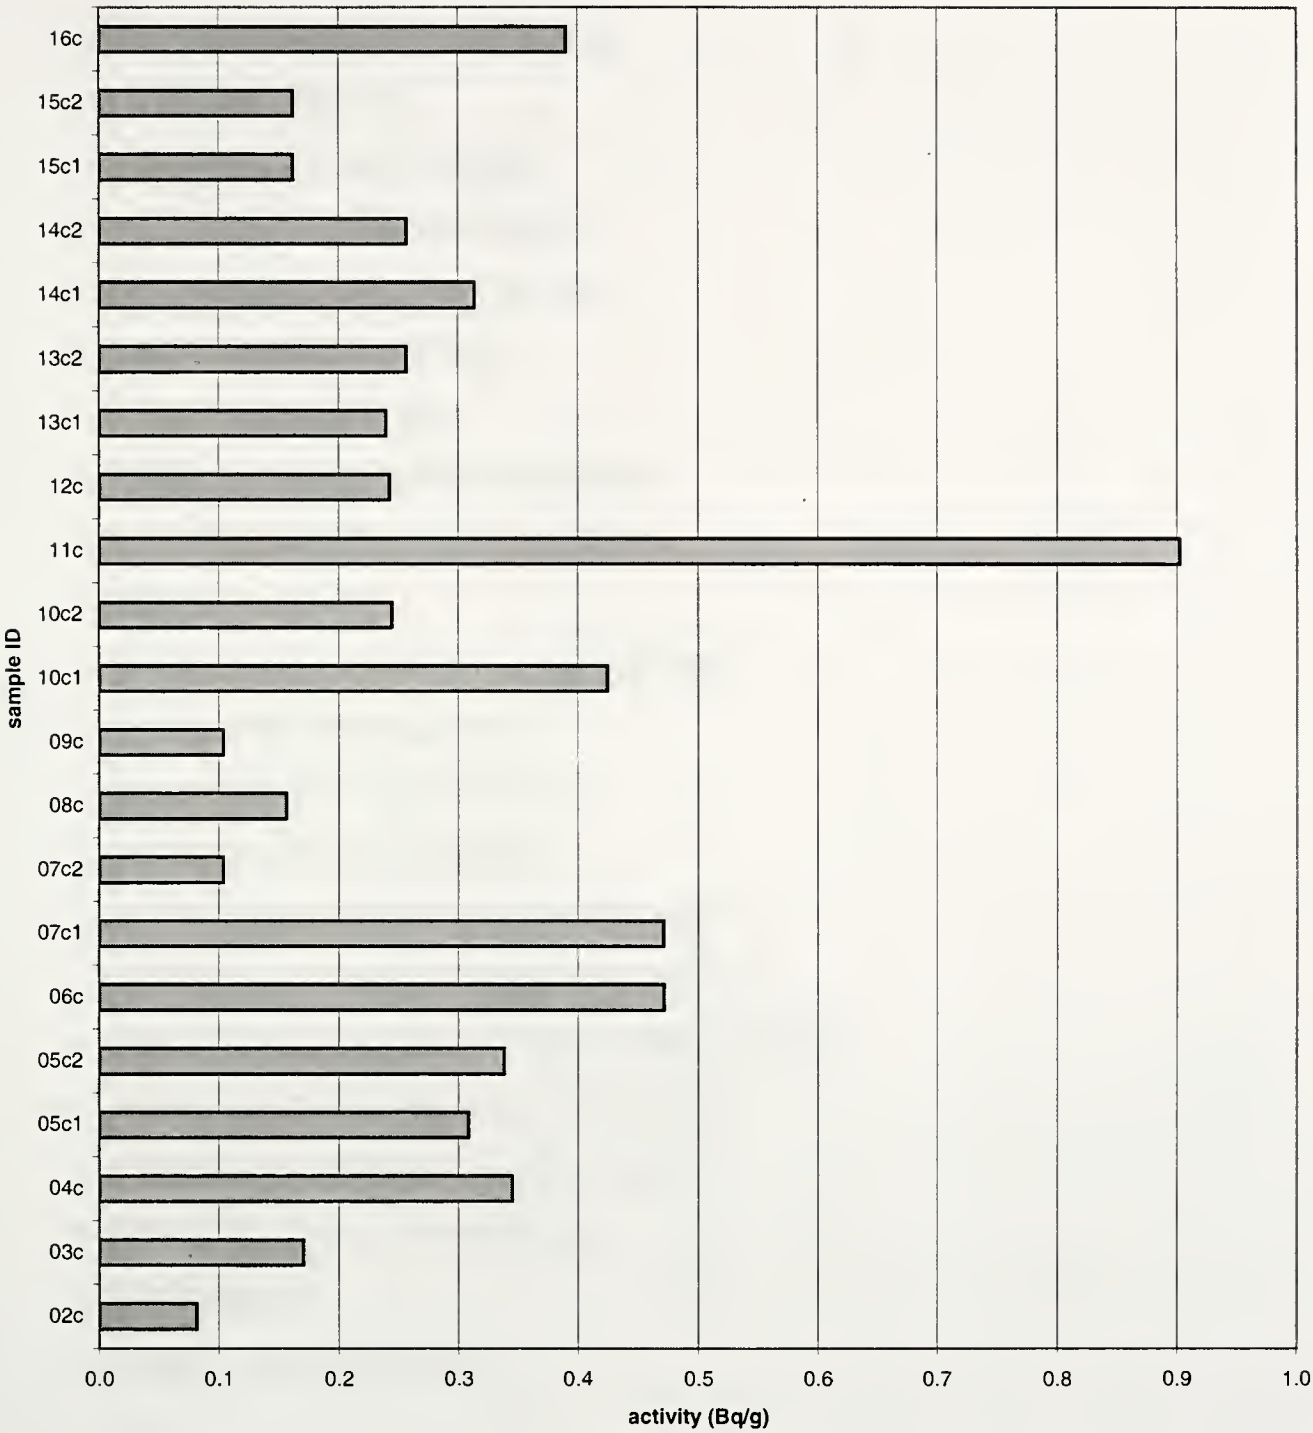

Figure 14: Total Activities of Gamma-ray Emitters in Coal Samples

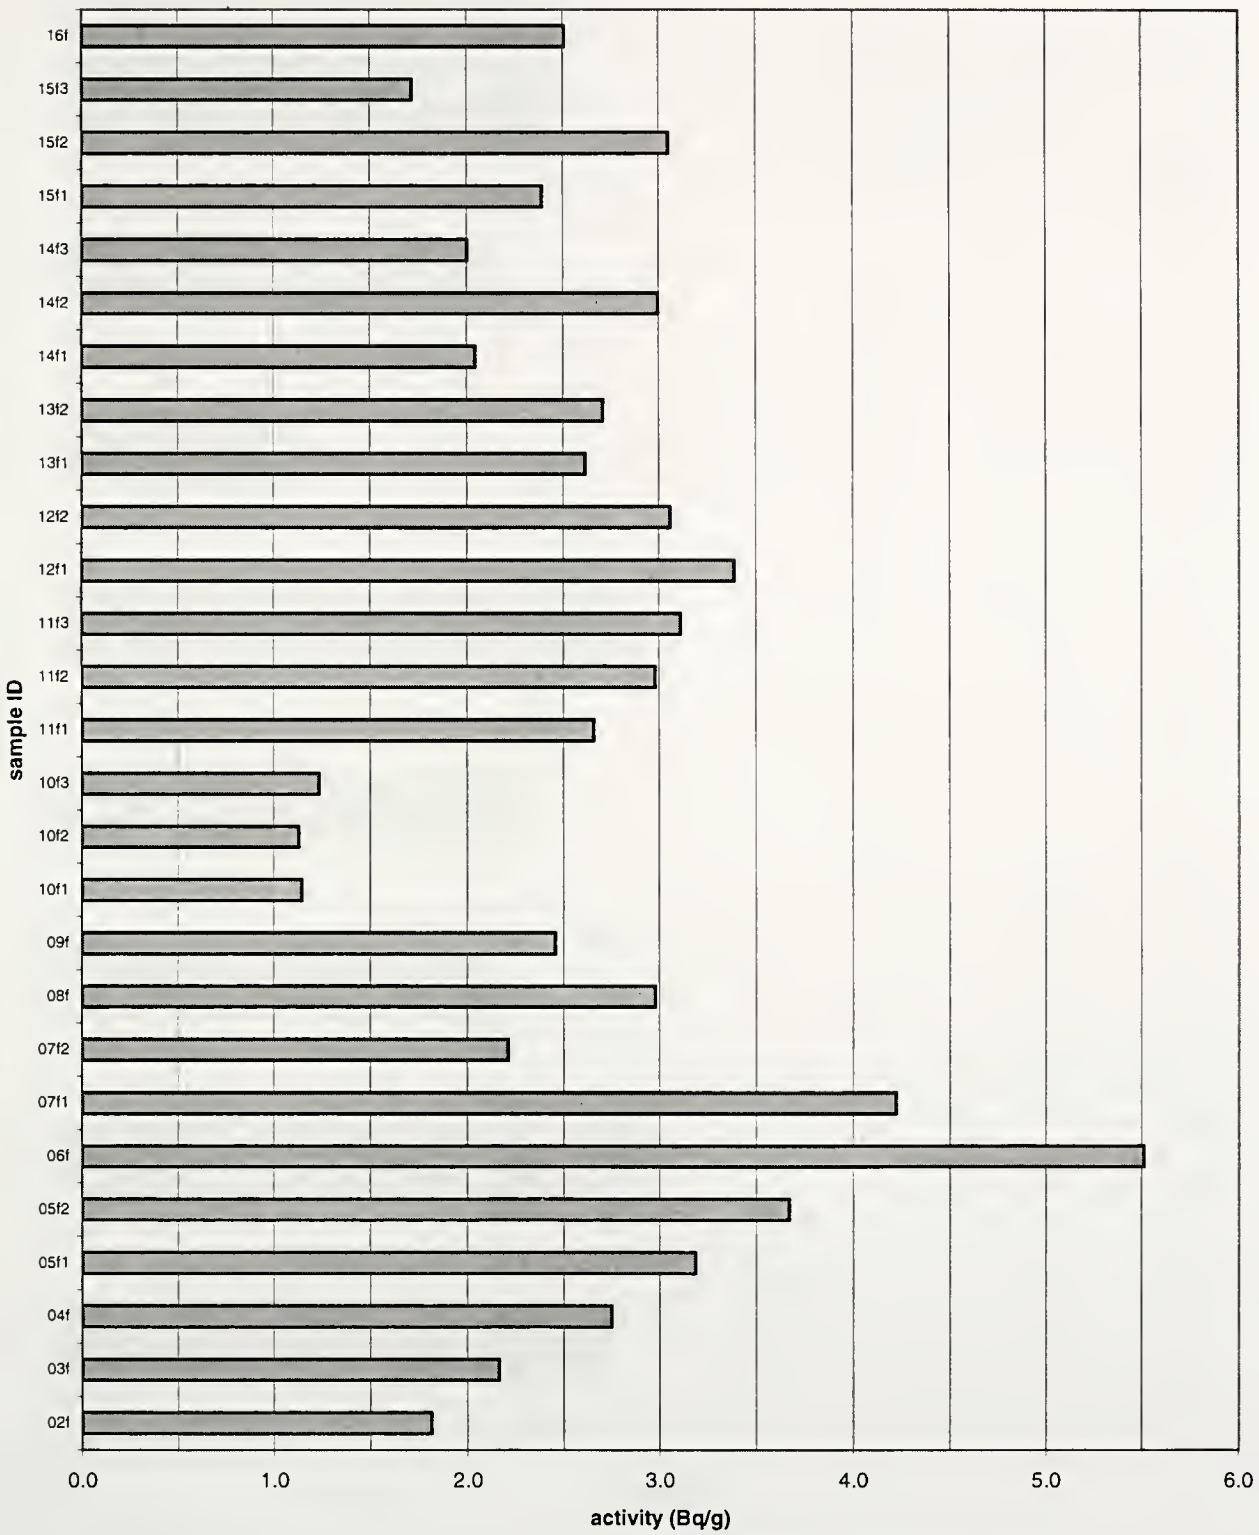

Figure 16: Total Activities of Gamma-ray Emitters in Fly Ash

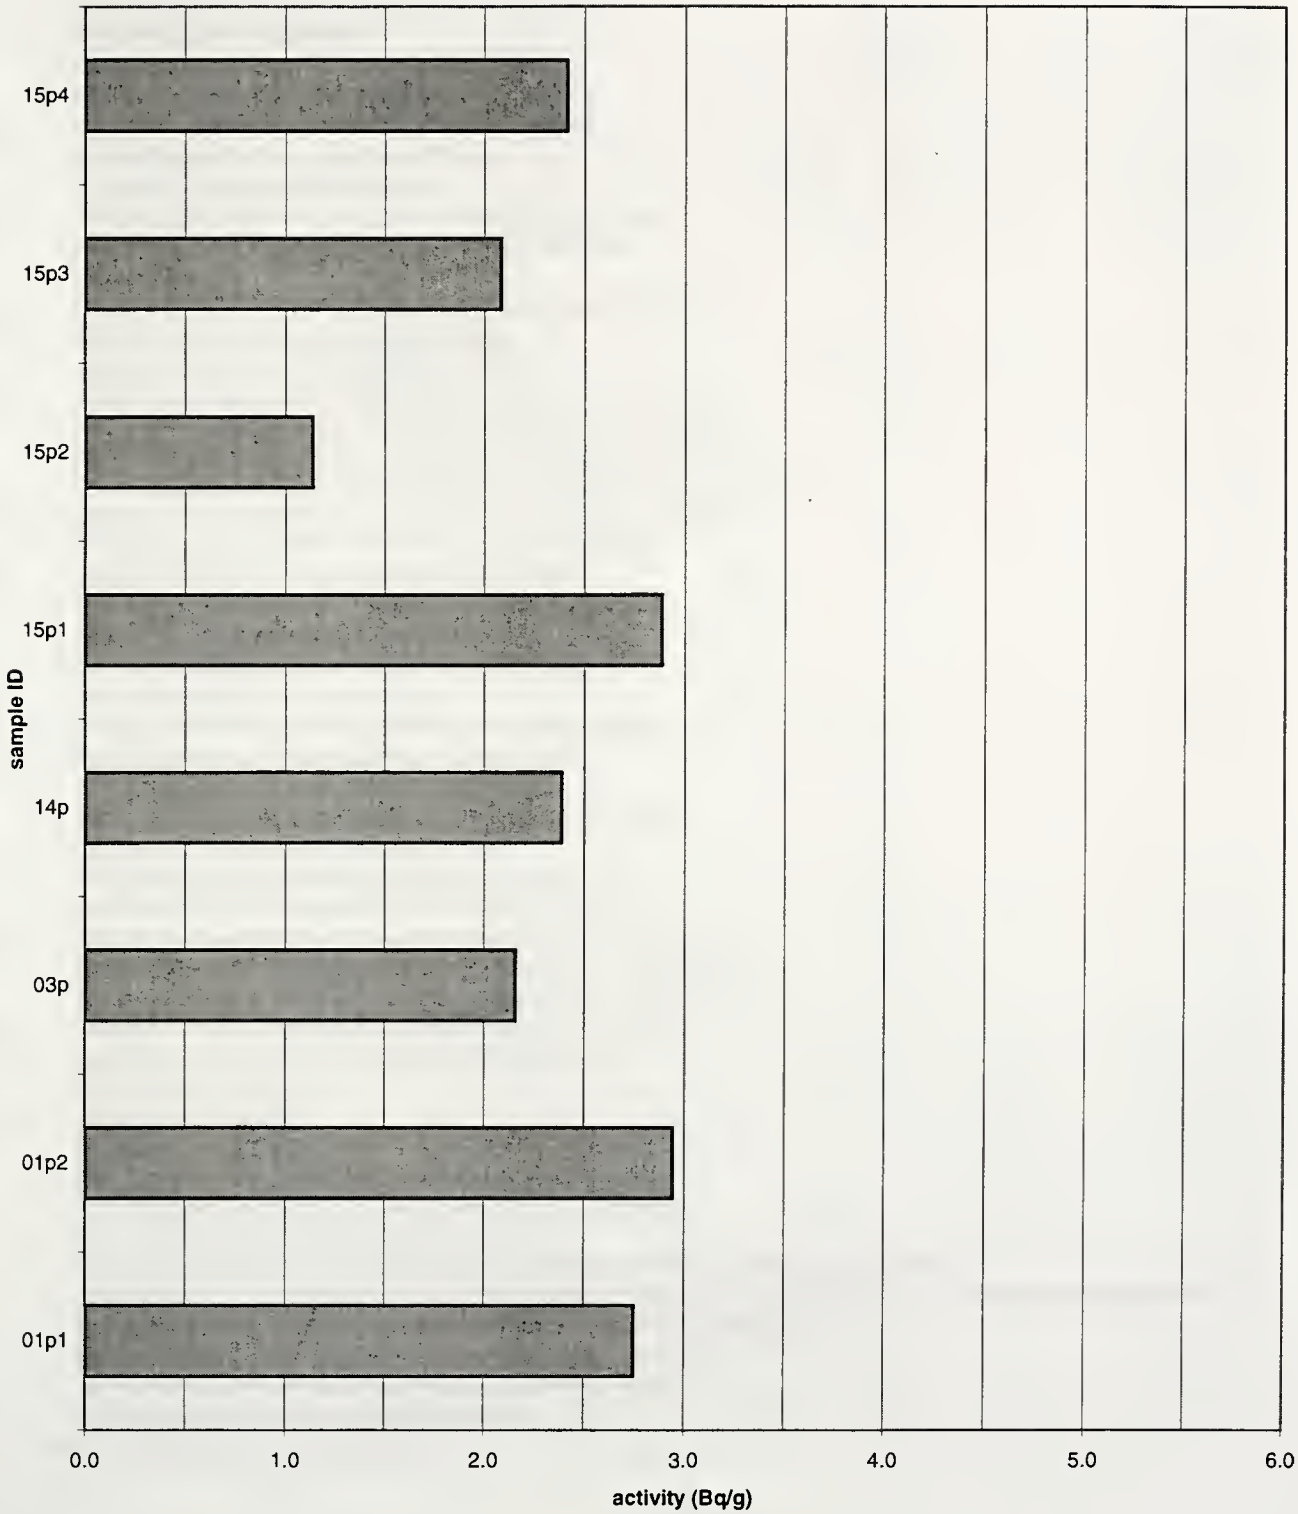

Figure 17: Total Activities of Gamma-ray Emitters in Commingled Ash

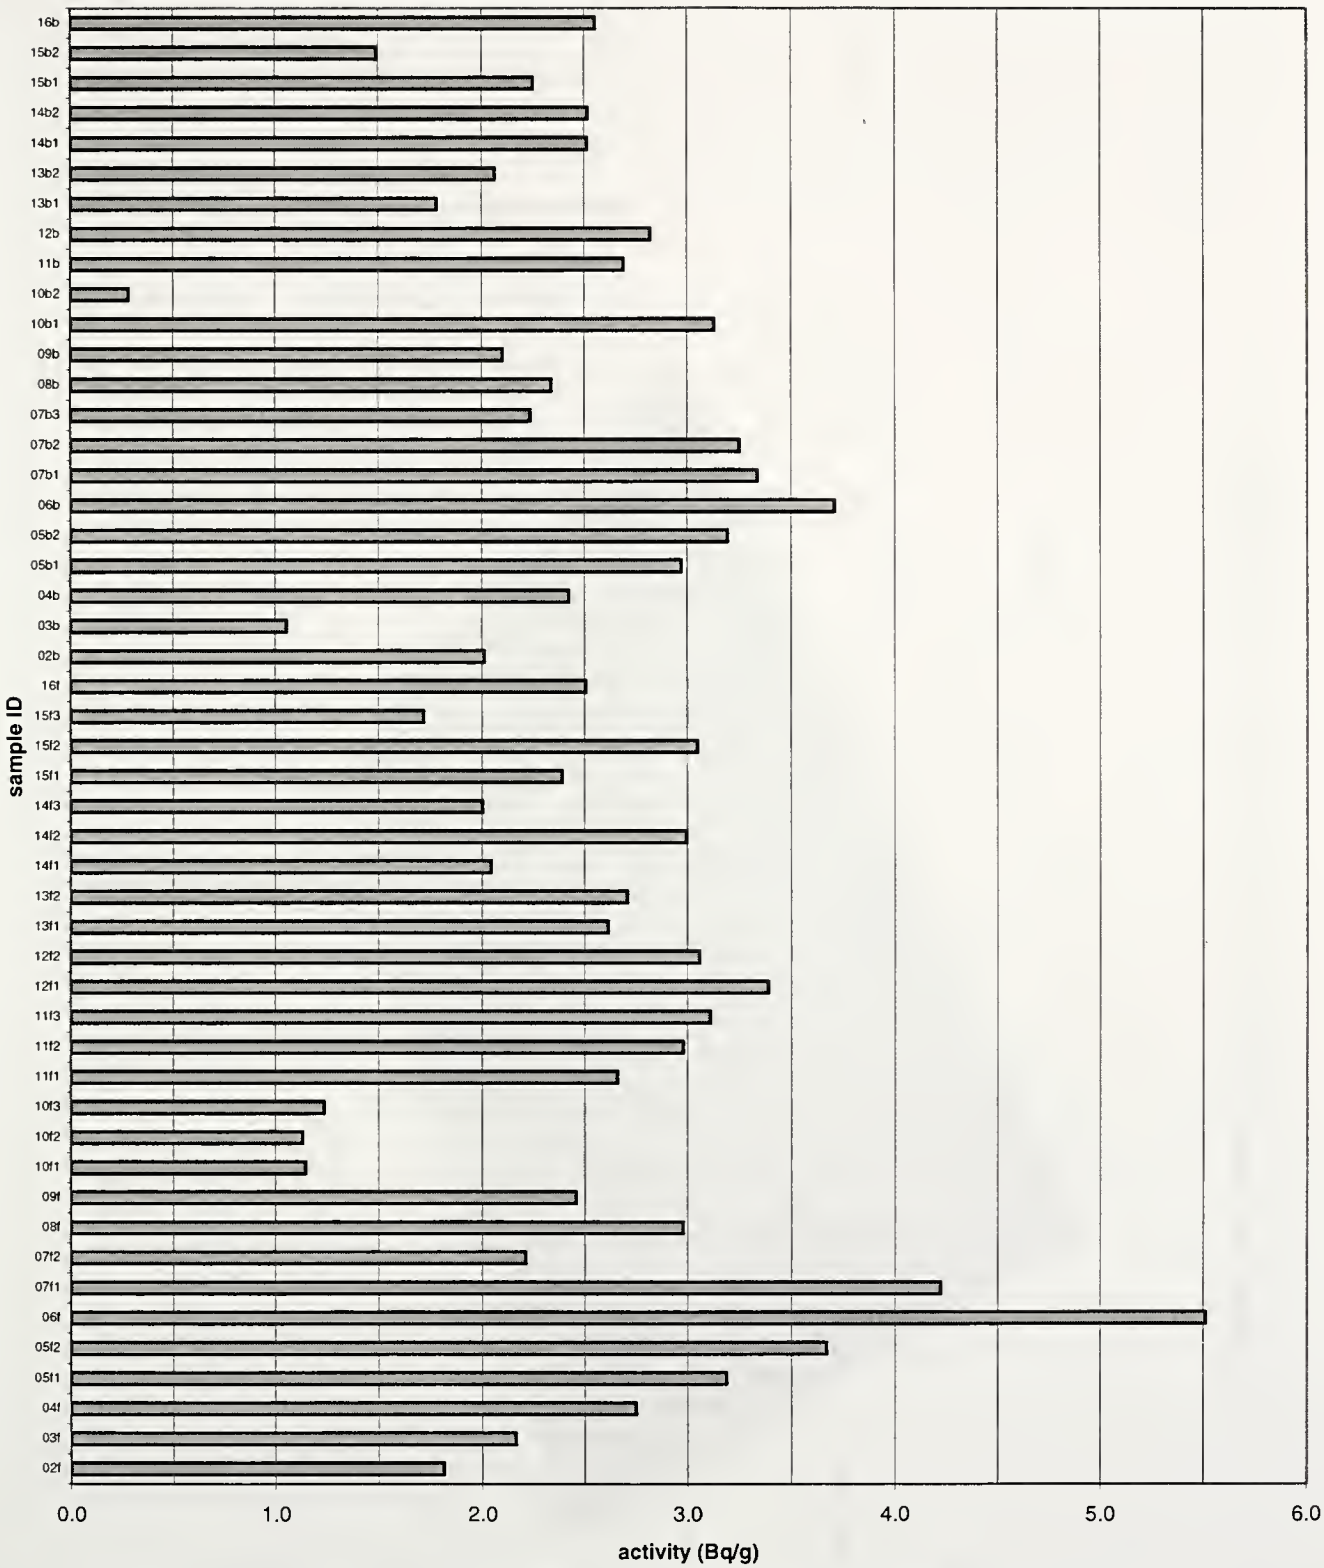

Figure 18: Total Activities of of Gamma-ray Emitters in Bottom and Fly Ash Samples

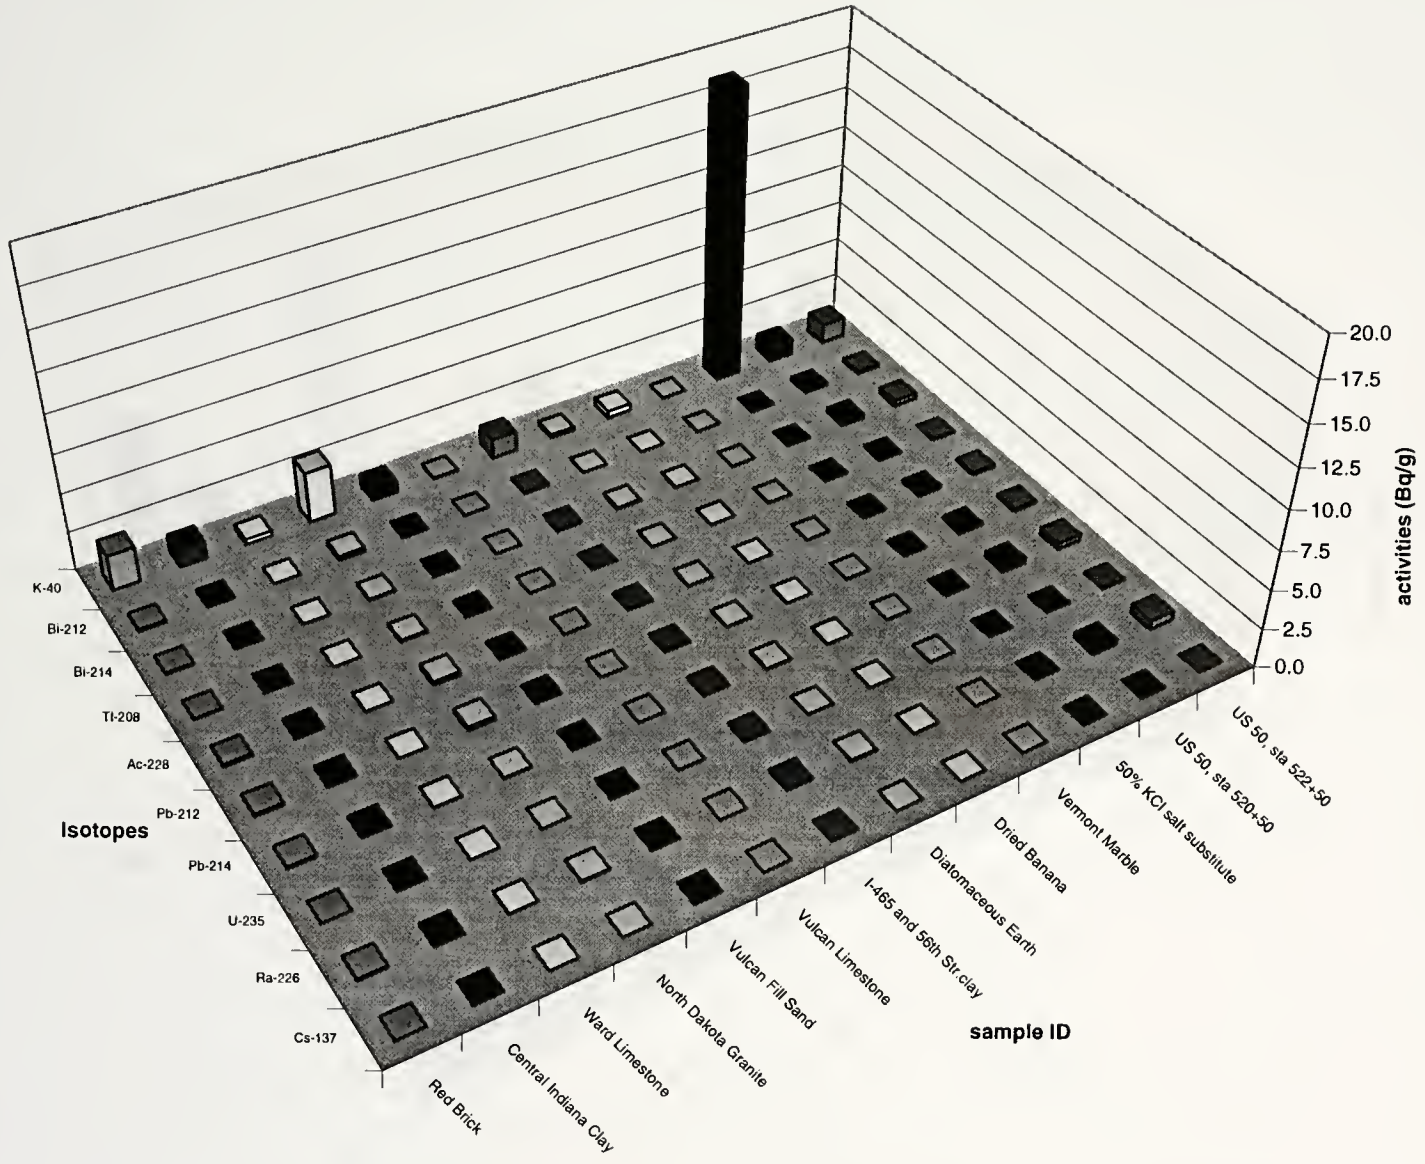

Figure 19a: Isotopic Activities of Gamma Emitters in Common Materials

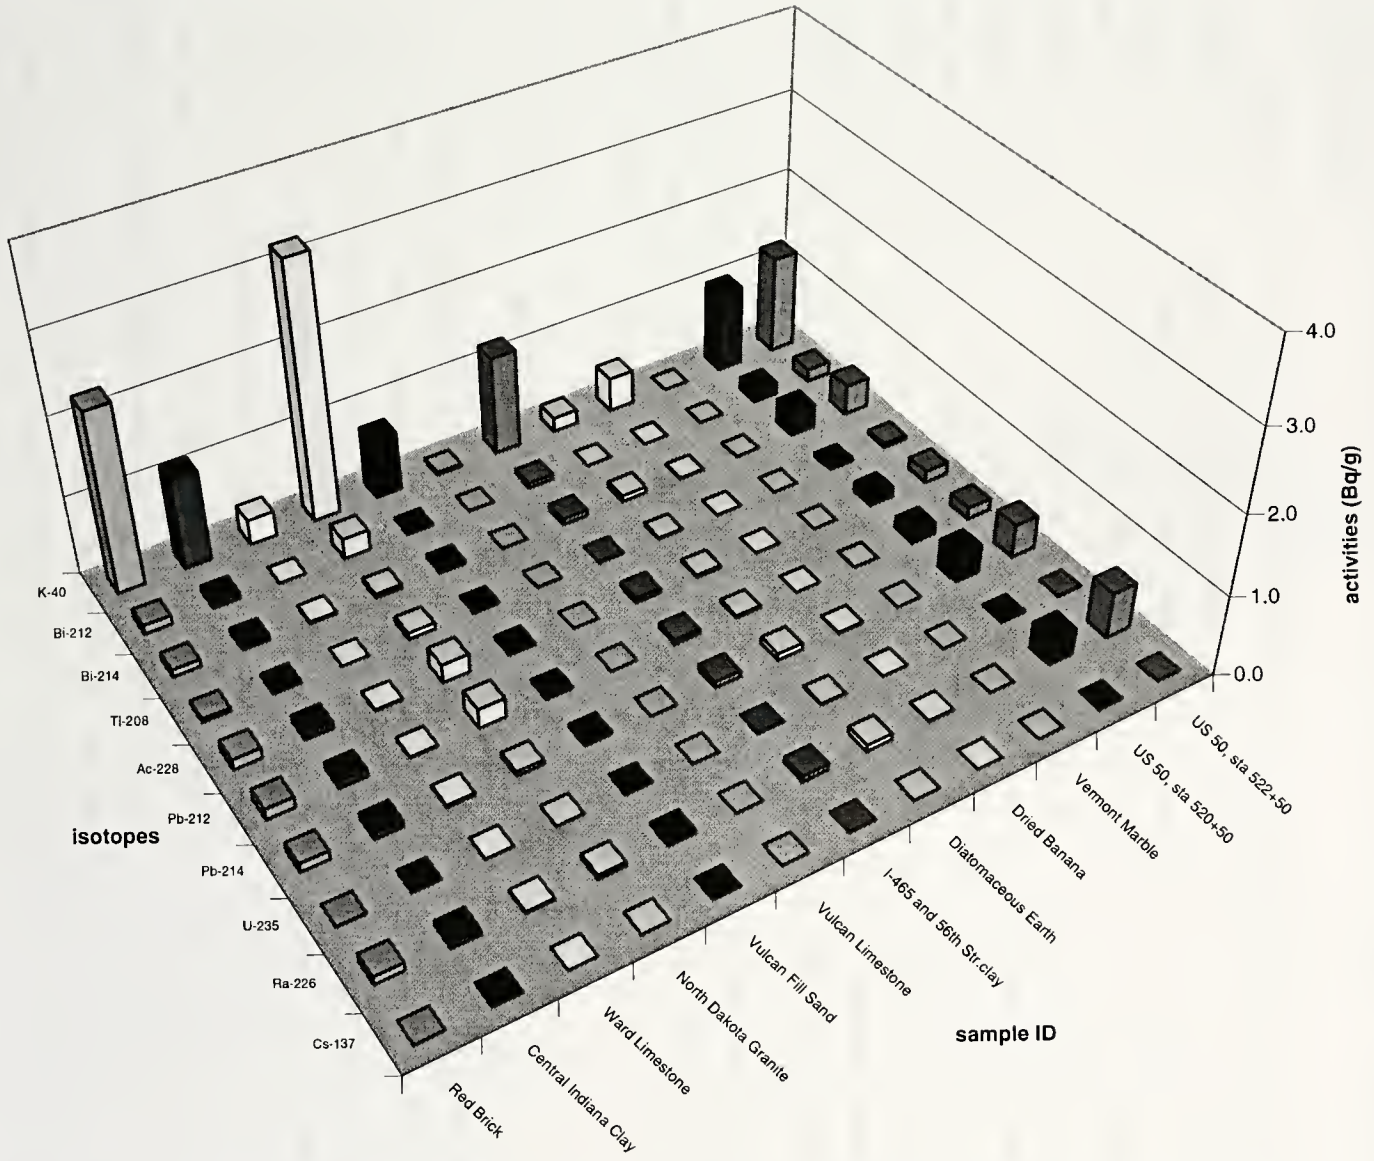

Figure 19b: Isotopic Activities of Gamma Emitters in Common Materials (enlarged without KCl)

of Indiana limestone, fill sand from central Indiana, marble from Vermont, granite from North Dakota, and diatomaceous earth (crushed coral). Two samples of commingled ash from the US 50 highway project in southern Indiana are also included. The sample identified as "50% KCl" was a salt substitute, a replacement for sodium chloride, that contained 50 % NaCl and 50% KCl. A sample of dried bananas was also included.

Natural materials have a large range of activities. The marble sample contained no measurable amounts of gamma radiation, while the granite sample was the most radioactive of the natural materials surveyed. The limestone sample from a Vulcan Materials-owned quarry contained only ^{40}K. Red brick, both clays, fill sand, diatomaceous earth, the limestone sample from the quarry of Ward Stone and granite contained trace amounts of most isotopes. Clay was the only material in the entire study that contained ^{137}Cs, because of the very close proximity to the surface of the earth, where significant amounts of radioactive fallout from nuclear tests collects, and its ability to sorb cesium in the soil subsurface. The activity of ^{40}K in the salt substitute was several times larger than the specific activities of other samples, isotopic and total. Since bananas are a source of potassium, they naturally contain ^{40}K, and trace amounts of other radionuclides were present because plants tend to uptake some heavy metals.

The activities of ^{226}Ra, ^{214}Pb, and ^{214}Bi in the US 50 samples were larger than those of all other materials. ^{40}K activities in these ash samples were greater than those of all other materials except KCl, one clay sample, brick, and granite.

5.2.2 Comparison of Isotopic Activities of Natural Materials to Coal and Ash

Figures 20 through 23 (a and b) compare the isotopic activities of gamma-ray emitting isotopes of each group of samples to natural materials. The activity of KCl dwarfs the activity of any other sample in the study. In most cases the activities of the natural materials were larger than those of coal, except for ^{40}K. Figure 20a displays the isotopic activities of natural samples and coal in greater detail without KCl. The samples of brick, clay, granite, diatomaceous earth, fill sand, and construction ash have larger activities than most coals, while limestone and marble have smaller activities. Coal 11c appears to distinguish itself from other coals. It has a large contribution of ^{226}Ra, ^{214}Pb, and ^{214}Bi. With the exception of granite, these isotopes are larger than the analogous activities for the natural samples. Almost all ash samples display larger isotopic activities than the other samples. The exception to this was, of course, ^{40}K.

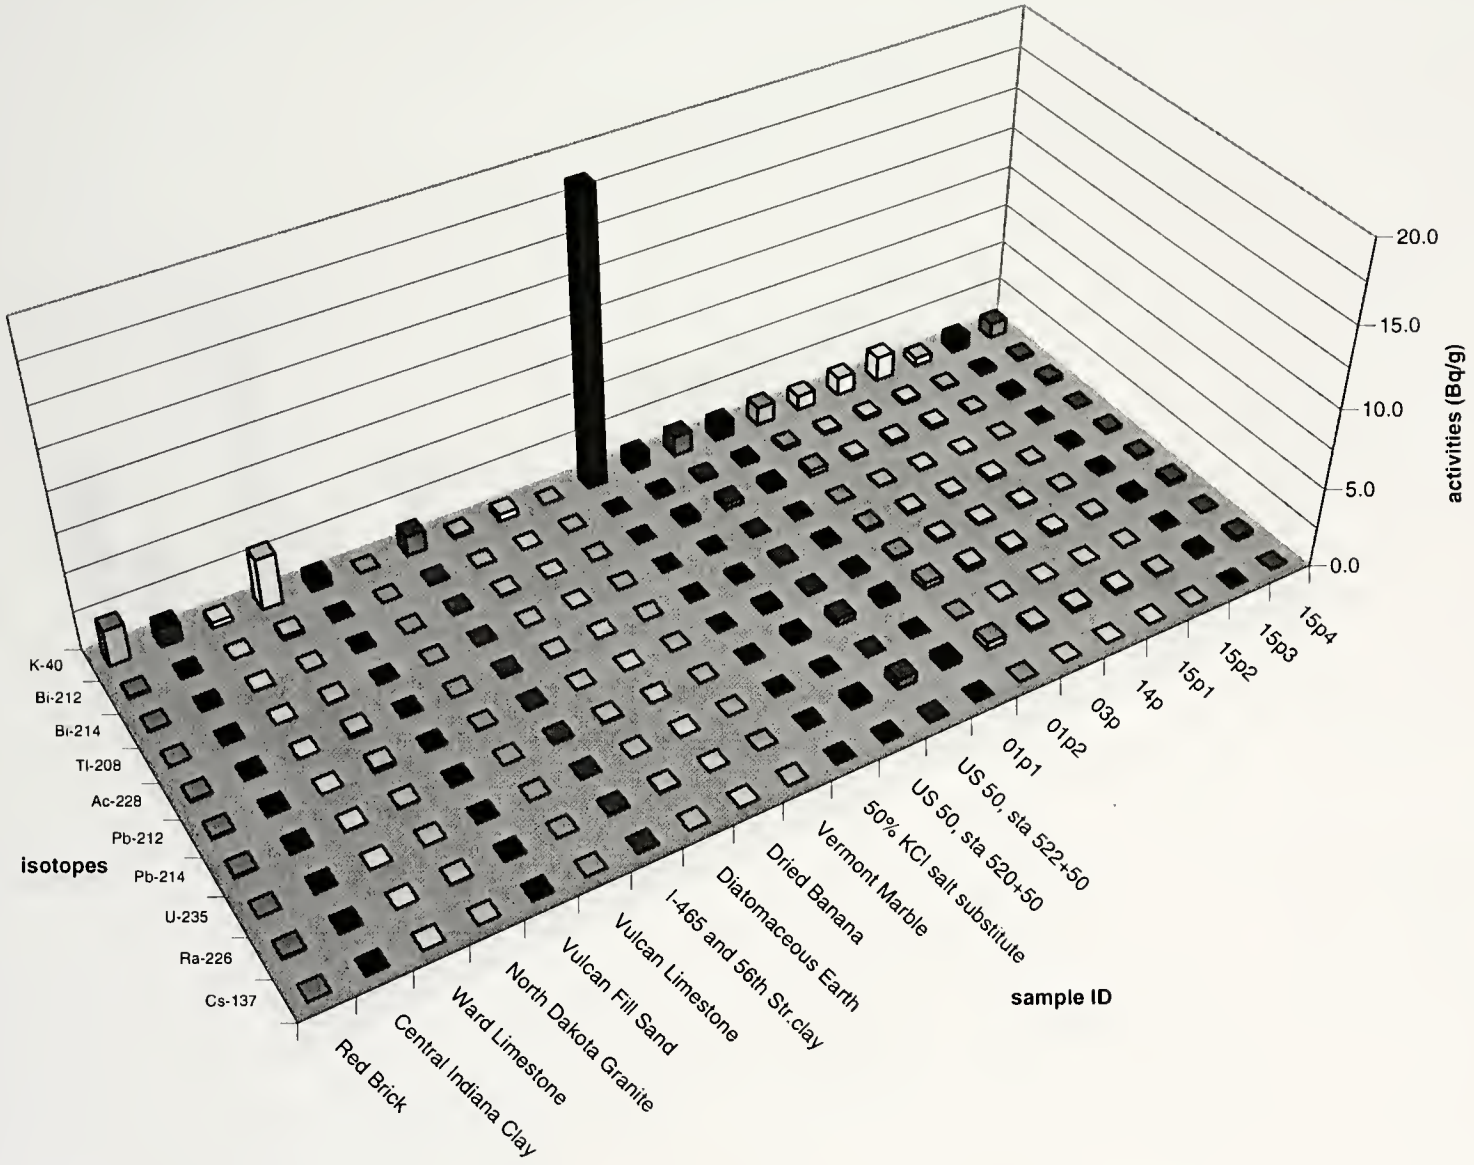

Figure 23a: Comparison of Isotopic Activities of Common Materials to Commingled Ash

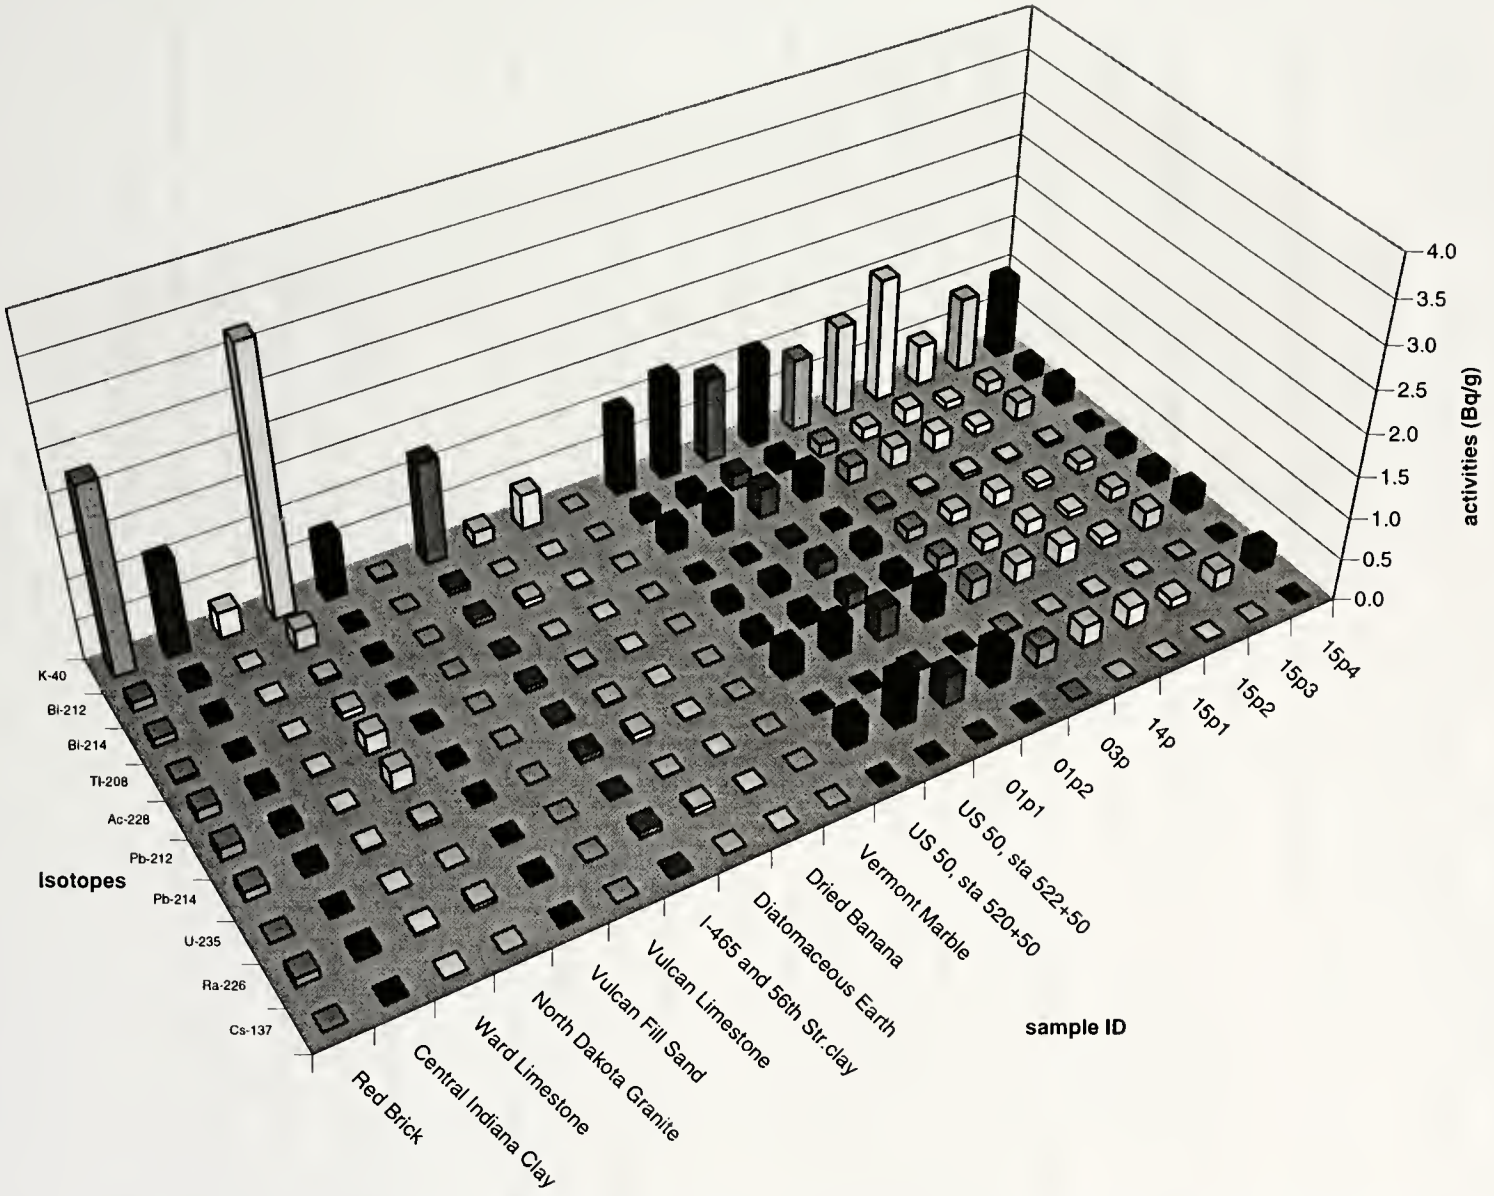

Figure 23b: Comparison of Isotopic Activities of Common Materials to Commingled Ash (enlarged without KCl)

5.3 Total Activities of Natural Samples

Total activities of natural samples are in Figure 24. Salt substitute has the largest activity of all samples surveyed, despite having only one isotope contributing to the total. Clay, brick, granite, and the US-50 construction ash have the largest activities of the remaining samples.

5.4 Comparison of Total Activities of Natural Samples to Coal and Ash

As expected, the total activities of coal were less than those of natural samples (Figure 25). Limestone, marble, and diatomaceous earth are the only materials that have total activities less than coal. Once again, coal 11c separates itself from the group, having the highest total activity among coals.

Generally, the total activities of bottom ash are comparable to those of the natural materials. In Figure 26, all natural samples, except Vulcan limestone and marble, were contained within the range of bottom ash activities. The total activity of granite was less than the activities of all 22 bottom ash samples, brick was less than four bottom ashes, and KCl activity was more than a factor of five greater than the highest bottom ash activity, 06b. Traditional fill materials, limestone and sand, were less active than most bottom ashes. These results suggest that bottom ash, activities ranging from 0.281 to 3.71 Bq/g, was nearly equivalent to many of the building materials currently in use.

The results for fly ash were somewhat different than those of bottom ash. In Figure 27, five natural samples, both samples of limestone, marble, diatomaceous earth, and fill sand, fell outside the range of fly ash activities. KCl activity was about three times larger than the highest fly ash activity, and granite activity was less than the total activities of two fly ash samples. These results indicate that fly ash was more active than many construction materials.

As shown in Figure 28, commingled ash was approximately equivalent to bottom ash in terms of comparison to natural materials. The activities of granite and brick are greater than all commingled ash activities, and KCl activity is about six times greater than the largest commingled ash activity. The activities of the construction ash samples were also comparable because of their probable origin from commingled ash storage. The total activity of commingled ash was approximately equivalent to the total activity of traditional construction materials.

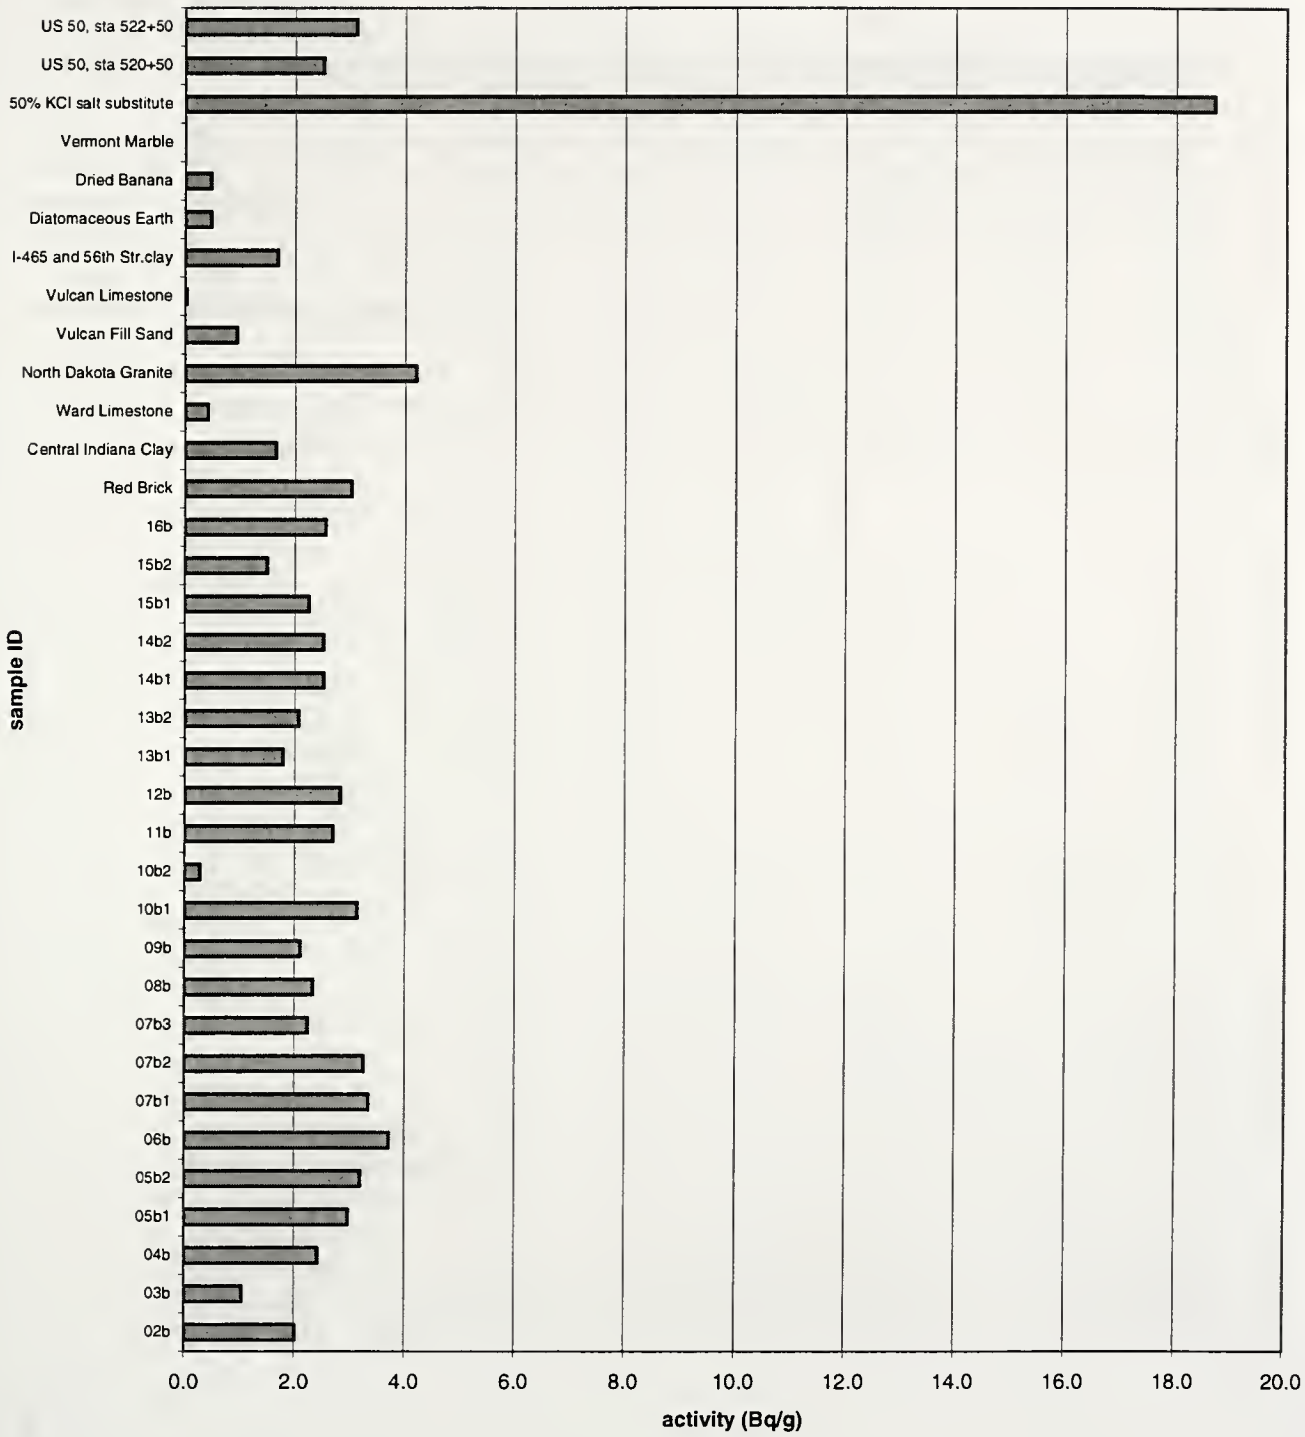

Figure 26: Comparison of Total Activities of Bottom Ash and Common Materials

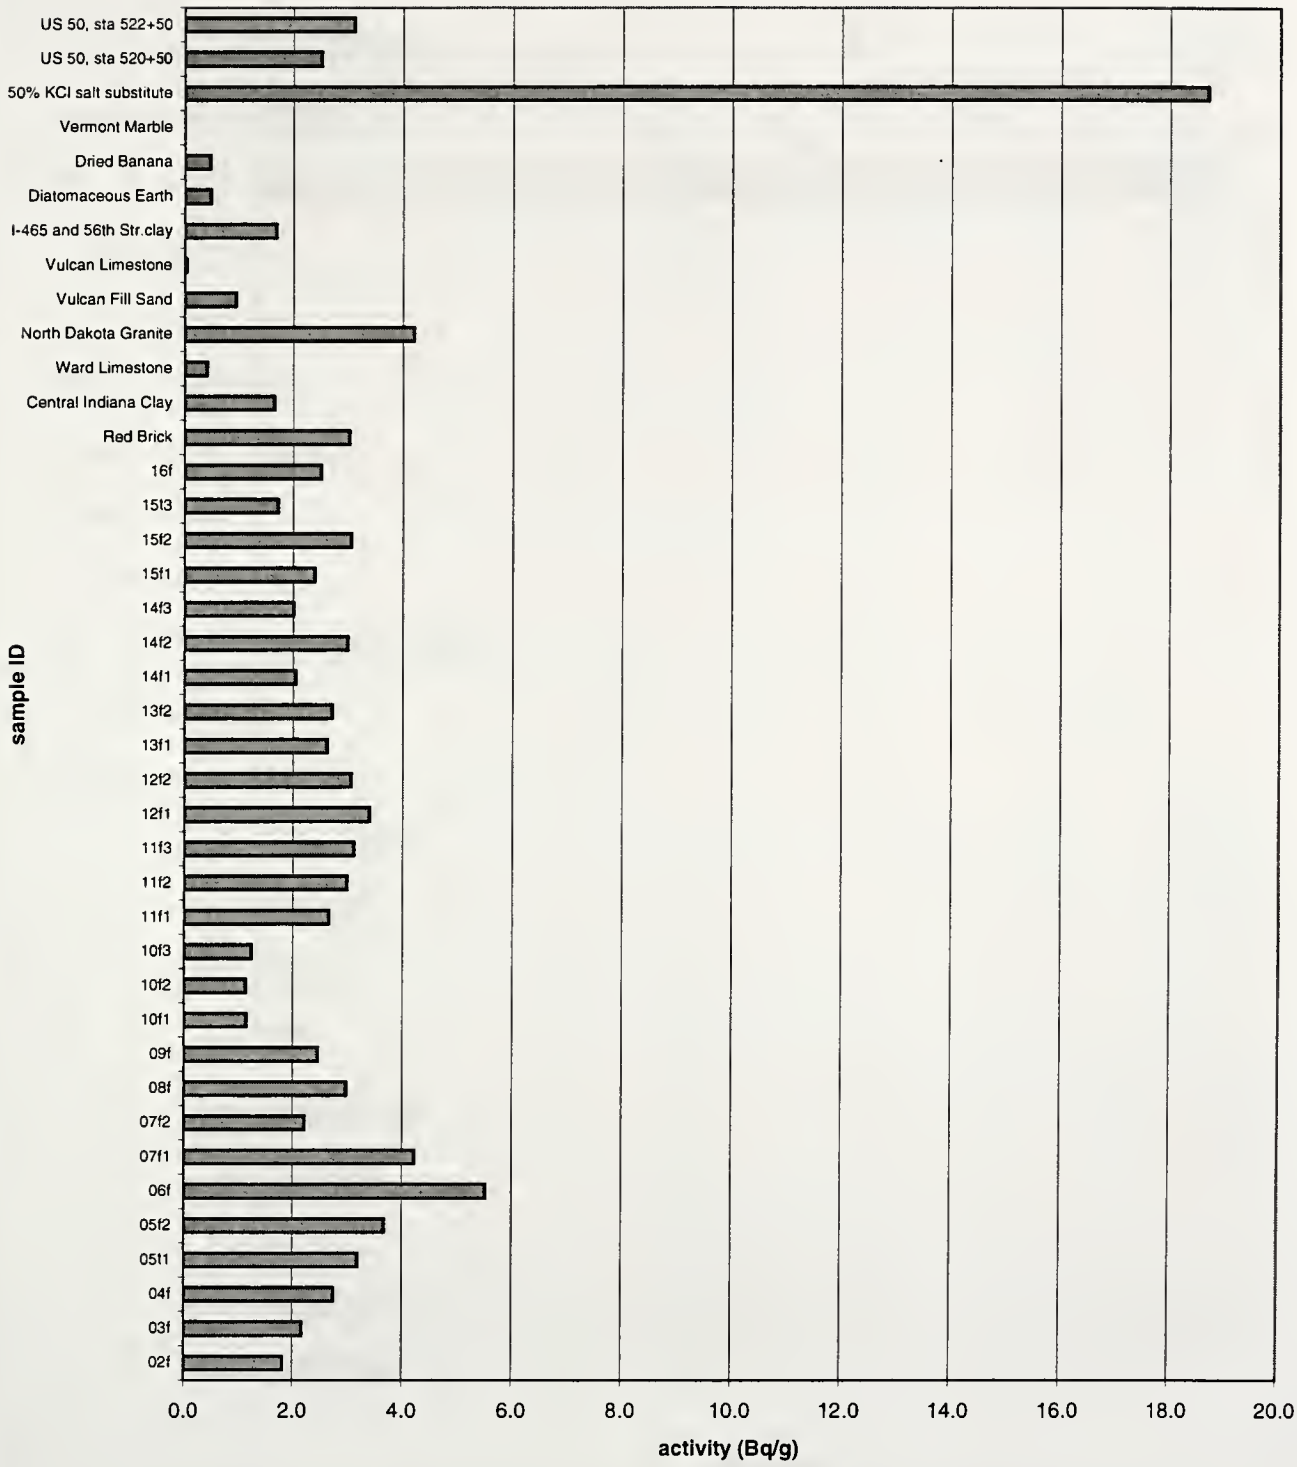

Figure 27: Comparison of Total Activities of Fly Ash and Common Materials

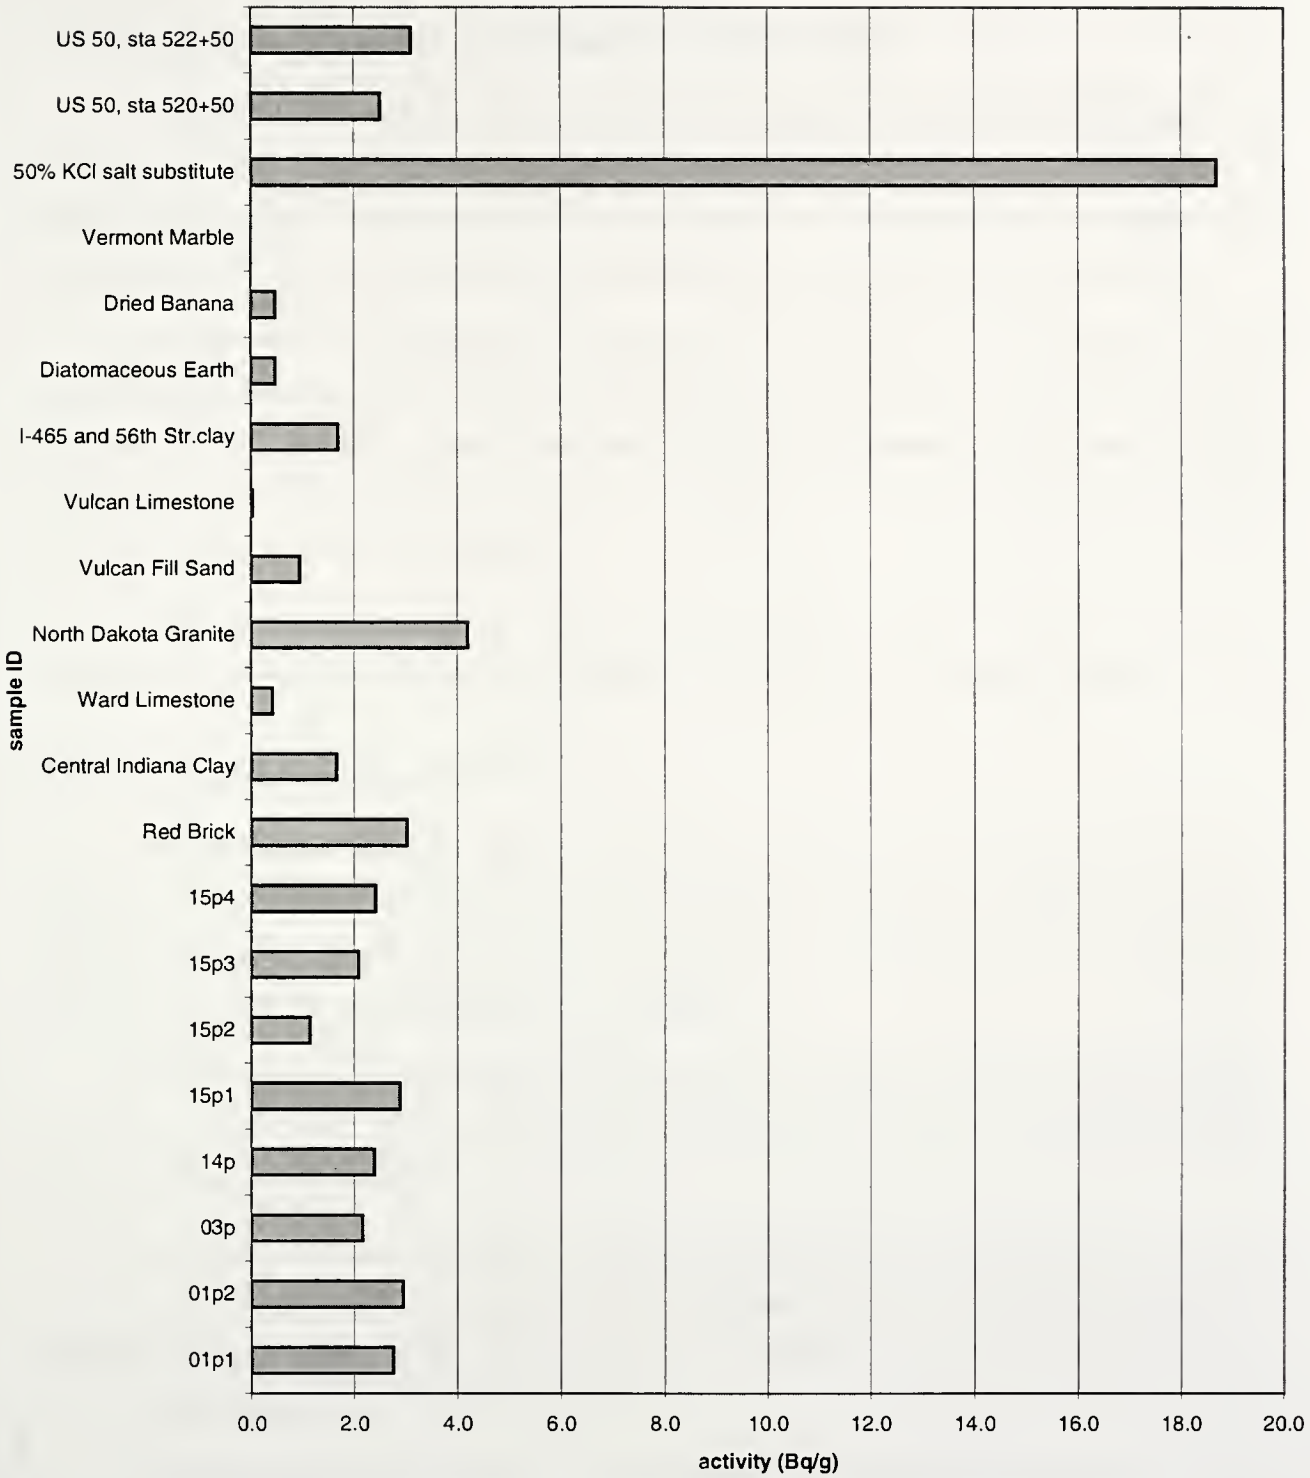

Figure 28: Comparison of Total Activities of Commingled Ash and Common Materials

5.5 Exposure to Gamma Radiation from Coal Ash Embankments

Exposure for people working on a coal-ash embankment was calculated for a 2000 hour work-year of occupational exposure, which was much greater than exposures expected for the public. A distance of one meter, the approximate height of the human torso, above the surface of an embankment of material was used for exposure calculations. The embankment was infinite in both area and depth.

Densities used in the calculation of the exposure are in Figure 29. These densities were the measured densities of one-liter test samples. The densities of ash range from 0.302 to 1.693 g/cm^3. Under actual circumstances ash densities are much higher than experimental densities, due to the effects of ash compaction. A larger density results in lower exposures because more shielding is present in a fixed volume to attenuate more gamma rays.

Along with density, exposure is a function of activity. Larger activities result in larger exposures. Activities used in the calculation of exposure were those that were presented above.

5.6 Total Dose Equivalent from Coal Ash

The annual dose equivalent from an embankment of bottom, fly, or commingled ash is given in Figures 30, 31, and 32. Dose equivalent ranges from 8.09 to 37.5 mrem for bottom ash, 7.90 to 59.1 mrem for fly ash, and 10.9 to 39.6 mrem for commingled ash. The averages are 18.1, 25.9, and 20.9 mrem/yr for bottom, fly, and commingled ash, respectively.

Bottom ashes that have the largest exposures, above 20 mrem/yr are 05b2, 06b, 07b1, 07b2, 10b1, 11b, 12b, and 16b. Of these 05b2, 06b, 07b2, and 10b1 have densities and activities among the highest of all bottom ash samples.

In the case of fly ash, the highest dose equivalents, above 30 mrem, correspond to the samples with the lowest densities. 12f2 has the highest dose equivalent and the second-lowest density. It is apparent that 12f2 does not shield as well because of its low density. Conversely, 16f had the highest density and the fourth-lowest dose equivalent.

For commingled ash the samples that correspond to the highest densities and the highest activities have the lowest dose equivalents. 01p1 produces the second-lowest dose equivalent with the second-highest density and third-highest activity.

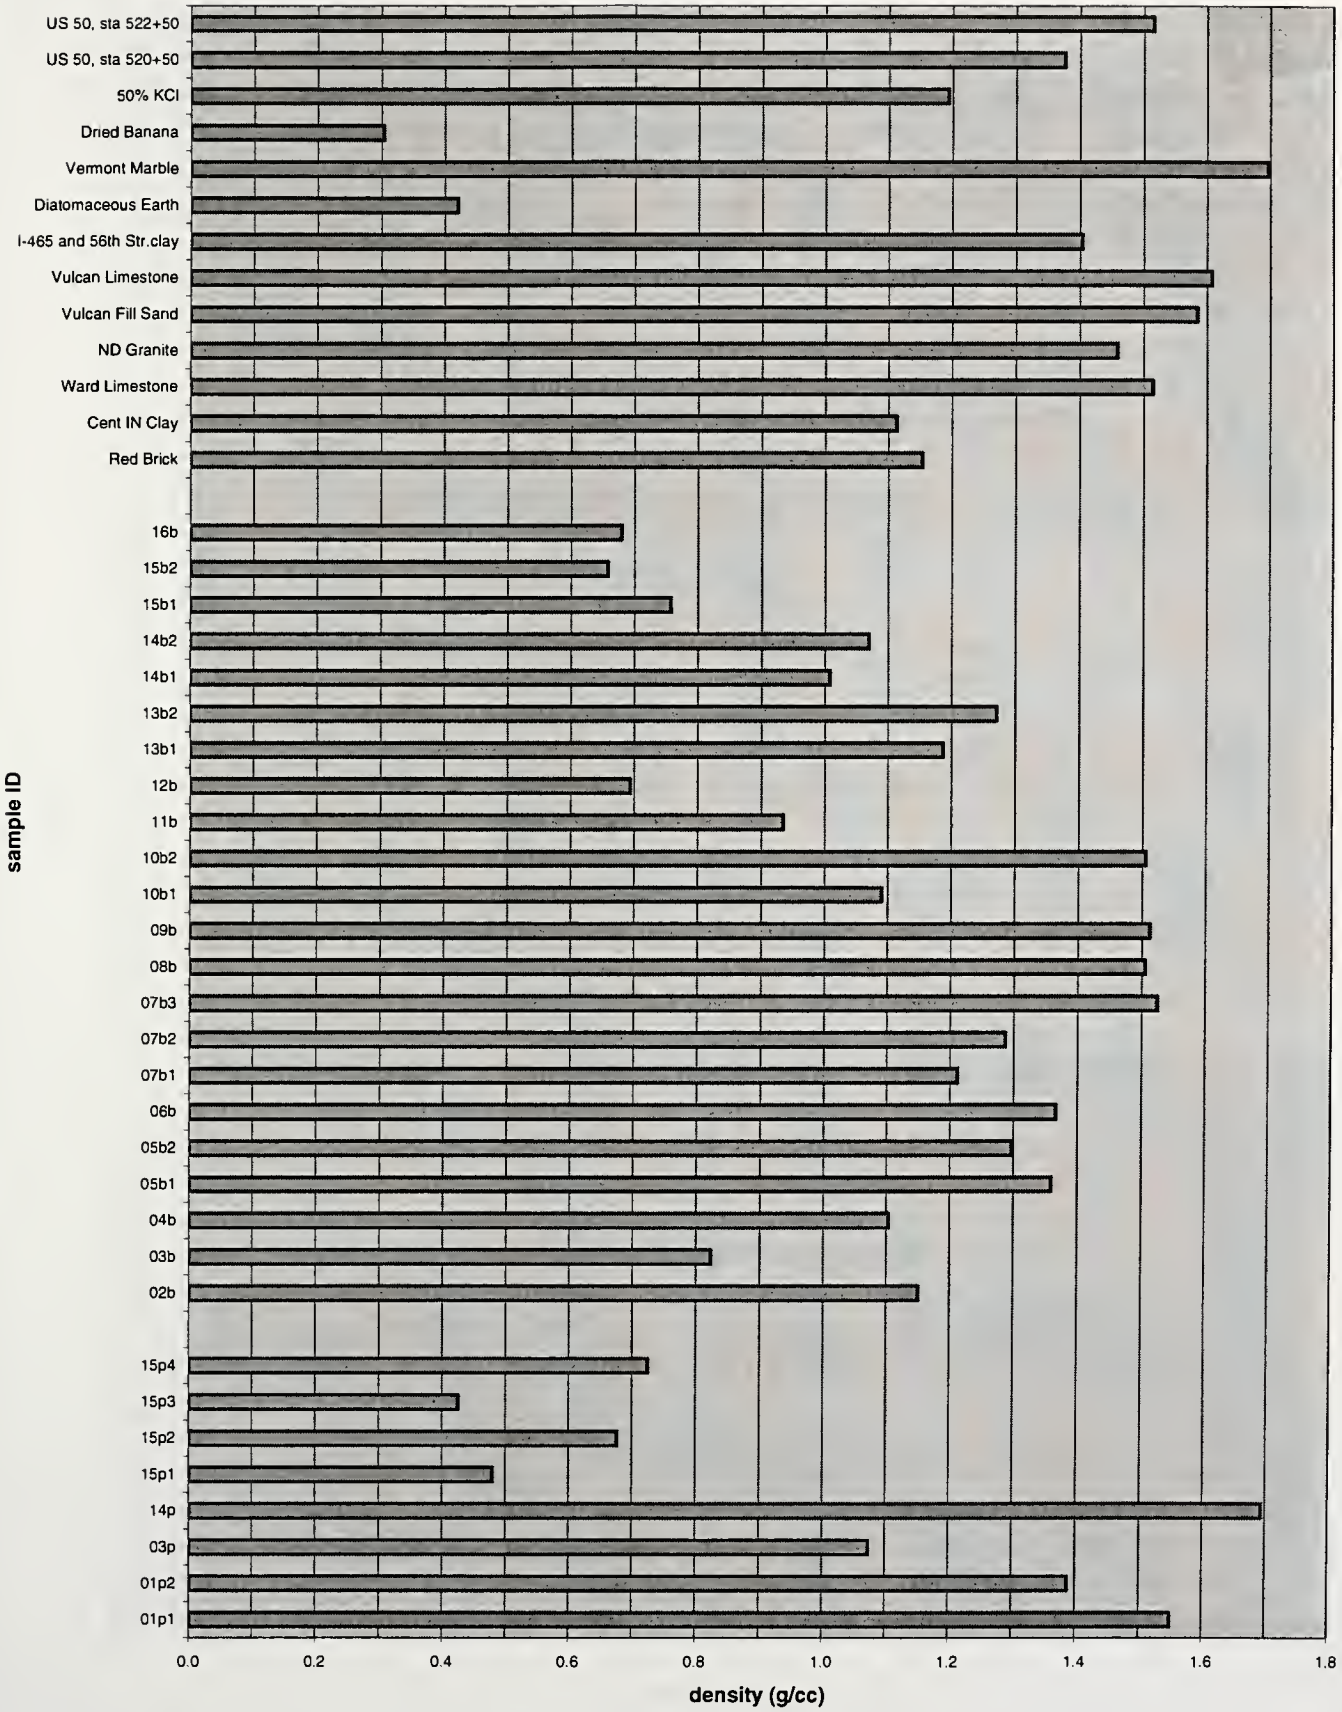

Figure 29: Densities of 1-liter Samples

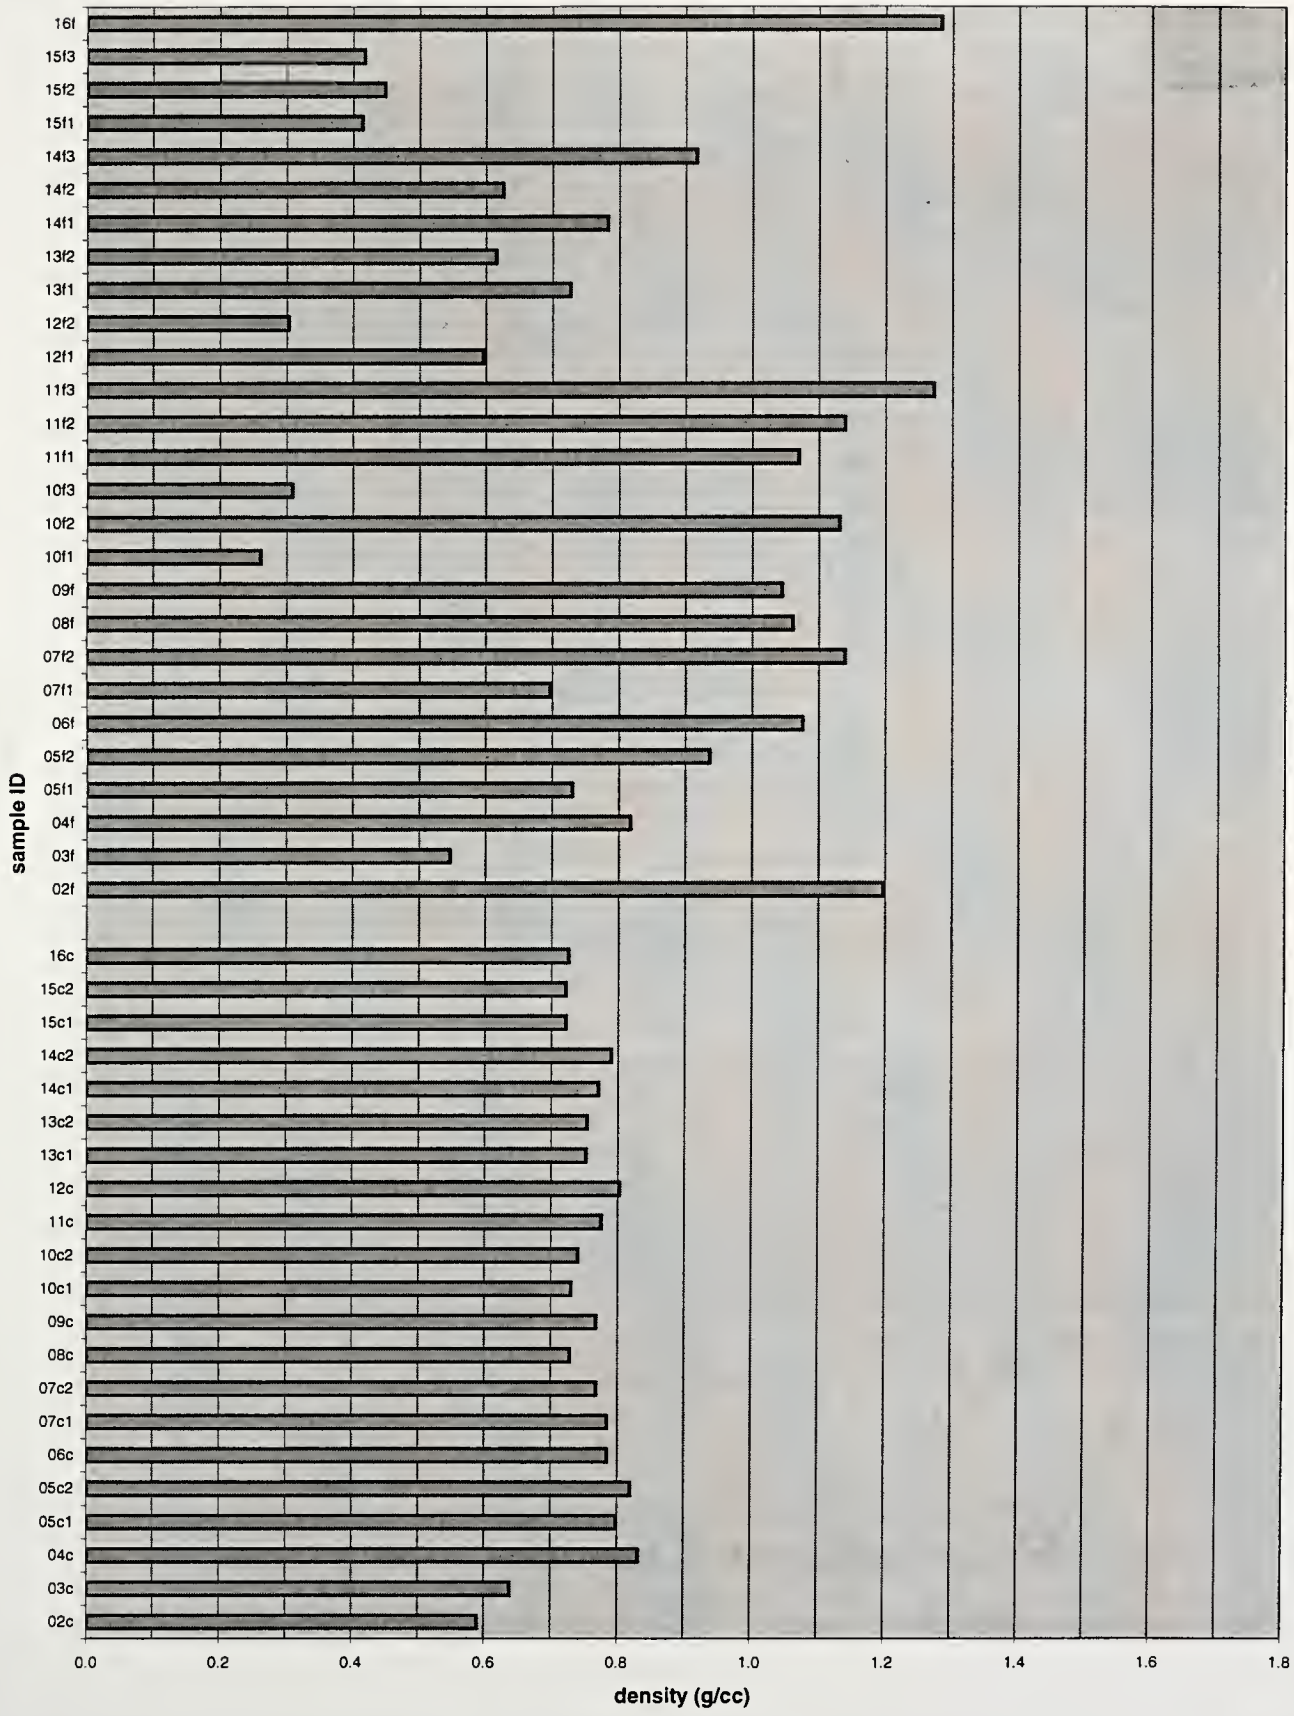

Figure 29 (continued): Densities of 1-liter Samples

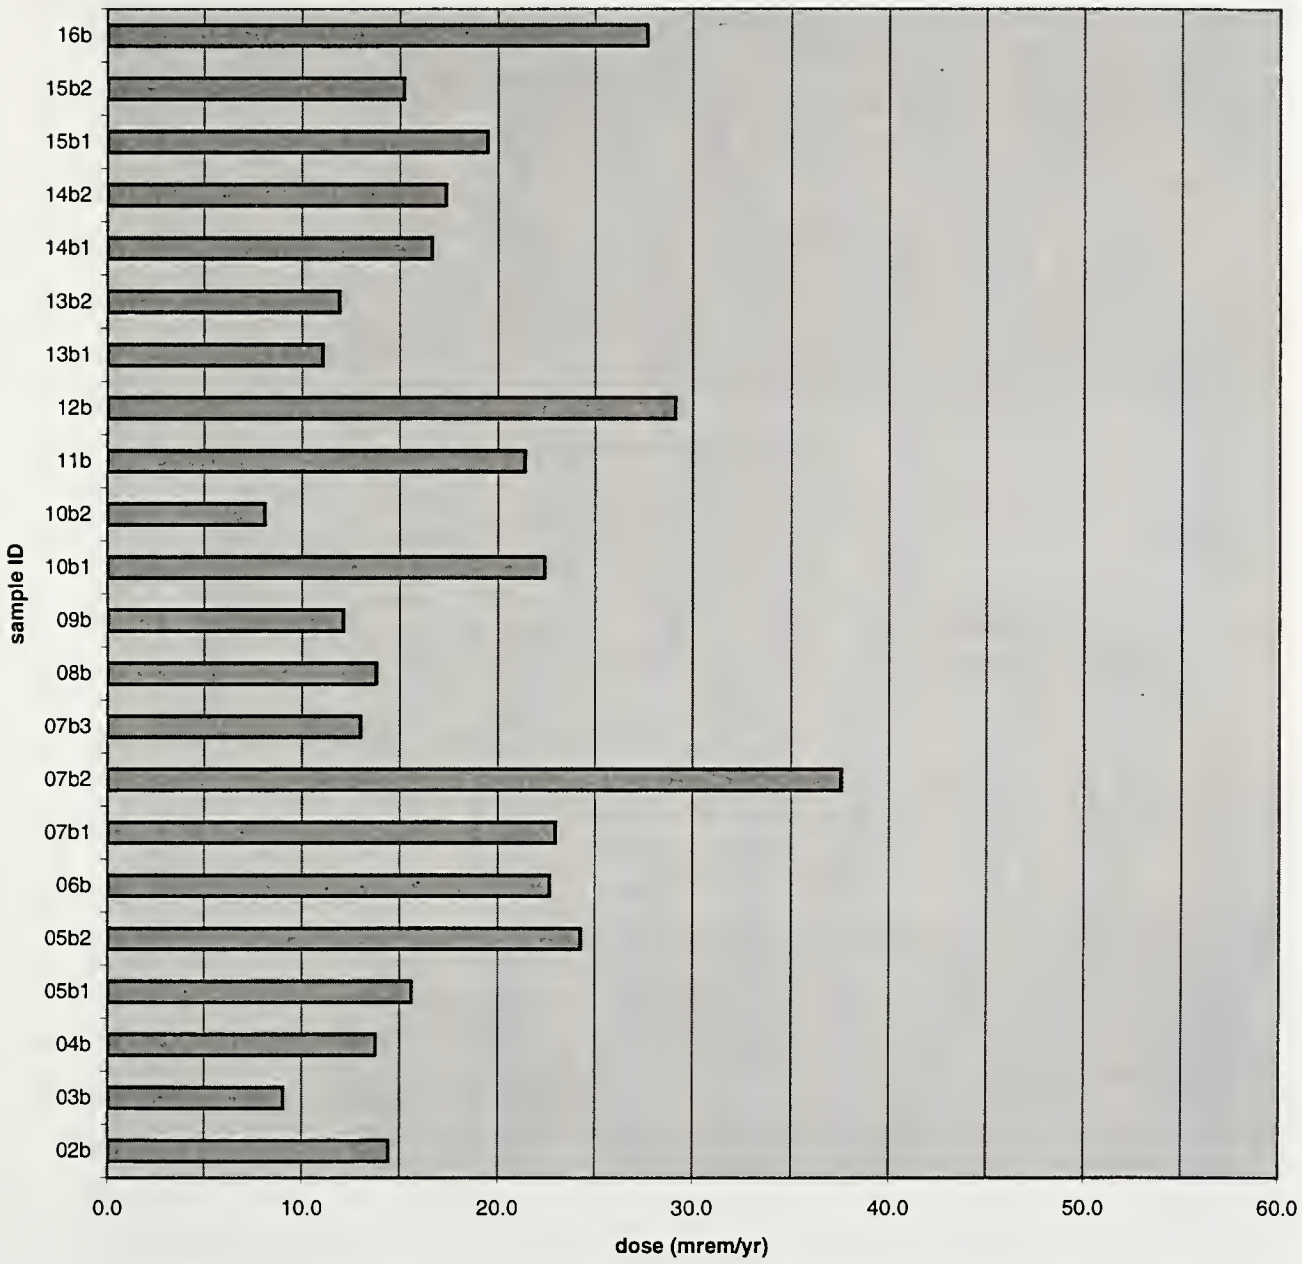

Figure 30: Dose Equivalent Rate of Gamma Rays from Bottom Ash Samples

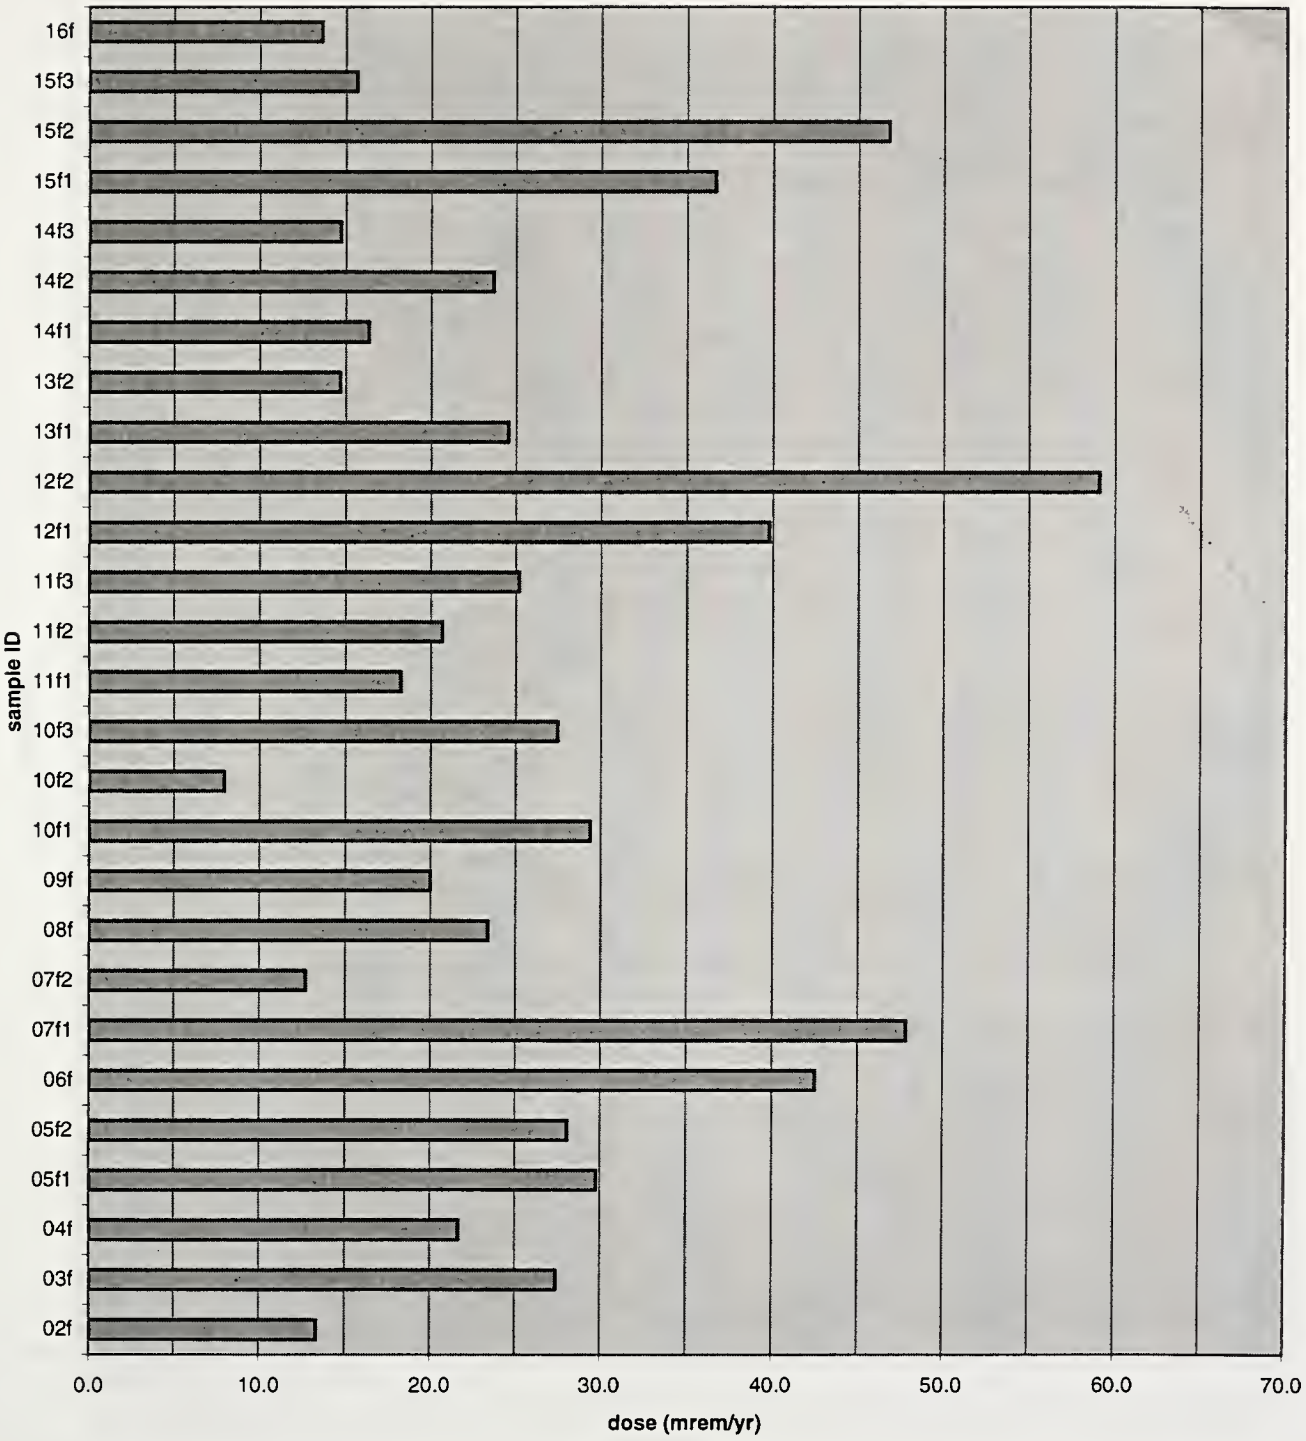

Figure 31: Dose Equivalent Rate of Gamma Rays from Fly Ash Samples

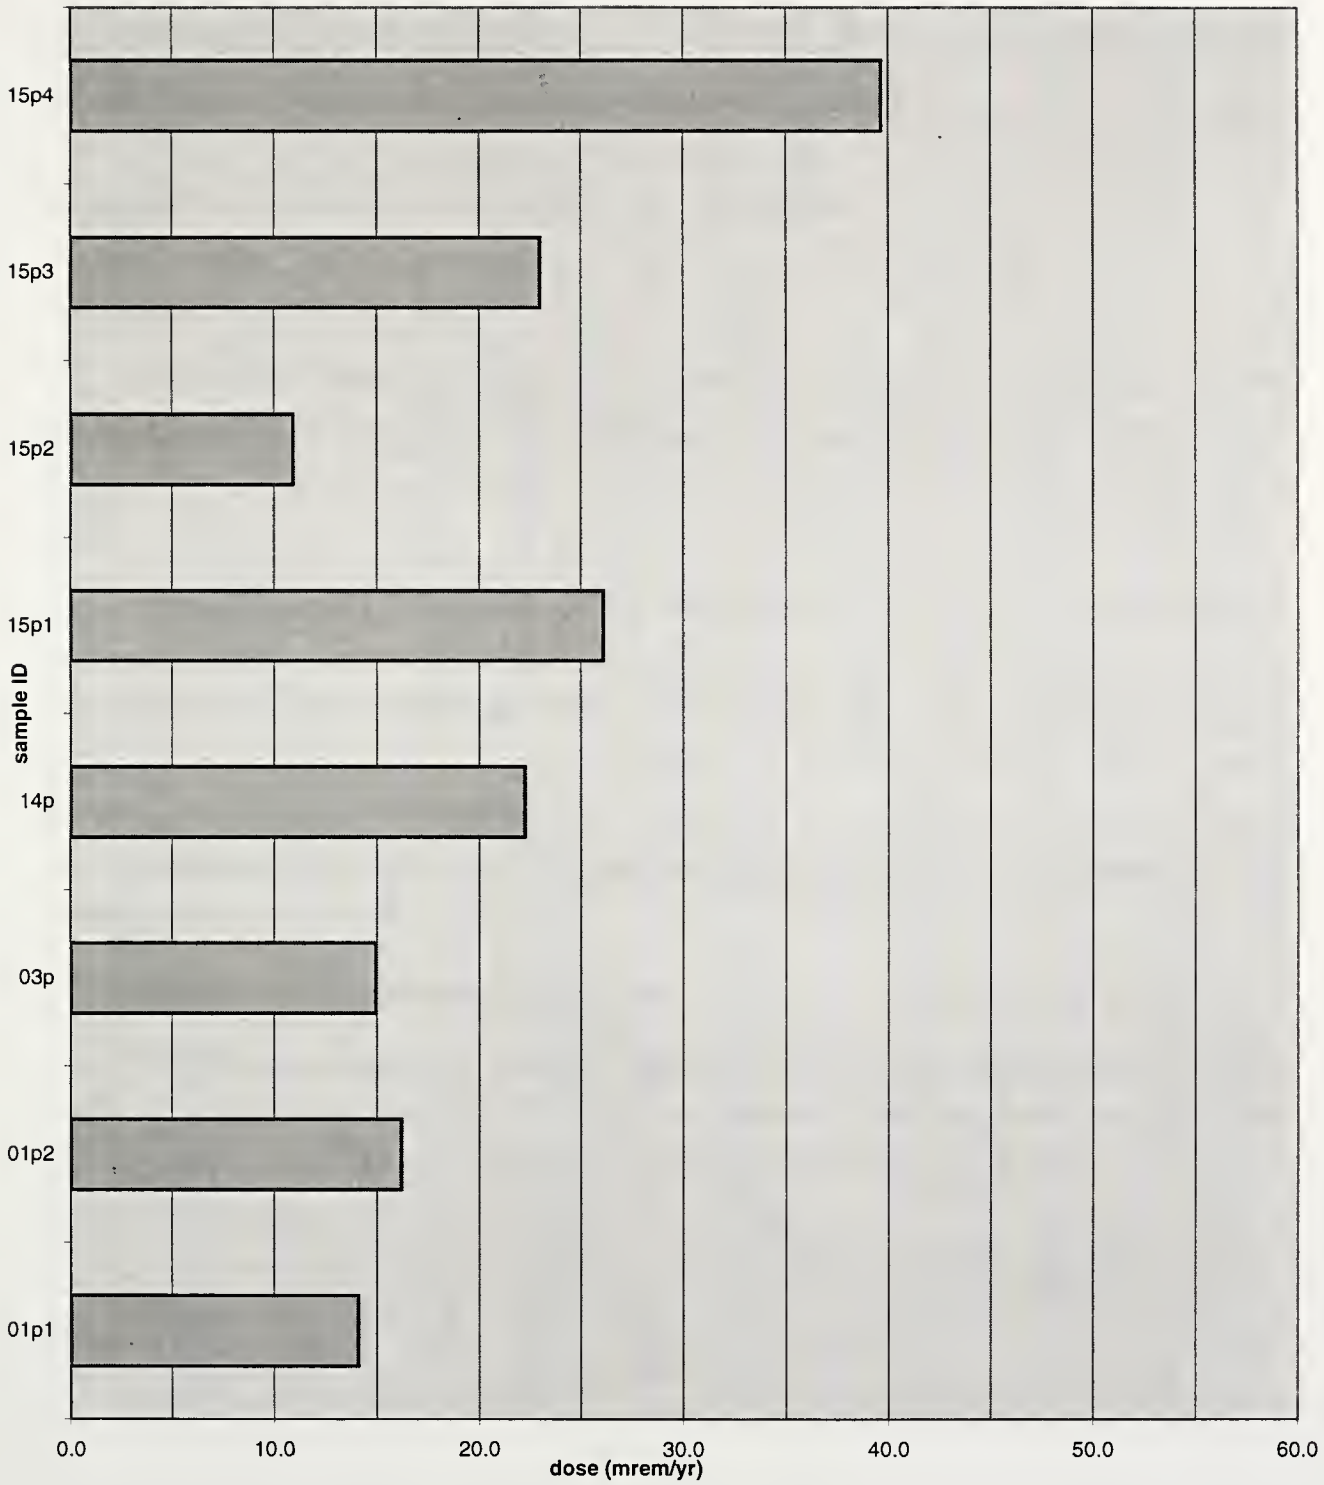

Figure 32: Dose Equivalent Rate of Gamma Rays from Commingled Ash Samples

The dose equivalent from fly ash was significantly higher than from bottom and commingled ash (Figure 33). This correlated to the dependence on activity discussed earlier. Larger densities in bottom and commingled ash may also result in more shielding of gamma radiation.

5.7 Comparison of Exposure from Coal Ash to Natural Materials

5.7.1 Exposure from Natural Materials

All dose equivalents from natural samples were less than sixteen mrem/yr (Figure 34). The highest exposures resulted from those materials that had the highest activity, i.e. granite, brick, and clay. Limestone and marble produced the lowest exposure because of their relatively high density and lack of activity.

The samples from US 50 construction were comparable to the exposures from brick and granite. The same assumptions relating to embankment size and exposure time, which were applied to the ash, were applied to the common materials. The calculated exposures for some of the common materials included in this study can be considered to be the exposures that many people experience in common situations. For example, the assumptions that were applied to an embankment can approximate the conditions experienced by farmers in a field, miners in a surface mine, or, in a more abstract situation, baseball players on a clay field.

5.7.2 Comparison of Natural Materials to Coal Ash

For all types of coal ash the exposures experienced are higher than those of natural materials. Figures 35, 36, and 37 illustrate this point. The higher exposures in coal ash are most likely due to the lower densities of the ash, since the activities were approximately equal. Lower densities resulted in less self-attenuation of gamma rays.

CHAPTER 6

Conclusions

Merely mentioning the possibility of radiation exposure to many people causes alarm. Many times this alarm is premature, though, because the facts about radiation exposure in certain situations are misunderstood. Such is the case when discussing radiation levels in coal ash. Based on the results presented, coal ash is a radiogenically feasible alternative material in the construction of road embankments.

Coal ash contains levels of gamma-ray emitters that are higher than those of traditional construction materials (i.e. clay, sand, brick, and limestone) but the levels of gamma-ray emitters that exist in coal ash are not exceedingly high. Consider the fact that the limit promulgated by the Environmental Protection Agency (EPA) is 100 mrem/yr for public exposure to a single man-made source, and the Nuclear Regulatory Commission (NRC) limit is 5 rem/yr for occupational exposure. Although these limits do not apply directly to coal ash and they encompass all types of radiation exposure, which have not been addressed here, they represent an accepted standard.

The exposure levels projected for gamma radiation with coal ash residuals used with embankment construction were well below these standards. Even then, these estimates were based on highly conservative assumptions (i.e., see Section 4.5.1 Model Assumptions).

Figure 38 accordingly provides a qualification of the projected 'worst-case' emission levels for fly ash and bottom ash relative to a number of other common radiation sources (i.e., inhaled radon, brick housing, cosmic sources, terrestrial sources, etc.). Even excluding any exposure whatsoever to coal ash residuals, these cumulative, 'background' dosages are about 320 mrem/yr for the average adult human. By comparison, of the coal-ash data recorded during this study, samples 7b2 and 12f2 respectively produced the highest levels of bottom ash and fly ash exposure for a 2000 hour work-year. This is approximately equal to the dose equivalent received by living in a brick home for one year.

Given these quantities, it can be seen that exposures from coal ash embankments are relatively low. In turn, these residuals would only contribute small amounts of exposure each year when used as an alternative material in road construction.

Appendices

Appendix A: Isotopic Activities of Gamma-ray Emitting Isotopes

Appendix B: Total Activities of Gamma-ray Emitting Isotopes

Appendix C: Sample Densities

Appendix D: Dose Equivalent from an Embankment Composed of Gamma-ray Emitting Materials

Appendix E: Dose Equivalent from Common Sources

Appendix F: Key Definitions Listing

Appendix G: Sampling Sites within the State of Indiana (16 sites)

Appendix A

Isotopic Activities (Bq/g) of Gamma-ray Emitting Isotopes

(Complete Samples and Common Materials)

Appendix E

Dose Equivalent (mrem/yr) from Common Sources

Television	2
Internal Radiation	20
Terrestrial Sources	30
Cosmic Radiation	30
Brick Houses	40
Inhaled Radon	200

Appendix F
Key Definitions Listing

1. **Activity:** Rate of decay of radionuclides.

2. **Bequerel:** The metric unit of activity is called a Bequerel (Bq), which corresponds to one particle (i.e., nucleus, alpha particle, beta particle, or photon) emitted per second.

3. **Curie & picoCurie:** The English unit of activity is called a Curie (Ci). Units of Curies are considerably larger than Bequerels. 3.7×10^{10} Bq is equivalent to one Curie. A picoCurie (pCi), a unit most used to describe very low levels or radiation, is 10^{-12} Curies.

4. **rad:** Radiation Absorbed Dose is a measure of the amount of energy that is deposited per unit mass of an incident material.

5. **rem:** Radiation Equivalent Man is a measure of the amount of biological effect on a human caused by radiation exposure. It is the number of rads multiplied by the relative biological effectiveness (RBE).

6. **intensity:** The intensity of a gamma ray refers to the average number of times it is released during a nuclear decay. The intensity of a 1460 keV gamma ray from the decay of Potassium-40 is 0.1067, meaning that this particular gamma ray is emitted by 10.67% of all Potassium-40 decays.

7. **absorption/attenuation coefficient:** An attenuation coefficient is the probability that a particle will pass unimpeded through a shield with a thickness of one centimeter. An absorption coefficient is the probability that a particle deposits energy into a shield that is one centimeter thick. Both of these values have units of inverse centimeters.

8. **spectrum:** Energy spectrums provide a representation of the energy and number of photons being emitted by a given material. Each radionuclide contributes part of a composite spectrum displayed by a multi-channel analyzer. Each specific radionuclide can be identified by its unique contribution to this spectrum.
