40 Variability Bugs in the Linux Kernel

A Qualitative Study

Iago Abal
Claus Brabrand
Andrzej Wasowski

Abstract

Feature-sensitive verification is a recent field that pursues the effective analysis of the exponential number of variants of a program family. Today researchers lack examples of concrete bugs induced by variability, and occurring in real large-scale software. Such a collection of bugs is a requirement for goal-oriented research, serving to evaluate tool implementations of feature-sensitive analyses by testing them on real bugs. We present a qualitative study of 40 variability bugs collected from bug-fixing commits to the Linux kernel repository. We investigate each of the 40 bugs, recording the outcome of our analysis into a database. In addition, we provide self-contained simplified C99 versions of the bugs, facilitating understanding and tool evaluation. Our study provides insights about the nature and occurrence of variability bugs in a large C software system, and shows in what ways variability affects and increases the complexity of software bugs.

1 Introduction

Many software systems today have to support a large amount of variability. In some systems, like the Linux kernel, configuration options, here referred as *features* [20], are used to tailor functional and non-functional properties to the needs of a particular user. In systems adopting the Software Product Line methodology [1] selection of features is used to tailor production of an individual software product for a particular market niche. Highly configurable systems can get very large, and can encompass large amounts of features. Reports of industrial systems with thousands of features are known [4] and open-source examples of similar size have been documented in detail [5].

Different features in a configurable system interact in non-trivial ways, because they need to influence each others functionality. When such interactions are unintended, they induce bugs that manifest themselves in certain configurations but not in others, or that manifest differently in different configurations. A bug in an individual configuration can be found by analyzers based on standard program analysis techniques like type-checking, model checking or static analysis. However, since the number of configurations is exorbitant (exponential in the number of features) it is not feasible to analyze each of these configurations separately.

Family-based [32], a form of feature-sensitivity, analyses tackle this problem by considering all configurable program variants as a single unit of analysis, instead of analyzing the individual variants separately. In order to avoid duplication of effort, common parts are analyzed once and the analysis forks only at differences between variants. Recently, various family-based extensions to classic analysis techniques have been developed, including techniques based on *well-formedness checking* [14], *type checking* [2, 22], *dataflow analysis* [9, 6], *model checking* [3, 13, 12, 17], and *bounded model checking of software* [29].

Most of the research so far has focused on the inherent scalability problem. However, we still lack evidence that these extensions are adequate for specific purposes in real-world scenarios. In particular, little effort has been put into understanding what kind of bugs appear in highly configurable systems, and what are their variability characteristics. Gaining such understanding would help to ground research on family-based analyses in actual problems.

The understanding of complexity of variability bugs is not common among practitioners and in available artifacts. While bug reports abound, there is little knowledge on what of those bugs are caused by feature interactions. Very often, as a result of the complexities of a large project like Linux, developers are not entirely conscious of the features

that affect the software they work on. Also, having no feature-sensitive tool support, getting this information requires strenuous manual navigation of the source code. As a result, few bug reports clearly identify the affected configuration.

The objective of this work is to understand the complexity and nature of *variability bugs* (including *feature interaction bugs*) occurring in a large highly-configurable system, the Linux kernel. We address this objective via a qualitative in-depth analysis and documentation of forty cases of such bugs. We make the following contributions:

- *Identification of 40 variability bugs in the Linux kernel*, including in-depth analysis and presentation for non-experts.
- *A database containing the results of our analysis*, encompassing a detailed data record about each bug. These bugs comprise common types of errors in C software, and cover different types of feature interactions. We intend to grow the collection in the future with the help of the research community. The current version is available at <http://VBDb.itu.dk>.
- *Self-contained simplified C99 versions of all bugs*. These ease comprehension of the underlying causes, and can be used for testing bug-finders in a smaller scale.
- *An aggregated reflection over the collection of bugs*. Providing insight on the nature of bugs induced by feature interactions in a large project like Linux.

We adopt a qualitative manual methodology of analysis (supported by tools only for smaller tasks)—a choice motivated by three reasons. First, family-based automated analysis tools that scale for the Linux kernel do not exist. In fact, without this qualitative analysis it was unclear what tools should be built. Second, using conventional (not family-based) analysis tools on individual variants after preprocessing does not scale (if applied exhaustively) or yields low probability of finding bugs (if applied by random sampling). Also, it is inherently difficult to map errors in variants back to their variational program origins. Third, perhaps most important, searching for bugs with tools only allows to find cases that these tools cover, while we were interested in exploring the nature of variability bugs widely.

Reflecting on the collected material, we learn that variability bugs are very complex, they involve many aspects of programming language semantics, they are distributed in most parts of Linux project, involve multiple features and span code in remote locations. Detecting these bugs is difficult for both people and tools. Once family-based analyses able to capture these bugs are available, it will be interesting to conduct extensive quantitative experiments to confirm our qualitative intuitions.

We direct our work to designers of program analysis and bug finding tools. We believe that the collection of bugs can inspire them in several ways: (i) it will provide a set of concrete, well described challenges for analyses, (ii) it will serve as a benchmark for evaluating their tools, and (iii) it will dramatically speed up design of new techniques, since they can be tried on simplified Linux-independent bugs. Using realistic bugs from a large piece of software in evaluation can aid tuning the analysis precision, and incite designers to support certain language constructs in the analysis.

The paper proceeds with presenting background on software bugs and variability in Sect. 2. The methodology of the study is presented in Sect. 3. Sections 4–5 describe the analysis in detail: first the considered dimensions, then the aggregate observations. We finish surveying threats to validity (Sect. 6), related work (Sect. 7) and a conclusion (Sect. 8).

2 Background

We use the term *software bug* to refer to both faults and errors as defined by IEEE Standard Glossary of Software Engineering [31]. A *fault* is an incorrect instruction in the software, introduced into the code as a result of a human mistake. Faults induce *errors*, that are incorrect program states, such as a pointer being null when it should not be. Errors may cause the software to fail or behave incorrectly. In this work we collected bugs (errors) that had manifested as failures during execution (typically resulting in a kernel panic), as well as defects (faults) that were spotted by the compiler when building a specific kernel configuration. While the latter might look harmless (for instance an unused variable) we assume that they might be side-effects of serious misconceptions potentially leading to other bugs.

A *feature* is a unit of functionality additional to the core software [11]. The core (*base variant*) implements the basic functionality present in any variant of a program family. The different selections of features (*configurations*) define

```

1 void foo(int a) {
2     printf("%d\n", 2/a); // ERROR (6) ×
3 }
4 int main(void) { // START ⇒(1)
5     int x = 1; (2)
6     #ifdef CONFIG_INCR // NO |
7     x = x + 1; |
8     #endif |
9     #ifdef CONFIG_DECR // YES ↓
10    x = x - 1; (3)
11    #endif ↓
12    foo(x); (4)→
13 }

```

Figure 1: Example of a program family and a variability bug.

the set of program variants. Often, two features cannot be simultaneously enabled, or one feature requires enabling another. Feature dependencies are specified using a *feature model* [20] (or a decision model [18]), denoted here by ψ_{FM} ; effectively a constraint over features defining legal configurations.

Preprocessor-based program families [21] associate features with macro symbols, and define their implementations as statically conditional code guarded by constraints over feature symbols. The macro symbols associated to features (*configuration options*) are often subject to naming conventions, for instance, in Linux these identifiers shall be prefixed by `CONFIG_`. We follow the Linux convention through out this paper. Figure 1 presents a tiny preprocessor-based C program family using two features, *INCR* and *DECR*. Statements at lines 7 and 10 are conditionally present. Assuming an unrestricted feature model $\psi_{\text{FM}} = \text{true}$, the figure defines a family of four different variants.

A *presence condition* φ of a code fragment is a *minimal* (by the number of referred variables) Boolean formula over features, specifying the subset of configurations in which the code is included in the compilation. A code fragment with presence condition φ is thus present in a configuration κ iff $\kappa \models \varphi$. The concept of presence condition extends naturally to other entities; for instance, a presence condition for a bug specifies the subset of configurations in which a bug occurs. Concrete configurations, denoted by κ , can also be written as Boolean constraints—conjunctions of feature literals. As an example, consider the decrement statement in l. 10, which has presence condition *DECR*, thus it is part of configurations $\kappa_0 = \neg \text{INCR} \wedge \text{DECR}$ and $\kappa_1 = \text{INCR} \wedge \text{DECR}$.

Features can influence the functions offered by other features—a phenomenon known as *feature interaction*, which can be either intentional or unexpected. In our example, the two features interact because both modify and use the same program variable x . Enabling either *INCR* or *DECR*, or both, results in different values of x prior to calling `foo`.

As a result of variability, bugs can occur in some configurations but not in others, and can also manifest different failures in different variants. If a bug occurs in one or more configurations, and does not occur in at least one other configuration, we call it a *variability bug*. Figure 1 shows how one of the program variants in our example family, namely κ_0 , will crash at line 2 when we attempt to divide by zero. Because this bug is not manifested in any other variant, it is a variability bug—with presence condition $\neg \text{INCR} \wedge \text{DECR}$.

Program family implementations are usually conceptually stratified in three layers: the *problem space* (typically a feature model), a *solution space* implementation (for instance C code), and the *mapping* between the problem and solution spaces (build system and the preprocessor in Linux). We show how the division-by-zero bug could be fixed (depending on the interpretation) in our running example, in each layer separately.

Fix in code. If function `foo` should accept any `int` value, then the bug is fixed by appropriately handling zero as input.

```

2 printf("%d\n", 2/a); ⇒
2 if (a != 0)
3     printf("%d\n", 2/a);
4 else
5     printf("NaN\n");

```

Fix in mapping. If we assume that function `foo` shall not be called with a zero argument, a possible fix is to decrement x only when both *DECR* and *INCR* are enabled.

```

9 #ifdef CONFIG_DECR ⇒
10 x = x - 1;
11 #endif
9 #ifdef CONFIG_DECR && CONFIG_INCR
10 x = x - 1;
11 #endif

```

Fix in model. If the bug is caused by an illegal interaction, we can introduce a dependency in the feature model to prevent the faulty configuration κ_0 . For instance, let *DECR* be only available when *INCR* is enabled. Assuming feature model $\psi_{\text{FM}} = \text{DECR} \rightarrow \text{INCR}$ forbids κ_0 .

3 Methodology

Objective. Our objective is to qualitatively understand the complexity and nature of *variability bugs* (including *feature-interaction bugs*) occurring in a large highly-configurable system: the Linux kernel. This includes addressing the following research questions:

- RQ1: Are variability bugs limited to any particular type of bugs, “error-prone” features, or specific location?
- RQ2: In what ways does variability affect software bugs?

Subject. We study the Linux kernel, taking the Linux stable GIT¹ repository² as the unit of analysis. Linux is likely the largest highly-configurable open-source system. It has about ten million lines of code and more than ten thousand features. Crucially, data about Linux bugs is available freely. We have free access to the bug tracker³, the source code and change history⁴, and to public discussions on the mailing list⁵ (LKML) and other forums. There also exist books on Linux development [8, 24]—valuable resources when understanding a bug-fix. Access to domain specific knowledge is crucial for the qualitative analysis.

We focus on bugs already corrected in commits to the Linux repository. These bugs have been publicly discussed (usually on LKML) and confirmed as actual bugs by kernel developers, so we minimize the chance of including fictitious problems. The patches have been reviewed and approved, so the information about the nature of the bug fix is reliable.

Methodology. Our methodology has three parts: first, we identify the variability bugs in the kernel history. Second, we analyze and explain them. Finally, we reflect on the aggregated material to answer our research questions.

Part 1: Finding Variability Bugs. We have settled on a semi-automated search through Linux commits to find variability bugs via historic bug fixes. As of April 2014 the Linux repository has over 400,000 commits, which rules out manual investigation of each commit. We have thus *searched* through the commits for variability bugs using the following steps:

1. *Selecting variability-related commits.* We retain commits matching regular expressions of Fig. 2. Expressions in Fig. 2(a) identify commits in which the author’s *message* relates the commit to specific features. Those in Fig. 2(b) identify commits introducing changes to the feature mapping or the feature model. We reject *merges* as such commits do not carry changes.
2. *Selecting bug-fixing commits.* We narrow to commits that fix bugs, matching regular expressions that indicate bugs within the commit message (see Fig. 3).
3. *Manual scrutiny.* We read the commit message and inspect the changes introduced by the commit to remove obvious false positives. We order commits by the number of hits in the first two searches, and down prioritize very complex commits (given the information provided in the commit message and the number of lines modified by the patch).

Part 2: Analysis. The second part of the methodology is significantly more laborious than the first part. For each variability bug identified, we carefully analyze the commit message, the patch fix, and the actual code to build an understanding of the bug. When more context is required, we find and follow the associated LKML discussion. Code inspection is supported by CTAGS⁶ and the Unix GREP utility, since we lack feature-sensitive tool support.

1. *The semantics of the bug.* For each variability bug we want to understand the *cause* of the bug, the *effect* on the program semantics and the relation between the two. This often requires understanding the inner workings of the kernel, and translating this understanding to general programming language terms accessible to a broader audience. As part of this process we try to identify a relevant runtime execution *trace* and collect links to available information about the bug online.
2. *Variability related properties.* We establish what is the presence condition of a bug (precondition in terms of configuration choices) and where it was fixed (in the code, in the feature model or in the mapping).
3. *Simplified version.* Last but not least, we condense our understanding in a *simplified version of the bug*.

We have analyzed 40 Linux bugs following this method and stored the created reports in a publicly available database. The detailed content of the report is explained in Sect. 4.

Part 3: Data Analysis and Verification. We reflect on the collected data set in order to find answers to our research questions. This step is supported with some quantitative data but, importantly, we do not make any quantitative conclusions about the population of the variability bugs in Linux (such conclusions would be unsound given the above research method). It purely characterizes diversity of the data set obtained. This allows to present the entire collection of bugs in an aggregated fashion (see Sect. 5).

Finally, in order to reduce bias we confront our method, findings, and hypotheses in an interview with a full-time professional Linux kernel developer.

4 Dimensions of Analysis

We begin by selecting a number of properties of variability bugs to understand, analyze and document in bug reports. These are described below and exemplified by data from our database. We show an example record in Fig. 4, a null-pointer dereference bug found in a driver, which was traced back to errors both in the feature model and the mapping.

Type of bug (type). In order to understand the diversity of variability bugs we establish the type of bugs according to the *Common Weakness Enumeration (CWE)*⁷—a catalog of numbered software weaknesses and vulnerabilities. We

(b) Simplified version.

Figure 4: Bug 6252547b8a7: a record example and a simplified version.

follow CWE since, it was applied to the Linux kernel before [30]. However, since CWE is mainly concerned with security, we had to extend it with a few additional types of bugs, including type errors, incorrect uses of Linux APIs, etc. The types of bugs in the obtained taxonomy are listed in Tbl. 1; our additions lack an identifier in the rightmost column. The bug types directly indicate what kind of analysis and program verification techniques can be used to address the bugs identified in the kernel. For instance the category of memory errors (Tbl. 1) maps almost directly to various program analyses: for null pointers [16, 10, 19], buffer overruns [34, 15, 7], memory leaks [16, 10], etc.

Bug Description (descr). Understanding a bug requires rephrasing its nature in general software engineering terms, so that the bug becomes understandable for non kernel-experts. We obtain such a description by studying the bug in depth, and following additional available resources (such as mailing list discussions, available books, commit messages, documentation and online articles). Whenever use of the Linux terminology is unavoidable, we provide links to the necessary background. Obtaining the description is often non-trivial. For example, one bug in our database (commit eb91f1d0a53) was fixed with the following commit message:

```

Fixes the following warning during bootup when compiling with CONFIG_SLAB:

[ 0.000000] -----[ cut here ]-----
[ 0.000000] WARNING: at kernel/lockdep.c:2282 lockdep_trace_alloc+0x91/0xb9()
[ 0.000000] Hardware name: [ 0.000000] Modules linked in:
[ 0.000000] Pid: 0, comm: swapper Not tainted 2.6.30 #491
[ 0.000000] Call Trace:
[ 0.000000] [<ffffffffff81087d84>] ? lockdep_trace_alloc+0x91/0xb9
...

```

It is summarized in our database as:

Warning due to a call to kmalloc () with flags __GFP_WAIT and interrupts enabled

The *SLAB* allocator is initialized by `start_kernel ()` with interrupts disabled. Later in this process, `setup_cpu_cache ()` performs the per-CPU *kmalloccache* initialization, and will try to allocate memory for these caches passing the `GFP_KERNEL` flags. These flags include `__GFP_WAIT`, which allows the process to sleep while waiting for memory to be available. Since, as we said, interrupts are disabled during *SLAB* initialization, this may lead to a deadlock. If *LOCKDEP* and other tracing/debugging options are enabled, the situation is detected and reported as a warning.

We add a one line header to the description, here shown in bold, to help browsing of bugs in the constructed database.

Figure 5: Fix for simplified bug 6252547b8a7. The patch is given in unified diff format, where a '+' prefix indicates additions and a '-' prefix indicates removals.

Program configurations (config). In order to confirm that a bug is indeed a variability bug we investigate under what presence condition it appears. This allows to rule out bugs that appear unconditionally and enables further investigation of variability properties of the bug, for example the number of features and nature of dependencies that enable the bug.

Our example bug (Fig. 1) is present when *DECR* is enabled but *INCR* is disabled. The Linux bug captured in Fig. 4 requires enabling *TWL4030_CORE*, and disabling *OF_IRQ*, in order to exhibit the erroneous behaviour (see *config* entry in the left part).

Bug fix location (fixed). We analyze the fixing commit to establish whether the source of the bug is in the code, in the feature model, or in the mapping. Understanding this can help direct future research on building diagnostics tools: are tools needed for analyzing models, mappings, or code? Where is it best to report an error?

The bug of Fig. 4 has been fixed both in the model and in the mapping (cf. Fig. 5). The fixing commit asserts that: first, *TWL4030_CORE* should not depend on *IRQ_DOMAIN* (fixed in the model), and, second, that the assignment of the variable *ops* to *&irq_domain_simple_ops* is part of the *IRQ_DOMAIN* code and not of *OF_IRQ* (fixed in the mapping).

Error trace (trace). We manually analyze the execution trace that leads to the error state. Slicing tools cannot easily be used for these purpose, as none of them is able to handle static preprocessor directives appropriately. Constructing a trace allows us to understand the nature and complexity of the bug. A documented failing trace allows other researchers to understand a bug much faster.

There are two types of entries in our traces: function calls and statements. Function call entries can be either static (tagged *call*), or dynamic (*dyn-call*) if the function is called via a function pointer. A statement entry highlights relevant changes in the program state. Every entry starts with a non-empty sequence of dots indicating the nesting of function calls, followed by the location of the function definition (file and line) or statement (only the line). The statement in which the error is manifested is marked with an *ERROR* label.

In Fig. 4(a) the trace starts in the driver loading function (*twl_probe*). This is called from *i2c_device_probe* at *drivers/i2c/i2c-core.c*, the generic loading function for *I2C*⁸ drivers, through a function pointer (*driver->probe*). A call to *irq_domain_add* passes the globally-declared struct *domain* by reference, and the *ops* field of this struct, now aliased as **d*, is dereferenced (*d->ops->to_irq*).

The *ops* field of *domain* is not explicitly initialized, so it has been set to null by default (as dictated by the C standard). Thus the above error trace unambiguously identifies a path from the loading of the driver to a null-pointer dereference, when *OF_IRQ* is disabled. Had *OF_IRQ* been enabled, the *ops* field would have been properly initialized prior to the call to *irq_domain_add*.

Simplified Bug. Last but not least, we synthesize a simplified version of the bug capturing its most essential properties. We write a small C99 program, independent of the kernel code, that exhibits the same essential behavior (and the same

⁸A serial bus protocol used in micro controller applications.

problem). The obtained simplified bugs are easily accessible for researchers willing to try program verification and analysis tools without integrating with the Linux build infrastructure, huge header files and dependent libraries, and, most importantly, without understanding the inner workings of the kernel. Furthermore, the entire set of simplified bugs constitute an easily accessible benchmark suite derived from real bugs occurring in a large-scale software system, which can be used to evaluate bug finding tools in a smaller scale.

Simplified bugs are derived systematically from the error trace. Along this trace, we preserve relevant statements and control-flow constructs, mapping information and function calls. We keep the original identifiers for features, functions and variables. However, we abstract away dynamic dispatching via function pointers, struct types, *void* pointers, casts, and any Linux-specific type, when this is not relevant for the bug. When there exist dependencies between features, we force valid configurations with `#define`. This encoding of feature dependencies has the advantage of making the simplified bug files self-contained.

Figure 4(b) shows the simplified version of our running example bug with null pointer dereference. Lines 2–4 encode a dependency of `TWL4030_CORE` on `IRQ_DOMAIN`, in order to prevent the invalid configuration `TWL4030_CORE ∧ ¬IRQ_DOMAIN`. We encourage the reader to study the execution trace leading to a crash by starting from `main` at line 20. This takes a mere few minutes, as opposed to many hours necessary to obtain an understanding of a Linux kernel bug normally. Note that the trace is to be interpreted under the presence condition from the bug record (decisions are specified in comments next to the `if` conditionals).

Traceability information. We store the URL of the repository, in which the bug fix is applied, the commit hash, and links to relevant context information about the bug, in order to support independent verification of our analysis.

5 Data Analysis

In order to address the research questions, we have reflected on the entire body of information gathered, arriving at detailed observations presented below. In the following, we sometimes aggregate data with numbers. The numbers are used solely for descriptive purposes—no statistical conclusions should be drawn from them (we emphasize this using a gray font).

We start by presenting the observations that support our first research question, RQ1:

OBSERVATION 1: *Variability bugs are not limited to any particular type of bugs.*

Table 1 lists the type of bugs we found, along with occurrence frequencies in the collection. For example, 15 bugs have been classified under the category of *memory errors*, four of which are null pointer dereferences. We note that variability bugs cover a wide range of qualitatively different types of bugs from type errors, through data-flow errors such as uninitialized variables, to locking policy violations (double locks).

We found 15 bugs, type errors and compiler warnings, caught by the compiler at build time. Despite the compiler checks, the bugs had been admitted to the repository in the first place. Since compiler errors cannot easily be ignored, we take this as evidence that the author of the commit (and the maintainer who accepted it) could not find the bug, because they compiled the code in configurations that do not exhibit it (compiler checks are not family-based).

OBSERVATION 2: *Variability bugs appear to not be restricted to specific “error prone” features.*

Table 2 shows the complete list of features involved in the bugs: a total of 74 qualitatively different features, ranging from *debugging* options (e.g., `QUOTA_DEBUG` and `LOCKDEP`), to *device drivers* (e.g., `TWL4030_CORE` and `ANDROID`), to *network protocols* (e.g., `VLAN_8021Q` and `IPV6`), to *computer architectures* (e.g., `PARISC` and `64BIT`). Three features are involved in three of the bugs, 10 features occur in two bugs, and the remaining 61 are involved in only a single bug.

OBSERVATION 3: *Variability bugs are not confined to any specific location (file or kernel subsystem).*

Figure 6 shows in which subsystems the bugs are located and the relative size of each subsystem as of March 2014—we approximate subsystems by directories. The size of each subsystem is measured in lines of code (LOC), we take the sum of LOC (for any language) as reported by CLOC⁹ (version 1.53). E.g., with six squares, the `kernel/` subsystem has approximately 150 KLOC and represents about 1% of the Linux code. Superimposed onto the size visualization,

⁹<http://cloc.sourceforge.net/>

the figure also shows in which directories the bugs occur. With five red (dark) squares, the directory `kernel/` thus houses five of the bugs of our collection.

We found bugs in ten of the main Linux subsystems, showing that variability bugs are not confined to any specific subsystem. These are qualitatively different subsystems of Linux ranging from *networking* (`net/`), to *device drivers* (`drivers/`, `block/`), to *filesystems* (`fs/`) or *encryption* (`crypto/`). Note that Linux subsystems are often maintained and developed by different people, which adds to diversity of our collection.

We found no bug in ten directories, representing less than the 3% of the Linux kernel code in total. Further, three of them (`tools/`, `scripts/`, and `samples/`) contain example and support code (build infrastructure, diagnostic tools, etc.) that does not run on a compiled kernel.

We are now ready to answer RQ1:

CONCLUSION 1: *Variability bugs are indeed not confined to any particular type of bug, error-prone feature, or location in the Linux kernel.*

We have found variability bugs falling in 19 different types of semantic errors, involving 74 qualitatively different features, and located in 10 major subsystems of the Linux kernel.

We now turn to evidence regarding research question RQ2:

OBSERVATION 4: *We have identified 29 bugs that involve non-locally defined features; i.e., features that are “remotely” defined in another subsystem than where the bug occurred.*

Understanding such bugs involves functionality and features from different subsystems, while most Linux developers are dedicated to a single subsystem. For example, bug 6252547b8a7 (Fig. 4) occurs in the `drivers/` subsystem, but one of the interacting features, `IRQ_DOMAIN`, is defined in `kernel/`. Bug 0dc77b6dabe, which occurs in the loading function of the `extcon-class` module (`drivers/`), is caused by an improper use of the `sysfs` virtual filesystem

Table 1: Types of bugs among the 40 bugs. The first column gives the frequency of these bugs in our collection.

15	memory errors:	CWE ID
4	null pointer dereference	476
3	buffer overflow	120
3	read out of bounds	125
2	insufficient memory	-
1	memory leak	401
1	use after free	416
1	write on read only	-
8	compiler warnings:	CWE ID
5	uninitialized variable	457
1	unused function (dead code)	561
1	unused variable	563
1	void pointer dereference	-
7	type errors:	CWE ID
5	undefined symbol	-
1	undeclared identifier	-
1	wrong number of args to function	-
7	assertion violations:	CWE ID
5	fatal assertion violation	617
2	non-fatal assertion violation	617
2	API violations:	CWE ID
1	Linux <code>sysfs</code> API violation	-
1	double lock	764
1	arithmetic errors:	CWE ID
1	numeric truncation	197

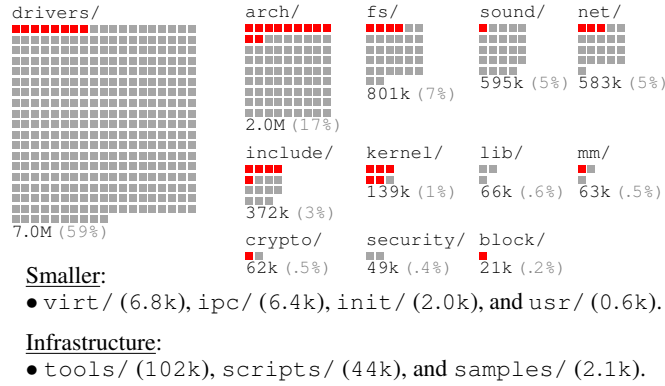

Figure 6: Location of the 40 bugs in the main Linux directories as of March 2014. Each square represents 25 thousand lines of code. The precise number of LOC and its percentage of the total is given below the squares. A red (dark) square symbolizes the occurrence of one of the bugs.

Figure 7: In which layer(s) are the bugs fixed.

API—feature *SYFS* in *fs/*. We confirmed with a Linux developer that cross-cutting features constitute a frequent source of bugs.

OBSERVATION 5: *Variability can be implicit and even hidden in (alternative) configuration-dependent macro, function, or type definitions specified in (potentially different) header files.*

Hidden variability significantly complicates the identification of variability-related problems. For example, in bug 0988c4c7fb5, function `vlan_hwaccel_do_receive` is called if a VLAN-tagged network packet is received. This function, however, has two different definitions depending on whether feature `VLAN_8021Q` is present or not. Variants without `VLAN_8021Q` support are compiled with a mockup-implementation of this function that unconditionally enters an error state. Another example is bug 0f8f8094d28 which can be regarded as a trivial out of bounds access to an array, except that the length of the array (`KMALLOC_SHIFT_HIGH+1`) is architecture-dependent, and only the PowerPC architectures, for a given virtual page size, are affected. Both `vlan_hwaccel_do_receive` and `KMALLOC_SHIFT_HIGH` have alternative definitions at different locations.

OBSERVATION 6: *Variability bugs are fixed not only in the code; some are fixed in the mapping, some are fixed in the model, and some are fixed in a combination of these.*

Table 2: Features involved in the bugs.

64BIT	CRYPTO_TEST	JFFS2_FS_WBUF_VERIFY	PPC64	SHMEM	TREE_RCU

Figure 8: Numbers of features involved in a bug (*feature-interaction degree*).

Figure 7 shows whether the bugs in our sample were fixed in the *code*, *mapping*, or *model*. Even though we only documented bugs that manifested in code, 13 bugs in our sample were fixed in the mapping, in the model, or in two layers.

Examples of simple fixes in the mapping and in the model are commits 472a474c663 and 7c6048b7c83, respectively. The former adds a new `#ifndef` to prevent a double call to `APIC_init_uniprocessor`—which is not idempotent, while the latter modifies `STUB_POULSBO`’s `KCONFIG` entry to prevent a build error.

Bug-fix 6252547b8a7 (Fig. 5) removes a feature dependency (`TWL4030_CORE` no longer depends on `IRQ_DOMAIN`) and changes the mapping to initialize the struct field `ops` when `IRQ_DOMAIN` (rather than `OF_IRQ`) is enabled. An example of multiple fix in mapping and code is commit 63878acfab, which removes the mapping of some initialization code to feature `PM` (power management), and adds a function stub.

This stratification into code, mapping and model may obscure the cause of bugs, because an adequate analysis of a bug requires understanding these three layers. Further, each layer involves different languages; in particular, for Linux: the code is C, the mapping is expressed using both CPP and GNU MAKE, and the feature model is specified using KCONFIG.

Presumably, this complexity may cause a developer to fix a bug in the wrong place. For instance, the dependency of `TWL4030_CORE` on `IRQ_DOMAIN` removed by our bug-fix 6252547b8a7 was added by commit aeb5032b3f8. Apparently aeb5032b3f8 introduced this dependency into the feature model to prevent a build error, so to fix a bug, but this had undesirable side-effects. According to the message provided in commit 6252547b8a7, the correct fix to the build error was to make a variable declaration conditional on the presence of feature `IRQ_DOMAIN`.

OBSERVATION 7: *We have identified as many as 28 feature-interaction bugs in the Linux kernel.*

We define the *feature-interaction degree* of a bug, or just *degree* of a bug, as the number of individual features occurring in its presence condition. Intuitively, the degree of a bug indicates the number of features that have to interact so that the bug occurs. A bug present in any valid configuration is a bug independent of features, or a 0-degree bug. Bugs with a degree greater than zero are variability bugs, thus occurring in a nonempty strict subset of valid configurations. Particularly, if the degree of a bug is greater than one, the bug is caused by the interaction of two or more features. A software bug that arises as a result of feature interactions is referred to as a *feature-interaction bug*.

Feature-interaction bugs are inherently more complex because the number of variants to be considered is exponential in the degree of the bug. Bug 6252547b8a7 (cf. Fig. 4(b)) is the result of a two-feature interaction. The code slice containing the bug involves three different features, and represents four variants (corrected for the feature model), but only one of the variants presents a bug. The `ops` pointer is dereferenced in variants with `TWL4030_CORE` enabled, but it is not properly initialized unless `OF_IRQ` is enabled. A developer searching for this bug needs to either think of each variant individually, or consider the combined effect of each feature on the value of the `ops` pointer. None of these are easy to execute systematically even in a simplified scenario, and outright infeasible in practice, as confirmed by a professional Linux developer.

Feature interactions can be extremely subtle when variability affects type definitions. Commit 51fd36f3fad fixes a bug in the Linux high-resolution timers mechanism due to a numeric truncation error, that only happens in 32-bit architectures not supporting the `KTIME_SCALAR` feature. In these particular configurations `ktime_t` is a struct with two 32-bit fields, instead of a single 64-bit field, used to store the remaining number of nanoseconds to execute the timer. The bug occurs on attempt to store some large 64-bit value in one of these 32-bit fields, causing a negative value to be stored instead. Interestingly, one of the Linux developers we interviewed also mentioned the difficulty to optimize

for cache-misses due to variability in the alignment of struct fields.

OBSERVATION 8: *We have identified 12 bugs involving three or more features.*

An example of a 3-degree bug is ae249b5fa27, caused by the interaction of *DISCONTIGMEM* (efficient handling of discontinuous physical memory) support in PA-RISC architectures (feature *PARISC*), and the ability to monitor memory utilization through the `proc/` virtual filesystem (feature *PROC_PAGE_MONITOR*). We also found 5-degree bugs such as commit 221ac329e93, caused by 32-bit PowerPC architectures not disabling kernel memory write-protection when *KPROBES* is enabled—a dynamic debugging feature that requires modifying the kernel code at runtime.

Figure 8 summarizes the degree of our bugs. To the best of our knowledge, this is the first documented collection of feature-interaction bugs in the operating systems domain. So far, most feature-interaction bugs have been identified, documented, and published in telecommunication domain [11].

OBSERVATION 9: *Presence conditions for variability bugs also involve disabled features.*

Table 3 lists and groups the structure of the presence conditions for our sample. We observe two main classes of bug presence conditions: *some-enabled*, where one or more features have to be enabled for the bug to occur; and *some-enabled-one-disabled*, where the bug is present when enabling zero or more features and disabling *exactly one* feature. We identified 19 bugs in *some-enabled* configurations, and another 19 bugs in *some-enabled-one-disabled*. (Note that one of the presence conditions has the form, $(a \vee a') \wedge \neg b$, but, since it is implied by either $a \wedge \neg b$ or $a' \wedge \neg b$, we include it in the *some-enabled-one-disabled* class.)

Testing of highly configurable systems is often approached by testing one or more maximal configurations, in which as many features as possible are enabled—in Linux this is done using the predefined configuration *allyesconfig*. This strategy allows to find many bugs with *some-enabled* presence conditions simply by testing one single maximal configuration. But, if negated features occur in practice as often as in our sample, then testing maximal configurations only, will miss a significant amount of bugs.

In our experience, the implementation of features in Linux is crosscutting many code locations, and features code is intermixed. As a result, disabling a feature can both add or delete code from another feature, and we expect negated features to be often part of bugs presence conditions. Bug 6252547b8a7 (Fig. 4) is such an example. Disabling *OF_IRQ* causes the null pointer dereference because this feature is responsible for initializing the `ops` struct field. Another example is bug 60e233a5660, where the implementation of a function `add_uevent_var`, when feature *HOTPLUG* is disabled, fails to preserve an invariant causing a buffer overflow.

OBSERVATION 10: *Effective testing strategies exist for the observed bug presence conditions.*

Given the observed patterns (*some-enabled* and *some-enabled-one-disabled*) in Tbl. 3, we can think of a better testing strategy than maximal configuration testing. We propose a *one-disabled configuration testing* strategy, where we test

Table 3: The structure of the presence conditions (i.e., in which configurations the 40 bugs occur).

19	<i>some-enabled:</i>	
6	a	
7	$a \wedge b$	
5	$a \wedge b \wedge c$	
0	$a \wedge b \wedge c \wedge d$	
1	$a \wedge b \wedge c \wedge d \wedge e$	
19	<i>some-enabled-one-disabled:</i>	
4	$\neg a$	
11	$a \wedge \neg b$	<i>one of which is: $(a \vee a') \wedge \neg b$</i>
3	$a \wedge b \wedge \neg c$	
0	$a \wedge b \wedge c \wedge \neg d$	
1	$a \wedge b \wedge c \wedge d \wedge \neg e$	
2	<i>other configurations:</i>	
1	$\neg a \wedge \neg b$	
1	$a \wedge \neg b \wedge \neg c \wedge \neg d \wedge \neg e$	

configurations in which exactly one feature is disabled, corresponding to the formulas $\forall g \in \mathbb{F}: (\bigwedge_{f \in \mathbb{F} \setminus \{g\}} f) \wedge \neg g$. Table 4 compares the two strategies, maximal configuration testing and *one-disabled* configuration testing. We also add an entry for exhaustive testing of all configurations, serving as a baseline (the cost is exponential there).

Maximal configuration testing has constant cost—ideally only one configuration has to be tested, and thus scales to program families with an arbitrarily large number of features (\mathbb{F}). It appears to be a fairly good heuristic: 48% of bugs in our sample, 19 out of 40, could be found this way. One-disabled configuration testing has a linear cost on $|\mathbb{F}|$, thus it is reasonably scalable, even for program families with thousands of features like Linux. Remarkably, the 95% of our bugs, 38 out of 40, could be found by testing the $|\mathbb{F}|$ one-disabled configurations. Note that these configurations also find the bugs with a *some-enabled* presence condition (except for hypothetical cases requiring *all* features enabled).

In practice, we must consider the effect of the feature model in the testing strategy. Due to mutually exclusive dependencies between features there is often no maximal configuration, but many locally maximal configurations. Also, because some features depend on others to be present, we often cannot disable features individually. The practical consideration of having a feature model is that enumerating the configurations to test requires selecting *valid* configurations only, which is a NP-complete problem itself. Yet, we expect that enumerating valid one-disabled configurations would be tractable, given the scalability of modern SAT solvers (hundreds of thousands of variables and clauses) and the size of real-world program families (only thousands of features).

Our overall conclusion regarding RQ2 is:

CONCLUSION 2: *Variability significantly increases the complexity of bugs.*

Our analysis indicates that variability affects the complexity of bugs along several dimensions. Let us summarize them:

- A number of n features gives rise to up to 2^n variants that the developer needs to consider;
- The implementation of features is intermixed and undesired interactions can easily occur, for instance, through program variables;
- Interactions can occur between features from different subsystems, demanding cross-subsystem knowledge from Linux developers;
- Variability can be implicit and even hidden in alternative macro, function, and type definitions specified at different locations;
- Variability bugs may be the result of errors in the code, in the mapping, in the feature model, or any combination thereof;
- Further, each of these layers involves different languages (C, CPP, GNU MAKE and KCONFIG);
- Not all these bugs will be detected by maximal configuration testing due to interactions with *disabled* features;
- The existence of compiler errors in the Linux tree shows that conventional feature-insensitive tools are not enough to find variability bugs.

6 Threats to Validity

6.1 Internal Validity

Bias due to selection process. As we extract bugs from commits, our collection is biased towards bugs that were found, reported, and fixed. Since users run a small subset of possible Linux configurations and developers lack feature-sensitive

Table 4: Maximal vs *one-disabled* configuration testing. The cost is the number of configurations satisfying the formula, disregarding the feature model. Benefit shown as bug coverage for our sample.

test formula(s)	cost	benefit
$\bigwedge_{f \in \mathbb{F}} f$	$O(1)$	48% (19/40)
$\forall g \in \mathbb{F}: (\bigwedge_{f \in \mathbb{F} \setminus \{g\}} f) \wedge \neg g$	$O(\mathbb{F})$	95% (38/40)
ψ	$O(2^{ \mathbb{F} })$	100% (40/40)

tools, potentially only a subset of bugs is found.

Further, our keyword-based search relies on the competence of Linux developers to properly identify and report variability in bugs. Note, however, that in Linux, variability is ubiquitous and often “hidden”. For instance, the *ath3k* bluetooth driver module file contains no explicit variability, yet after variability-preserving preprocessing and macro expansion we can count thousands of CPP conditionals involving roughly 400 features. It is then unlikely that developers are always aware of the variability nature of the bugs they fix.

In order to further minimize the risk of introducing false positives, we do not record bugs if we fail to extract a sensible error trace, or if we cannot make sense of the pointers given by the commit author. This may introduce bias towards reproducible and lower complexity bugs.

Because of inherent bias of a detailed qualitative analysis method, we are not able to make quantitative observations about bug frequencies and properties of the entire population of bugs in the Linux kernel. Note, however, that we are able to make qualitative observations such as the existential confirmation of certain kinds of bugs (cf. Sect. 5). Since we only make such observations, we do not need to mitigate this threat (interestingly though, our collection still exhibits very wide diversity as shown in Sect. 5).

False positives and overall correctness. By only considering variability bugs that have been identified and fixed by Linux developers, we mitigate the risk of introducing false positives. We only take bug-fixing commits from the Linux stable branch, the commits of which have been reviewed by other developers and, particularly, by a more experienced Linux maintainer. The risk is not zero though, for instance, commit `b1cc4c55c69` adds a nullity check for a pointer that is guaranteed not to be null¹⁰. It is tempting to think that the above indicates a variability bug, while in fact it is just a conservative check to detect a *potential* bug.

The manual analysis of a bug to extract an error trace is also error prone, especially for a language like C and a complex large system such as Linux. Ideally, we should support our manual analysis with feature-sensitive program slicing, if it existed. A more automated approach based on bug-finders would not be satisfactory. Bug-finders are built for certain classes of errors, so they can give good statistical coverage for their particular class of errors, but they would not be able to assess the diversity of bugs that appear.

We derive simplified bugs based on manual slicing, filtering out irrelevant statements. We also abstract away C language features such as structs and dynamic dispatching via function pointers. While the process is systematic, it is performed manually and consequently error prone.

6.2 External Validity

Small number of bugs. The size of our sample speaks against the generalizability of the observations. The process of collecting and especially analyzing these 40 bugs costed several man-months, being unfeasible the study of a larger number of bugs. We expect that our database will continue to grow, also from third-party contributions, in the near future.

Single-subject study. We decided to focus exclusively on Linux, so our findings do not readily generalize to other highly configurable software. Yet, the size and nature of Linux make it a fair worst-case representative of software with variability. The type of bugs we found, especially memory errors, are the expected in any piece of configurable C software. Also the significance of the Linux kernel project itself, justifies investigation of its errors, even if it limits generalizability.

7 Related Work

Bug databases. ClabureDB is a database of bug-reports for the Linux kernel that serves a similar purpose as ours [30]. ClabureDB ignores variability, whereas we classify bugs according to their variability characteristics. The second major difference is in the level of detail used to describe each bug. We provide, not only an error classification, but a record with information enabling non Linux experts to rapidly understand the bugs and benchmark their analyses. A

¹⁰<https://lkml.org/lkml/2010/10/15/30>

key ingredient for this is a simplified C99 version of each bug where irrelevant details are abstracted away, along with explanations and references intended for researchers with limited experience with the Linux kernel. The main strength of ClabureDB is its size, enabled by the use of bug finders for populating the database. In contrast, we analyzed bugs manually based on developer-confirmed bugs from bug-fixing commits and hence free from false-positives. There exist no bug finder that can be used to uncover bugs induced by feature interactions in a system like the Linux kernel, so none of our bugs is covered in ClabureDB adequately.

Mining variability bugs. Nadi et al. mined commits from the Linux GIT repository to understand the nature of *variability anomalies* in the Linux kernel [27]. An *anomaly* refers to errors in the *mapping*, which can be automatically detected by checking the satisfiability of propositional constraints over features, such as incorrect mapping of code to an invalid feature combination, or code mapped to nonexistent features. While we conduct our study in a similar way, we focus on a much broader class of semantic errors in code, including data- and control-flow bugs.

Apel and coauthors used a model-checker to automatically find feature interactions in a simple email client [3]. They rely on a technique known as *variability encoding (configuration lifting)* [29]), in which features are encoded as Boolean variables and conditional compilation directives are transformed into regular conditional statements. The resulting variability-encoded “*meta-program*” is then fed to a model-checker. Our focus, however, is not on identifying feature interactions in the Linux kernel, but on understanding nature of variability bugs widely. This cannot be done with a model-checker searching for a particular class of interactions. In fact, understanding variability bugs should lead us to building bug finders that would scale to the kernel, enabling studies like [3] to be run for Linux in the future.

Medeiros et al. have studied *syntactic* variability errors [25]. They investigated releases in 41 families, and thousands of individual commits in 8 families, all much smaller than Linux. Since they focus exclusively on syntax errors, they are able to use a variability-aware C parser [23] to automate their bug finding and exhaustively find *all* syntax errors. Despite the size of their sample, they found only few tens of errors, suggesting that syntactic variability errors are rare in committed code. We focus on the wider category of much more complex *semantic* errors.

Nadi et al. present a method to mine feature dependencies in preprocessor-based program families. Their aim is to semi-automate the process of documenting the feature model for an existing codebase [26]. They infer dependencies using heuristics based on the nesting of CPP conditionals and three kinds of variability errors (parse-, type-, and link-errors), relying on the assumption that a configuration that does not build correctly is not a valid configuration. Again, our study considers a much wider class of errors than cannot be detected automatically at the moment.

Methodologically related work. Tian et al. studied the problem of distinguishing bug fixing commits in the Linux kernel source code repository [33]. They propose to use semi-supervised machine learning to classify commits according to tokens in the commit log along with code metrics extracted from the patch contents. Compared to previous keyword-based methods, they significantly improve recall (while precision remains the same). However, when building a benchmark suite, the main concern is to eliminate false positives to reduce human workload. We found our regular expression-based search method precise enough for our purpose. Indeed, most of time was invested in analyzing specific commits, not in finding potential candidates.

Yin et al. built a collection of hundreds of errors caused by misconfigurations in open source and commercial software [35]. Their goal is to offer a set of representative errors in large-scale software systems. They consider systems in which program parameters are read from configuration files, as opposed to systems configured with features. More importantly, they document errors from the *user* perspective, as opposed to our *programmer* perspective.

Padioleau et al. studied collateral evolution of the Linux kernel, following a method which is close to ours [28]. (Collateral evolution is when existing code is adapted to changes in the kernel interfaces.) They followed a similar process, but had a different objective. They identified potential collateral evolution candidates by analyzing patch fixes, and then manually selected 72 for a more careful analysis. Also, like us, they classify and perform an in-depth analysis of their data.

8 Conclusion

We have found 40 variability bugs, 28 of which are feature-interaction bugs, by mining bug-fixing commits from the Linux repository. We analyzed their cause-effect relation and variability properties, and documented the outcome into a collection of bug records. Additionally, we have condensed each of these bugs into a self-contained simplified C99

version of the bug, that keeps intact its variability properties. Simplified bugs help understanding the real bug, but also constitute a benchmark suite, systematically derived from real bugs in Linux, that can be used for preliminary tool evaluation.

We conclude, first, that variability bugs are not confined to any particular type of bug, error-prone feature, or source code location (file, or subsystem) of the Linux kernel. Second, that variability increases the complexity of bugs in Linux in several ways, remarkably: *a*) Variability adds an exponential number of variants to be considered; *b*) Variability can be hidden and thus difficult to identify by developers; *c*) The implementation of features is intermixed and undesired interactions can occur easily; *d*) These interactions can happen between features from different subsystems; *e*) Bugs can be traced back to the code, the mapping, the feature model, or any combination thereof. Commits with compile-time errors pushed to the Linux tree repository constitute evidence for this conclusion. We also get this confirmation from a professional Linux developer.

Acknowledgments. We thank kernel developers, Jesper Brouer and Matias Bjørling, for their invaluable input; Julia Lawall provided comments and suggestions, Norbert Siegmund and other colleagues have pointed us to related work. This work was supported by The Danish Council for Independent Research under a Sapere Aude project, VARIETE.
