The photoelectron photoemission spectra and thresholds for low coverages of Li and K adsorbed on water-ice have been measured, compared with photoionization spectra of the gas-phase atoms, and modeled by quantum chemical calculations. For both alkali metals the threshold for photoemission is dramatically decreased and the cross section increased on adsorption to the water-ice surface. Quantum chemical calculations suggest that the initial state is formed by the metal atoms adsorbed into the water-ice surface, forming a state with a delocalized electron distribution. This state is metastable and decays on the hundreds of seconds time scale at 92 K. The decay is markedly faster for Li than for K, probably due to diffusion into the ice film. © *2009 American Institute of Physics.*

I. INTRODUCTION

Photon and electron driven chemistry in water-ice or at the water-ice interface is believed to be significant in the chemistry and physics of both terrestrial and planetary atmospheres. Examples include formation of molecular oxygen and other products during high energy ($>$10 eV) photolysis,[1] hydrogen ion desorption and oxygen generation under electron bombardment,[2] electron and photon-induced chemistry of adsorbates on water-ice,[3,4] and the charging of nanosized ice particles in the mesosphere, leading to reduced mobility of the plasma around the particles and hence to the strong radar backscatter known as polar mesospheric summer echoes.[5,6]

The structure, dynamics, and chemistry of electrons solvated in or at the surface of water-ice have attracted particular attention. The ultrafast dynamics of electrons photoinjected into thin water-ice films on metal substrates were studied in detail by Bovensiepen and co-workers.[7–9] They found that electron transfer from the optically excited substrate into the ice conduction band was followed by solvation leading to electron localization on an ultrafast time scale. The solvated electrons were reported to have picosecond lifetimes, mainly limited by tunneling back to the metal substrate. Significantly, the electron lifetime was found to be morphology dependent, with evidence that the electron was localized at the ice-vacuum interface for water-ice clusters on metal substrates.[9] Sanche and co-workers studied the effect of electron attachment to water-ice films following low-energy electron bombardment.[3,10,11] They found that the solvated electrons formed following attachment from the gas phase have relatively long lifetimes, and support a variety of chemical reactions, including dissociative electron attachment to halocarbons. These authors proposed that such electron induced chemistry could be important in the reactions underlying ozone depletion in the stratosphere above the Arctic and Antarctic.[11]

Previously we investigated photoemission from ice films which had been doped with low coverages ($<$0.02 ML) of sodium atoms.[12,13] The motivation for those studies was also the understanding of atmospheric phenomena, specifically the reported coexistence of the positively charged particles with an excess electron population in polar mesospheric clouds.[6,14] It was found that photoemission from the Na doped water-ice surface had a surprisingly large cross section ($>$10^{-18} cm^2 per Na atom) in the visible region of the spectrum with a threshold near 2.3 eV.[12,13] This is considerably below the 8.7 eV threshold for the ionization of undoped water-ice.[15] These photoemission studies were complemented both by measurements of the transmission spectrum and by density functional theory (DFT) calculations of the Na doped water-ice surface. The initial state for photoemission was found to be a metastable surface trapped electron associated with Na atoms accommodated in the first layer of the ice surface.[12,13] Gunster *et al.*[16] also studied Na adsorbed on water-ice using metastable electron impact spectroscopy. They observed that at 100 K a reorganization of the ice was required for solvation of the 3*s* Na atom, and that this process was temperature dependent.

In this paper, we extend both photoemission measurements and DFT calculations to the cases of lithium and potassium doped water-ice surfaces. Both alkali metals make interesting contrasts with Na. In the case of Li, although the ionization potential of the atom is higher than for Na [5.39 eV compared with 5.13 eV (Ref. 17)], the atomic radius is smaller [2.05 Å compared with 2.23 Å (Ref. 17)] so that Li can potentially penetrate more readily into the ice surface where increased interaction with the lone pairs on the oxygen atoms of the water molecules should support delocalization of the outer *s* electron. In contrast, the K atom is significantly

FIG. 1. Dependence of the work function of the Cu(111) surface on the K coverage. The filled points are from TPPE and the open circles are the measurement of Dudde *et al.* (Ref. 28) where coverage was established by low-energy electron diffraction and Auger electron spectroscopy.

86 larger than Na [2.77 Å compared with 2.23 Å (Ref. 17)],
87 which may offset its much lower ionization potential [4.34
88 eV compared with 5.13 eV (Ref. 17)].

II. EXPERIMENTAL

A. Sample preparation

91 The method of preparation of AM doped water-ice sur-
92 faces was essentially as described previously,[13] so only the
93 key points will be repeated here. The ultrahigh vacuum
94 chamber consisted of an upper preparation and characteriza-
95 tion level and a lower level housing an electron time-of-flight
96 (eTOF) analyzer. The substrate for all experiments was a
97 Cu(111) single crystal in thermal contact with a liquid nitro-
98 gen reservoir. The base temperature was 92 K and the sub-
99 strate temperature was controlled by resistive heating. The
100 substrate was dosed with either the AM (for calibration mea-
101 surements, see below) or water. The AMs were deposited
102 from shrouded dispensers (SEAE Getters) and water from a
103 collimated effusive source. The rate of water deposition was
104 calibrated from measurements of the temperature programed
105 desorption (detected by a quadrupole mass spectrometer) as a
106 function of dosing time. In the experiments described in Sec.
107 III, a 3000 L (1 L=10^{-6} Torr s) thick film of ice was first
108 deposited onto the Cu(111) substrate, prior to adsorption of
109 the AMs. Such a thick ice film ensured that the electrons
110 detected arise only from the ice-vacuum interface and not
111 from the metal-ice interface.

112 Deposition of water onto Cu(111) at 92 K yields a po-
113 rous amorphous ice film.[18] These films were annealed to a
114 temperature of 160 K prior to deposition of the AM. This
115 was done for two reasons. First, the motivation for these
116 experiments is the investigation of photoinduced charging
117 phenomena in ice particles in the upper atmosphere. Anneal-
118 ing to 160 K, which converts the amorphous film to a cubic
119 ice phase,[18] yields a surface more relevant to ice particles in
120 the mesosphere.[19] Second, the amorphous ice film apparently
121 becomes charged, which strongly perturbs the eTOF
122 measurements.[13] The charging effect is absent in the crystal-

FIG. 2. The dependence of TPPE spectra of K/Cu(111) on the coverage at a photon energy of 3.8 eV. Data are plotted as photoemission intensity as a function of the final state energy.

123 line film, suggesting that the amorphous phase is less con-
124 ducting and/or has more electron binding sites than the crys-
125 talline film.[13] After annealing, the sample was returned to 92
126 K and the calibrated amount of the AM was deposited.

B. Calibration

128 The eTOF spectrometer was calibrated from the TOF
129 spectrum measured following the two-photon excitation of
130 the clean well-ordered Cu(111) substrate, assuming the well-
131 characterized surface state to be located 0.4 eV below the
132 Fermi level (E_F),[20] a work function of 4.95 eV,[21] and utiliz-
133 ing the known energy of the incident photons. Radiation was
134 from a 10 Hz, 5 ns pulse width dye laser pumped by the third
135 harmonic of a neodymium-doped yttrium aluminum garnet
136 laser. The laser was *p* polarized and incident on the surface at
137 45° to the surface normal for all measurements.

138 The coverage of AM was determined as follows. From
139 the calibrated eTOF spectrum, it is straightforward to deter-
140 mine the work function as a function of exposure time to a
141 fixed flux of AM. By comparing these data with literature
142 measurements of the work function as a function of AM
143 coverage, the exposure time required for a specific coverage
144 of AM is obtained. Literature data are available for the
145 coverage-dependent work function of all three AMs
146 studied.[22] As an example, data for K on Cu(111) are shown
147 in Fig. 1. As can be seen, the profile of the coverage-
148 dependent work function is accurately reproduced by the
149 exposure-dependent work function obtained from the eTOF
150 measurements.

151 The two-photon photoemission (TPPE) spectra for the
152 Cu(111)/AM surfaces as a function of photon energy ($h\nu$)
153 and coverage are of interest in their own right.[20,22–24] The

FIG. 3. (a) TPPE spectra for .05 ML Li/Cu(111) at the indicated photon energies. (b) Position of the resonance (○) and the surface state (●) from TPPE spectra for 0.05 ML Li/Cu(111). The dashed lines are least-squares linear fits.

154 spectra as a function of K coverage are shown in Fig. 2 and
155 the energy dependence for the Cu(111)/0.05 L Li surface in
156 Fig. 3. For the clean Cu(111) surface, the TPPE spectrum
157 shows the surface state located 0.4 eV below E_F. On adsorp-
158 tion of low coverages of K, the surface state disappears being
159 replaced (or obscured) by a higher energy feature plus an
160 additional band at lower energy, which grows in with in-
161 creasing K coverage. Very similar behavior was seen for
162 Cu(111)/Na and Li surfaces, although for Li the lower energy
163 feature is weaker [Fig. 3(a)]. The dependence of the eTOF
164 spectrum on $h\nu$ for the Li doped surface is significant. As the
165 incident photon energy is changed by $\Delta h\nu$, the higher energy
166 feature shifts by 2 $\Delta h\nu$, while the lower energy one shifts by
167 $\Delta h\nu$ [Fig. 3(b)]. Thus the higher energy feature can be as-

168 signed to an AM induced state which is occupied and lies
169 close to E_F. The linear dependence on $h\nu$ for the lower en-
170 ergy feature identifies it as an unoccupied intermediate
171 state.[25] These data are consistent with a model in which AM
172 adsorption leads to a new occupied state close to E_F and an
173 unoccupied state ~3 eV above E_F, shifting lower with in-
174 creasing coverage. The latter can probably be assigned to an
175 AM induced image state, as described by Fischer et al.[24]
176 Very recently Zhao et al. reported TPPE measurements for
177 all AMs on both Cu(111) and Ag(111).[26] They reported an
178 image state 2 eV above E_F and characterized it in detail. The
179 picture for the occupied state is a little less clear-cut for the
180 K doped surface, where the energy of the TPPE signal as a
181 function of $h\nu$ was found to have a slope of 1.3 rather than
182 the expected value of 2. The origin of this is unknown, but
183 the result may suggest a mixed contribution from both an
184 occupied initial state and an unoccupied intermediate state
185 higher in energy than the image state.

III. RESULTS AND DISCUSSION   186

187 The yield of electrons from the Cu(111) substrate is a
188 strong function of laser intensity, reflecting the nonlinear
189 (two-photon) origin of the signal. When the Cu(111) crystal
190 is coated with only 4 L of water, the photoemission is
191 strongly attenuated, consistent with trapping of electrons in
192 the ice film and their subsequent ultrafast tunneling back to
193 the substrate.[7,27] When the 4 L film is replaced by a 3000 L
194 thick film and the same laser intensity is used, no photoemis-
195 sion is detected from the film, reflecting the high photoion-
196 ization (PI) threshold for water-ice. On application of even
197 0.02 L of AM, the same laser intensity yields a saturating
198 electron current. The origin of this extremely high yield of
199 photoemission was established for Na on water-ice to be a
200 very low threshold, so low, in fact, that single photon ioniza-
201 tion was occurring.[12,13] This was established by a linear in-
202 tensity dependence at very low fluence (0.1–1 μJ cm^{-2}).
203 Very similar behavior to that previously reported for Na
204 on water-ice was found for both Li and K deposited at less
205 than 0.05 L. The photoemission yields as a function of $h\nu$ for
206 both AMs are shown in Fig. 4. In both cases, photoemission
207 is detectable for photon energies as low as 2 eV, but the yield
208 climbs more or less exponentially between 2.1 and 3.5 eV for
209 K doped water-ice and 2.5 and 3.25 eV for the Li doped film.
210 These data are remarkably similar to those previously ob-
211 served for Na (cross section rising between 2.3 and 3.0 eV)
212 and taken together suggest a common origin for the initial
213 state, with a slight tendency for the threshold to decrease for
214 the heavier AM (although the effect is not large compared
215 with the error of ±0.2 eV in determining the threshold).
216 The energy distribution of the photoemitted electrons is
217 shown for 0.02 L K on water-ice as a function of $h\nu$ in Fig.
218 5. For $h\nu$ at and slightly above threshold (2.2 and 2.6 eV), an
219 asymmetric electron kinetic energy profile is observed, with
220 the lower limit being set by the ionization threshold and the
221 upper one by the photon energy. As $h\nu$ increases, the photons
222 sample deeper within the band of the initial state and the

FIG. 4. Photon energy dependence of the photoemission cross section of the water-ice surface doped with (a) 0.05 ML of Li and (b) 0.02 ML of potassium. The gray line indicates the inflection point for the sigmoid shaped curve. The laser beam was *p*-polarized and incident on the film at 45°.

223 curve broadens until, at high photon energy, a discrete band
224 is observed; very similar behavior was observed for Li and
225 Na.
**226**   Thus the strong similarities between the photoemission

FIG. 5. Photon energy dependence of the photoelectron spectra for 0.02 ML of K on water-ice.

FIG. 6. Schematic indicating the origin of the energy dependent spectra shown in Fig. 5.

spectra for the three AMs are also consistent with a common **227** initial state. Taking the vacuum level as 0 eV and assuming **228** the highest occupied level of water to be at −8.7 eV (i.e., the **229** photoemission threshold for pure water-ice), the threshold **230** data (Fig. 4) locate the highest energy edge of the initial state **231** to be at −2.5 eV for Li and slightly higher for Na and K. The **232** photoemission spectra (Fig. 5) suggest an inhomogeneous **233** distribution of sites for the initial state, with population in- **234** creasing for more negative energies. The appearance of a **235** discrete peak in the TOF spectrum at $h\nu > 4.4$ eV indicates **236** that the energy width of the inhomogeneous site distribution **237** is at least 2 eV. This is illustrated in Fig. 6, where the lower **238** energy photons sample only the high energy edge of the **239** distributions, while increasing $h\nu$ samples deeper into (and **240** eventually all of) the distribution, leading to broader and **241** more intense photoemission spectra. **242**

     Figure 4 also illustrates the PI cross section spectra for **243** Li and K on ice, calculated in the same way as previously for **244** Na.[13] The peak absolute cross section for photoemission was **245** measured to be $(5 \pm 2) \times 10^{-18}$ cm^2 atom^{-1} for K, (3 ± 2) **246** $\times 10^{-18}$ cm^2 atom^{-1} for Na,[13] and a somewhat higher value **247** for Li of $(5 \pm 4) \times 10^{-17}$ cm^2 atom^{-1}. Figure 7 shows the PI **248** spectra for the three alkali atoms in the gas phase.[28] The peak **249** cross sections are 8.1×10^{-20} cm^2 atom^{-1} for K, 1.0 **250** $\times 10^{-19}$ cm^2 atom^{-1} for Na, and 1.7×10^{-18} cm^2 atom^{-1} for **251**

FIG. 7. PI cross sections for atomic Li, Na, and K in the gas phase, as a function of photon energy (Ref. 27).

FIG. 8. Time-resolved decays of PI cross section. ○: the decay of K species formed by the deposition of 0.02 ML of K on 3000 L of H_2O. The photoemission signal was obtained with the photon energy of 4.4 eV. The decay rate is $(5 \pm 2) \times 10^{-3}$ s^{-1} (dashed-line). ●: the decay of the low-energy feature of 0.05 ML of Li in 3000 L of H_2O. Photon energy of 3.3 eV. The average value of the decay rate obtained from 5 data sets is $(1.4 \pm 0.4) \times 10^{-2}$ s (solid line). Measurements commenced 250 s after deposition was completed to allow the chamber to return to operating pressure and the surface to be transferred to the spectrometer.

FIG. 9. (Color) Calculated structures of a K atom bound to a model ice surface consisting of 18 H_2O molecules, at the B3LYP/6-311+g level of theory. The small white spheres are H atoms, the larger red spheres are O atoms, and the large purple sphere is the K atom. Panels (a) and (b) show a side- and a top-view of the K atom bound above the ice surface; panels (c) and (d) show a side- and a top-view of the K atom bound within the ice surface layer; panels (e) and (f) show a side- and a top-view of the K atom which has fully ionized leading to a stretched surface O–H bond.

252 Li. Thus the Li cross section is ~20 times larger than the
253 cross sections of Na and K (which are approximately equal),
254 both on the ice surface and in the gas phase. Furthermore, the
255 cross section of each AM is ~30 times larger when the atom
256 is adsorbed on ice, compared with the gas phase. A final
257 point is that the PI spectrum of Na/ice decreased by two
258 orders of magnitude for photon energies between 3.6 and 4.4
259 eV,[13] in contrast with the results from the present study for Li
260 and K on ice (Fig. 4). This behavior is again consistent with
261 the gas-phase PI spectra (Fig. 7).
262   The initial state when the AM adsorbs on the ice surface
263 is suggested to be a metastable form of a solvated electron
264 only loosely associated with its parent AM atom (see below).
265 This assignment is based on a number of factors. First, as
266 noted above, the PI cross sections for all three AMs in the
267 gas phase increase approximately 30-fold when the atoms are
268 adsorbed on ice. Second, we measured the transmission
269 spectrum of Na adsorbed on water-ice and observed a broad
270 band peaked around 2 eV,[12] which is strikingly similar to the
271 spectrum of the solvated electron formed in γ-irradiated
272 ice.[29] Finally, studies of the ionization potential of Na atom
273 doped water clusters in the gas phase were measured as 3.2
274 eV which is close to the threshold values recorded here.[30]
275   The picture emerging of a strong similarity between the
276 behaviors of the three AMs on the water-ice surface breaks
277 down when we consider the lifetime of the state formed on
278 deposition. In our study of Na on water-ice, it was observed
279 that the initial state was metastable and disappeared with a
280 temperature-dependent rate coefficient characterized by an
281 activation energy of around 10 kJ mol^{-1}.[13] This decay of the
282 initial state was assigned to more complete solvation of the
283 Na anion in the bulk of the ice and localization of the elec-
284 tron to form OH$^-$. Measurements of the decay of the initial
285 state formed on adsorption of the other AMs were made at 92
286 K (Fig. 8). A wide range in the first-order rate coeffi-
287 cients was found: Li$(1.4 \pm 0.4) \times 10^{-2}$ s^{-1}, Na(1.0 ± 0.2)

$\times 10^{-3}$ s^{-1}, and K$(4 \pm 2) \times 10^{-3}$ s^{-1}. Thus the initial state 288
formed when Li adsorbs on ice decays much more rapidly 289
than either Na or K. The error for adsorbed K is larger, 290
reflecting the departure of the kinetics from first order. This 291
may reflect some time dependent evolution in this film. De- 292
spite this larger error the main result, that Li decreases much 293
more rapidly than either Na or K, is clear. 294
    In order to better understand the key observation that 295
AM atoms bind to the ice surface with a resulting ionization 296
potential of ~3 eV (i.e., lowered by 1.4–2.4 eV compared 297
with the gas-phase), and also to understand why the photo- 298
electric emission signal decreases over time, we have carried 299
out a series of quantum chemistry calculations using the 300
GAUSSIAN 03 suite of programs.[31] The present calculations of 301
Li and K on ice extend our previous study[13] where we ex- 302
amined the binding of Na to a model ice structure which was 303
constructed using 12 H_2O molecules to build up two stacked 304
hexagonal rings, the top hexagon of 6 H_2O's representing the 305
ice surface. Six additional H_2O's were added around the 306
hexagons to simulate binding to adjacent unit cells in the ice. 307
The calculations were performed at the B3LYP/6-311+g 308
level of theory, which makes the geometry optimizations fea- 309
sible with this number of atoms (18 O, 36 H, and 1 AM). 310
    Figures 9 and 10 illustrate optimized structures that are 311
relevant to understanding the experimental results for K and 312

FIG. 10. (Color) Calculated structures of a Li atom bound to a model ice surface consisting of 18 H_2O molecules, at the B3LYP/6-311+g level of theory. The small white spheres are H atoms, the larger red spheres are O atoms, and the purple sphere is the Li atom. Panels (a) and (b) show a side- and a top-view of the Li atom bound above the ice surface; panels (c) and (d) show a side- and a top-view of the Na atom bound within the ice surface layer.

313 Li, respectively. Figures 9(a) and 9(b) illustrate the optimized
314 geometry of the $K-(H_2O)_{18}$ structure from the side and top
315 view of the puckered hexagonal H_2O rings. This structure is
316 the first local minimum on the potential energy surface that
317 occurs as the K atom approaches the ice. The ice structure is
318 least distorted in this case. The surface ring of 6 H_2O mol-
319 ecules has three unbound dangling H atoms (from alternate
320 H_2O's) that point upwards from the surface. The K atom lies
321 quite far above the surface hexagon, and is loosely bound to
322 one of the O atoms of the H_2O's in the ring with a dangling
323 H atom. The K–O bond length is 3.1 Å, and the Mulliken
324 charge on the K atom is essentially zero, indicating a very
325 weak interaction between the oxygen lone pairs and the
326 metal. The vertical ionization energy of this structure is 4.4
327 eV, which is essentially the same as an isolated K atom.
328   If the optimization is started with the K atom in the
329 surface hexagonal ring, the ice structure becomes distorted
330 so that the O atoms on four H_2O's are 2.7 Å from the K, as
331 shown in Figs. 9(c) and 9(d). The K atom is now bound more
332 strongly, by 33 kJ mol^{-1}, and the highest occupied molecu-
333 lar orbital (HOMO) is more delocalized, extending to about
334 8 Å in diameter. This is consistent with the large photoemis-
335 sion cross section measured in the present study, approxi-
336 mately a factor of 60 larger than the PI cross section for an
337 isolated K atom (Fig. 7). The calculated vertical ionization
338 potential is now 3.0 eV, which is in very good accord with
339 the measured threshold (Fig. 4).
340   If the optimization is started with the K atom even
341 deeper within the ice structure, the K 4s electron delocalizes
342 onto one of the H_2O molecules with a dangling surface H
343 atom, and the O–H bond stretches significantly from 0.96 to
344 2.1 Å [Fig. 9(e) and 9(f)]. The Mulliken charge on the
345 K (+0.9) indicates that the K is almost fully ionized, and the
346 HOMO is now localized as a p orbital on the H atom
347 stretched above the surface. The ionization potential of this

348 structure is 9.3 eV, and so its formation through a thermally-
349 activated rearrangement probably causes the photoemission
350 signal to decay with time (Fig. 8). These results are similar to
351 our previous experimental study and theoretical calculations
352 on Na on ice.[16] The decay rate of K is about 4 times that of
353 Na, consistent with the lower ionization potential of the
354 metal. It is likely that the distended O–H bond [Fig. 9(e) and
355 9(f)] then breaks, and the relatively mobile H atoms recom-
356 bines with another nearby H and departs from the surface as
357 H_2, leaving KOH solvated in the ice. The driving force for
358 the overall reaction is then the highly exothermic formation
359 of H_2 (bond energy 432 kJ mol^{-1}). The energy of the ionized
360 structure in Fig. (9(e) and 9(f)) is calculated to be 44 kJ
361 mol^{-1} above that of the lowest energy structure in Fig. 9(c)
362 and 9(d). At this level of theory an uncertainty of ± 30 kJ
363 mol^{-1} would be expected. Thus formation of the ionized
364 structure will involve an activation energy of at least 14 kJ
365 mol^{-1} There may also be restricted mobility of delocalized H
366 atoms at the surface, both effects contributing to the rela-
367 tively slow decay of the photoemission signal (time constant
368 ~200 s). These results are similar to our previous experi-
369 mental study and theoretical calculations of Na on ice.[13]
370   Figures 10(a) and 10(b) illustrate the optimized geom-
371 etry of the $Li-(H_2O)_{18}$ structure from the side and top views
372 of the H_2O rings. This structure is the first local minimum on
373 the potential energy surface that occurs as the Li atom ap-
374 proaches the ice. Compared with K [see Figs. 9(a) and
375 10(a)], the Li atom lies much closer to the surface, binding to
376 the O atoms of two H_2O's in the ring with a Li–O bond
377 length of only 1.9 Å. The Mulliken charge on the Li atom is
378 −0.1, indicating a stronger interaction between the oxygen
379 lone pairs and the metal atom, compared with Na (Ref. 13)
380 or K (see above). The 2s orbital of the Li, which is a large
381 component of the HOMO, becomes delocalized by this inter-
382 action with the surrounding H_2O's. However, the vertical
383 ionization energy of this structure is 3.8 eV: although this is
384 1.6 eV lower than the ionization potential of the isolated
385 atom (5.4 eV), it is still significantly higher than the thresh-
386 old measured in the present study (Fig. 4). If the optimiza-
387 tion is now started with the Li atom in the surface hexagonal
388 ring, the ice structure becomes distorted so that the O atoms
389 on three H_2O's are 2.2 Å from the Li (the O atom on a fourth
390 H_2O is 2.5 Å from the Li), as shown in Figs. 11(c) and 11(d).
391 The HOMO is more delocalized, again extending to about 9
392 Å in diameter, in accord with the very large PI cross section
393 (Fig. 4). The calculated vertical ionization potential is now
394 3.1 eV, which is in good accord with the measured threshold
395 (Fig. 4).
396   In contrast with Na (Ref. 13) and K [Figs. 9(e) and 9(f)],
397 Li does not exhibit the ionized state with a stretched surface
398 O–H bond. The decay of the photoemission signal for Li,
399 which is considerably faster than either Na (Ref. 13) or K
400 (see above), must be caused by another process. The most
401 likely candidate is the rapid diffusion of the Li atom into the
402 bulk of the ice layer. This process will be facilitated by the
403 smaller atomic radius [2.05 Å compared with 2.77 Å (Ref.
404 17)], which requires less distortion of the ice lattice [cf. Figs.
405 10(c) and 10(d) with Figs. 9(c) and 9(d)]. Note that if diffu-
406 sion into the bulk was the primary cause of the decay of the

407 photoemission signals from Na and K, then the Na signal
408 would be expected to decay faster than the K signal, whereas
409 it decays about 4 times slower.

IV. CONCLUSIONS

411   Photoemission from ice surfaces doped with low cover-
412 ages of the alkali metals Li and K have been investigated and
413 compared with earlier measurements for Na. A strikingly
414 similar pattern emerges for all three AMs, given that they
415 have significantly different PI thresholds and cross sections
416 in the gas phase. In particular, the photoemission threshold is
417 found to be much lower for all three AMs on ice compared
418 with the gas phase and relatively insensitive to the identity of
419 the AM. This is discussed in relation to the formation of a
420 metastable delocalized but incompletely solvated electron
421 stabilized at the water-ice–vacuum interface. The energy de-
422 pendence of the photoemission spectra suggests a broad in-
423 homogeneous site distribution for the initial state.

424   Calculations of the vertical ionization energies for AMs
425 on water-ice were made. The threshold which results from
426 the ice-AM structure minimized with the AM initially local-
427 ized above the film surface yields a threshold higher than
428 observed experimentally. If the energy minimization is made
429 with the AM localized in the ice hexagonal ring structure, the
430 low photoemission threshold was well reproduced for both
431 Li and K, as it was previously for Na.[15] This suggests a kind
432 of activated chemisorption process, with the incident AM
433 moving through the first physisorbed minimum to localize
434 within the ice surface. The chemisorbed state has a delocal-
435 ized electron distribution, consistent with the observed large
436 cross section.

437   The lifetime of the metastable initial state was deter-
438 mined from the decay of the photoemission signal. Li decays
439 much faster than Na and K. For the latter pair the quantum
440 chemical calculations suggest the formation of ionized AM
441 and an OH^- This was not observed for Li, suggesting that the
442 faster decay of the Li photoemission signal is caused by
443 more rapid diffusion into the ice film.
