## ACKNOWLEDGEMENTS

This thesis includes both work that was conducted and samples that were collected as part of the Deepwater Horizon National Resource Damage Assessment being conducted cooperatively among The National Oceanic and Atmospheric Administration (NOAA), The Gulf of Mexico Research Initiative (GoMRI), The DEEPEND Consortium (Deep Pelagic Nekton Dynamics of the Gulf of Mexico), other Federal and State Trustees, and British Petroleum. I thank the crew of the M/V *Meg Skansi* for their role in sample collection. I also thank Nova Southeastern University for providing the necessary laboratory facilities and supplies to carry out the project.

I am especially grateful to my advisor, Dr. Tamara Frank, for her guidance and support over the last three years. She has opened my eyes to the many wonders and mysteries of the deep sea through classwork, as well as valuable laboratory and field experiences. I thank my fellow lab assistant, Charles Fine, for his many contributions to the sample processing and quantitative analyses of the study. I also thank my committee members, Dr. Tracey Sutton and Dr. Charles Messing, for their contributions to this manuscript. Many tips and tricks using Microsoft Office, as well as the project data management, came from April Cook, to whom I am also extremely grateful. I commend Martha Nizinski of the NOAA NMFS National Systematics Lab for her contributions to the specimen identifications, and Lacey Malarky for her contributions to the statistical analysis of this thesis.

I especially thank my parents, Bill and Brenda Burdett, and my sister, Sarah, for their patience and love, and for their confidence in my abilities. Annual family vacations to Ocean City, Maryland sparked my interest in marine biology at a young age, and my family has always encouraged my curiosity. Without the love and support of my family and friends over the last three years, this work would not have been made possible.

## ABSTRACT

Geographic and Depth Distributions of Decapod Shrimps (Caridea: Oplophoridae) from the northeastern Gulf of Mexico with notes on ontogeny and reproductive seasonality

This thesis presents the first description of the geographic and depth distributions of pelagic decapod shrimps in the area located around the Deepwater Horizon oil spill, based on the NOAA (National Oceanic and Atmospheric Administration) NRDA (National Resource Damage Assessment) trawl samples collected from April – June, 2011. This information is important in ecosystem models investigating trophic effects of the spill because pelagic decapod shrimp are consumed by a variety of organisms occupying higher trophic levels. One of the most abundant and diverse groups of decapods is the Family Oplophoridae. Their roles in pelagic food webs in the Gulf of Mexico (GOM) and other deep-sea ecosystems makes them ideal candidates for study; however, only a limited amount of research has been conducted on their distribution and reproductive biology. In the northeastern GOM, all previous studies have been conducted at Standard Station in the eastern Gulf (27°N, 86°W) (Hopkins and Lancraft, 1984; Hopkins *et al.*, 1989; Hopkins and Gartner, 1992; Hopkins *et al.*, 1994). The current study is unique because 1) it provides data from regions of the Gulf where oplophorids have never been studied, 2) allows for comparisons of distributions and abundances of oplophorid species in both the mesopelagic and bathypelagic zones by using a continuous data set, and 3) compares assemblages from two distinct bathymetric environments in the northeastern GOM: continental slope (200-1000 m bottom depth) and offshore (>1000 m). As the study site also encompasses the region most strongly impacted by the Deepwater Horizon oil spill, these data represent the first quantification of any component of the decapod crustacean assemblage in this location after the oil spill, and will be used for comparison with data obtained during future DEEPEND Consortium (Deep Pelagic Nekton Dynamics of the Gulf of Mexico) cruises to monitor changes, or lack thereof, in the assemblage after exposure to Deepwater Horizon oil and dispersants in the water column.

## INTRODUCTION

The deep sea is the largest, yet least explored, environment in the world. The vast realm of the water column includes the epipelagic (0-200 m), mesopelagic (200-1000 m) bathypelagic (1000-4000 m), abyssopelagic (4000-6000 m), and hadopelagic (>6000 m) zones, and each has its own respective ecosystem and trophic structure. The Gulf of Mexico (GOM) is home to epipelagic, mesopelagic, and bathypelagic environments and has a high faunal diversity, including well over 100 species of decapod shrimp (Felder *et al.*, 2009).

One of the most abundant and diverse groups of micronektonic decapod crustaceans is the Family Oplophoridae which consists of 10 genera and over 70 recognized species (Wong *et al.*, 2015). The Family Oplophoridae is cosmopolitan, with species found in mesopelagic environments in every ocean; only a few benthic species are known (Fasham and Foxtan, 1979; Kensley, 1981; Krygier and Percy, 1981; Chace, 1986; Wasmer, 1986; Iwasaki and Nemoto, 1987; Kensley *et al.*, 1987; Krygier and Wassmer, 1988; Hendrickx and Estrada-Navarrete, 1989; Wasmer, 1993). Many of the pelagic species undergo diel vertical migrations (Foxtan, 1972; Chace, 1986).

Pelagic decapod shrimp species have significant roles and contributions to the food webs and biomass of micronekton in all deep-sea communities (Percy and Forss, 1966; Hopkins *et al.*, 1994). Micronekton is a collective term given to pelagic animals with body sizes ranging from 2-20 cm, and that have the ability to actively swim (Sutton, 2013). Oplophorids are primarily planktivores that feed on chaetognaths, juvenile fishes, and other smaller crustaceans in the water column (Foxtan and Roe, 1974; Omori, 1974; Hopkins, 1982; Roe, 1984), while they in turn are preyed upon by cephalopods, cetaceans, and many species of pelagic and commercially important fishes (Borodulina, 1972; Hopkins *et al.*, 1994).

Past studies on oplophorids in the northeastern GOM have been limited in location and depth. All previous studies have been conducted either solely in the bathypelagic zone (1000 to 4000 m depth) (Burghart *et al.*, 2007) or in a combination of the epipelagic (0-200 m) and mesopelagic (200 m to 1000 m) zones (Hopkins *et al.*, 1989; Hopkins *et al.*, 1994). This study is unique because it 1) covers a much larger

geographic location in the northeastern GOM, and 2) it compares distributions and abundance of oplophorid species in the epipelagic, mesopelagic, and bathypelagic zones using one continuous data set.

In addition to the major depth zones, the deep sea along continental margins has its own distinct features. Boundary zones at the slope along continental margins are found in oceanic ecosystems worldwide; however, very few studies on faunal composition, species diversity, abundance, and biomass have been conducted. These studies vary on local scales and must be individually tailored based on the physical and geographical limitations of each location of interest. These communities offer unique opportunities to study interactions between the neritic and oceanic ecosystems. Micronektonic composition studies in boundary zones have focused on fish species with limited inclusion of cephalopods and crustaceans (Reid *et al.*, 1991; Sutton, 2013; Feagans-Bartow and Sutton, 2014). A better understanding of oplophorid abundance and biomass patterns will contribute vital information needed to understand the community structure, trophic interactions, and relationships between these boundary ecosystems and adjacent oceanic systems.

The Deepwater Horizon oil rig exploded and sank on April 20, 2010. Over the next 87 days, 3.19 million barrels of oil spilled into the northeastern GOM until the well was finally capped on July 15, 2010, with the deepest hydrocarbon plume occurring at around 1100 m (Reddy *et al.*, 2011; U.S. District Court, 2015). A spill of this magnitude has potentially significant effects on the deep-sea ecosystem. The data presented here, collected one year after the spill, represent the first quantification of oplophorids in this region. Without a pre-spill baseline, these data can serve as an “impacted” dataset against which to monitor recovery, or lack thereof, of the oplophorid assemblage after the Deepwater Horizon event to compare with data from future studies in the northeastern GOM.

## MATERIALS AND METHODS

### *Sample collection and processing*

Samples were collected from April 20 to June 29, 2011 on the M/V *Meg Skansi* using a 10-m<sup>2</sup> mouth area, six-net MOCNESS (Multiple Opening and Closing Net and Environmental Sensing System) (Wiebe *et al.*, 1976) with 3-mm mesh. Temperature and salinity data were collected at each station using a separate CTD cast, as the sensors on the MOCNESS were not calibrated for these measurements. The sampling protocol of the MOCNESS deployment was standardized by a series of alphanumeric depth zones down to 1500 m at most locations (Table 1). In addition to the oceanic depth zones, sampling depths were chosen based on the following additional rationales: net 5 fished a depth below where a subsurface hydrocarbon plume was detected during the initial spill, net 2 fished through this hydrocarbon plume (Reddy *et al.*, 2011), net 3 fished where vertical migrating species are known to reside during the day, net 4 fished where vertical migrators are known to pass through during their diel vertical migrations, and net 5 fished the epipelagic zone where strong vertical migrators reside during the night. It is important to note that minor variations were made to this scheme at stations on or adjacent to the 1000-m isobaths (Table 1). The MOCNESS was deployed twice at each station: one day trawl and one night trawl.

Table 1. Depth codes used for *Meg Skansi* 7 data collection in the northeastern Gulf of Mexico

| <b>Depth Codes</b> |             |    |             |
|--------------------|-------------|----|-------------|
| 1                  | 1500-1200 m | 1a | 1500-1000 m |
| 2                  | 1200-1000 m | 1b | 1300-1200 m |
| 3                  | 1000-600 m  | 3a | 1000-0 m    |
| 4                  | 600-200 m   | 3b | 800-600 m   |
| 5                  | 200-0 m     | 3c | 900-800 m   |
|                    |             | 3d | 1000-800 m  |
|                    |             | 4a | 600-400 m   |
|                    |             | 4b | 400-200 m   |
|                    |             | 4c | 600-0 m     |
|                    |             | 5a | 200-100 m   |

Sampling stations were selected based on a subset of the Southeast Area Monitoring and Assessment Program (SEAMAP) sampling grid (Eldridge, 1988), which was bound by the 1000-m isobath to the north and the 27°N latitudinal line to the south. Within this area, stations occurred along every whole- and half-degree latitude-longitude crossing. In order to determine if differences existed between oplophorid assemblages along the slope and offshore in the GOM, stations were labeled as either slope or offshore before analyses took place. Slope stations were those that were on or landward of the 1000-m isobath, whereas offshore stations were those on the open ocean side of the 1000-m isobath (Figure 1). Standard Station (27°N, 86°W), a site in the northeastern GOM at which oplophorids have been extensively researched, coincides with the SE-5 sampling station in the current study. The Deepwater Horizon site is also located on the slope (Figure 1)

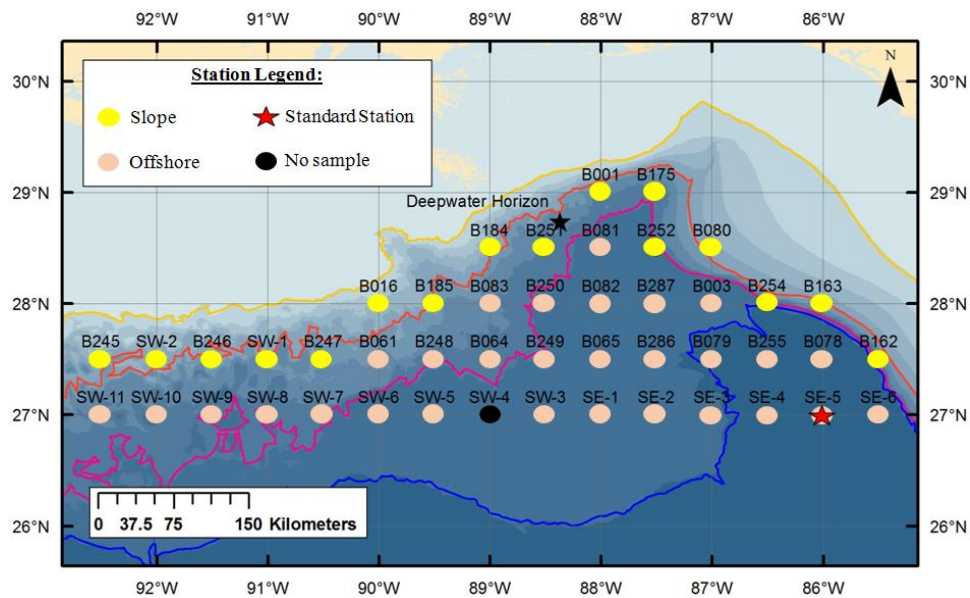

Figure 1. Map of 10 m<sup>2</sup> MOCNESS sampling stations during the Spring 2011 M/V *Meg Skansi* cruise with slope and offshore station distinctions. Standard Station is indicated with an orange star. The Deepwater Horizon oil rig is indicated by a black star.

The faunal composition and analyses presented here reflect the findings of the MS7 leg of a three-leg series. During the MS7 campaign, the MOCNESS system retrieved 516 trawl samples. The net 0 "oblique" samples and samples from which reliable flow data could not be calculated were omitted, leaving 340 discrete-depth

samples from 86 deployments at 45 stations for inclusion in quantitative analyses (Appendix I).

All samples collected during the MS7 survey were stored in a 10% formalin:seawater solution and archived at Alpha Analytical (Cambridge, MA), and then shipped to the Oceanic Ecology Lab at Nova Southeastern University for processing. Bulk samples were rough sorted into major taxonomic groups including crustaceans, fishes, cephalopods, and gelatinous zooplankton. Crustacean samples were then sent to the Deep Sea Biology lab at NSU, where they were identified to species level unless they were too damaged.

Specimens of Oplophoridae were identified using taxonomic keys and descriptions from Chace (1940), Crosnier and Forest (1973), Abele and Kim (1986), Holthuis (1993), and Felder *et al.* (2009). Chan *et al.*'s (2010) analysis of mitochondrial and rRNA genomes, suggested that Oplophoridae should be split into two separate families, with the genera *Janicella*, *Oplophorus*, and *Systellaspis* remaining in Oplophoridae, and the rest of the genera placed in a new family Acanthephyridae. However, recent evidence from Wong *et al.* (2015), based on a more comprehensive analysis of seven different genes from 30 oplophorid species, suggested that Oplophoridae should be treated as monophyletic as in the above-mentioned taxonomic keys. For this study, all genera are treated as oplophorids, consistent with the most up-to-date research and prior literature and taxonomic keys. After identification, carapace lengths of species used for ontogenetic analyses were measured (to the nearest millimeter) using digital calipers (CO030150 electronic digital caliper, Marathon Management). Wet weights were recorded to the nearest 0.01 g (P-114 balance, Denver Instruments) for each species in every sample. In addition to Oplophoridae, all families of micronektonic crustaceans were identified and weighed, allowing for an inter-familial comparison of biomass.

### ***Abundance, Biomass, and Diversity Index Calculations***

To compare assemblages of oplophorids found in slope stations with those found in offshore stations, raw counts were converted to standardized abundances (number of shrimp m<sup>-3</sup>) by dividing raw counts by volume-filtered data from the MOCNESS.

Biomass totals for each species were calculated in the same manner, with preserved wet weights being standardized to grams of shrimp m<sup>-3</sup> of water. Normality was tested for by using the Shapiro-Wilk test, and based on the non-normal distribution of data, Mann-Whitney *U* tests were applied to determine if slope and offshore assemblages differed significantly.

A scatterplot of the abundances of oplophorid species, with respect to slope and offshore locations, was generated to examine the monotonicity of the species assemblage in both locations. Monotonicity describes of the relationship of two variables as either positive (as the value of one variable increases, so does the other), negative (as the value of one variable increases, the other decreases), or non-monotonic (no relationship between the two variables). Oplophorid total abundance was also calculated for each station to determine how abundances varied from station to station with respect to slope and offshore locations. Intrastation variances were compared using a 1-way ANOVA test.

Species richness, diversity, and evenness measurements were calculated for slope and offshore oplophorid assemblages with respect to solar cycle and depth range. Species richness (*S*) is defined as the number of species in a given area. Species diversity was measured by using the Shannon Diversity index equation:

$$H' = -\sum p_i \ln(p_i)$$

where  $p_i$  represents the proportion of the population arising from the *i*th species.

Evenness, or distribution of individuals among species in the assemblage, was calculated using the Pielou's Evenness Index:

$$J' = H'/H'_{\max} = H'/\log S$$

where  $H'_{\max}$  is the value when all species are equally abundant. Once indices were calculated, independent sample t-tests were then performed on Shannon Diversity Index values, as per Jayaraman (2000), with respect to solar cycle, depth range, and region.

### ***Vertical Distribution***

To determine the vertical distribution of each oplophorid species, raw counts were converted to standardized abundances. The abundance of any given species in a specific depth range was calculated as the total number collected divided by the total flow data for all samples in that range at that location. Day and night abundances were then converted

to percentages. This allowed calculation of the percent of the total day or night assemblage for a given species in each depth range. These percentages were used to construct double-sided histograms that illustrate the vertical distribution of each species. Species were then categorized based on the percentage of their assemblage that migrated. Species were considered to be strong vertical migrators if more than 50% of the assemblage migrated, weak migrators if 15-50% of the assemblage migrated, or non-migrators if < 15% of the assemblage migrated.

### ***Gravid Female and Ontogenetic Data***

Gravid females were noted and abundances for each species were calculated with respect to depth range and month of capture. The percent of the total catch for each species composed of gravid females was also calculated.

The five species with the highest abundance of gravid females were used for analysis of ontogenetic trends. The carapace length of the smallest gravid female was considered the minimum mature size; anything smaller was considered immature, per Hopkins *et al.* (1989). Abundances of mature and immature individuals were calculated for each species, as well as a ratio of mature to immature (M:I) individuals, with respect to depth range and time of day. Ratios were then compared among the depth ranges in which  $\geq 90\%$  of the individuals for a given species was found.

## **RESULTS**

### ***Hydrography***

Sea surface temperatures ranged from as low as 24 °C from stations sampled in May to slightly over 29 °C at stations sampled in June. The thermocline ranged from 25 to 600 m across all stations. Temperatures at the deepest sampling depth (1500 m) at the offshore stations averaged  $4.3 \pm 0.02$  °C. Surface salinities remained fairly constant at  $36.5 \pm 0.4$  psu in both offshore and slope stations through all three months. The halocline was typically located between 125 and 500 m, with minor variations from station to station. At the deepest sample depths, salinity averaged  $34.9 \pm 0.01$  psu. Since the values and trends of temperature and salinity data did not vary within a given month of the

study, only representative T/S profiles for slope and offshore stations by month are presented in Figure 2, 3, and 4.

### *Oplophorid Abundance*

A total of 5,089 specimens belonging to eight oplophorid genera were collected. Species were divided into four categories based on their percent contribution to the assemblage: 1) dominant species each contributed  $\geq 10\%$  ( $= \geq 868$  specimens) of total oplophorid abundance; 2) abundant species each contributed between 1-9% ( $= 57-307$ ); 3) uncommon species each contributed  $< 1\%$  but enough specimens (21-46) of each species were available to construct meaningful estimates of their vertical distributions; 4) rare species each accounted for  $< 1\%$ , the same percentage as the uncommon species, but for rare species, there were too few specimens available ( $\leq 17$ ) to construct meaningful representations of vertical distributions. The three dominant species, *Acanthephyra purpurea*, *Acanthephyra stylorostratis*, and *Systellaspis debilis*, contributed  $\sim 62\%$  of the total number of specimens collected (Figure 5).

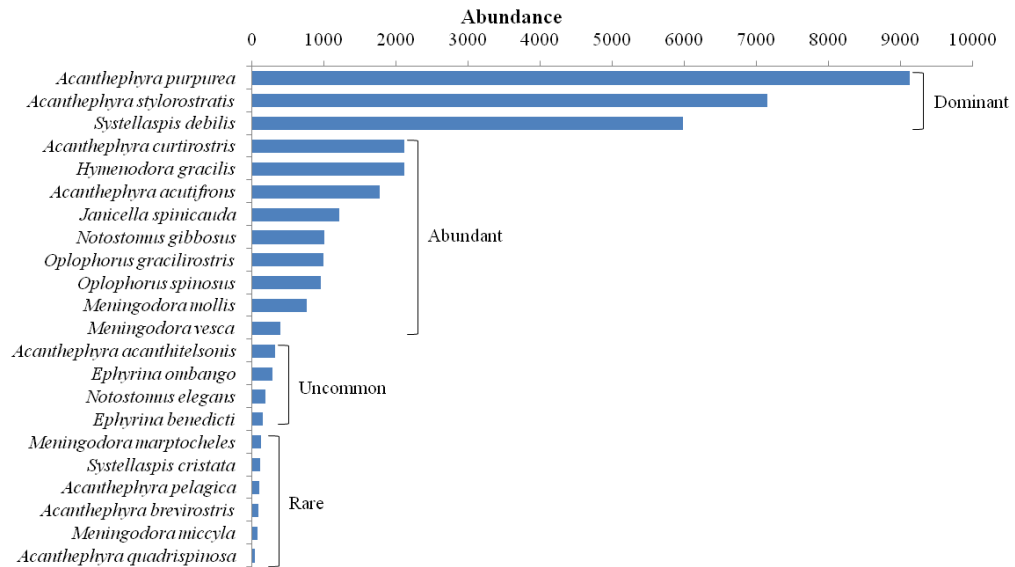

Figure 5. Total abundance ( $10^{-8} \text{ m}^{-3}$ ) of oplophorid species arranged from highest to lowest abundance.

### Oplophorid Biomass

Family Oplophoridae contributed approximately 43% of the total decapod biomass and approximately 31% of the total crustacean biomass, which was more than any other family of micronektonic crustacean (Figure 6).

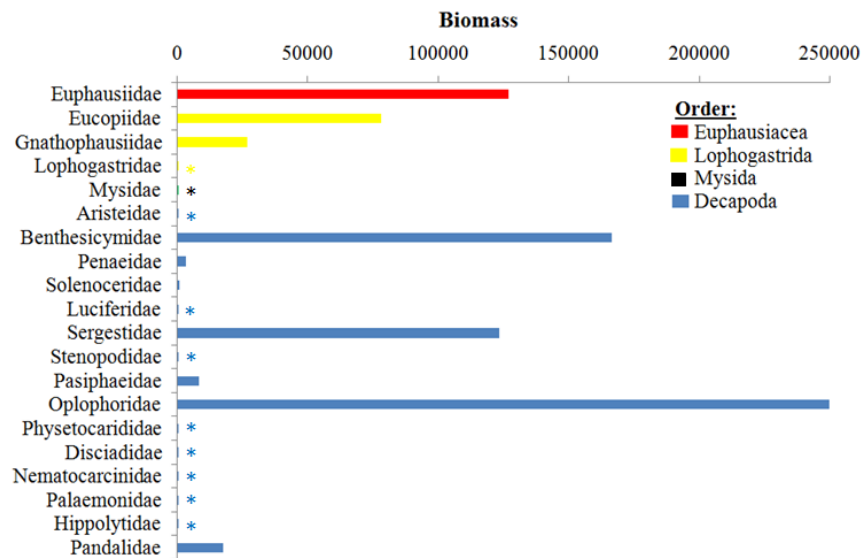

Figure 6. Biomass ( $10^{-9} \text{ g m}^{-3}$ ) of crustacean families by order.\* indicates biomass values less than  $5 \times 10^{-7}$ .

*AcanthePHYra purpurea* (18%), *Notostomus gibbosus* (18%), and *Systellaspis debilis* (16%) together accounted for ~52% of total oplophorid biomass (Figure 7).

*Acantheephyra purpurea* and *S. debilis* were also two of the three most abundant species. *Notostomus gibbosus* was considerably less abundant, but ranked among the top three in overall biomass due to the extremely large size of mature adults (up to 50 mm carapace lengths). *Acantheephyra acutifrons* (10%), *Acantheephyra stylostratis* (9%), *Acantheephyra curtirostris* (7%), and *Oplophorus gracilirostris* (5%) collectively accounted for ~31% to the total oplophorid biomass. The remaining species accounted for less than 16% of the total, each individually contributing less than 3%.

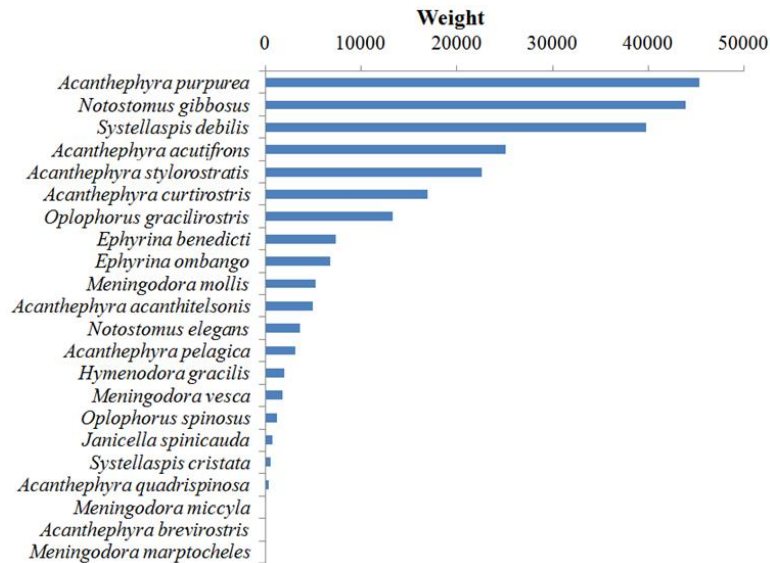

Figure 7. Total biomass ( $10^{-9} \text{ g m}^{-3}$ ) of oplophorid species arranged from highest to lowest values.

### ***Slope vs. Offshore Assemblage Comparison***

The pattern of species abundance was generally similar at slope and offshore stations (Figure 8), with *Acantheephyra purpurea*, *Systellaspis debilis*, and *Acantheephyra stylostratis* the first-, second-, and third-most abundant species, respectively, in both sets of samples; however, all three were more abundant along the slope than offshore. Interestingly, the fourth- through sixth-most abundant species were more abundant offshore, whereas the eighth through tenth were more abundant at slope sites. By contrast, *Janicella spinicauda* was the seventh-most abundant species at offshore stations, but only one specimen was caught along the slope (Figure 8).

The assemblage of oplophorid species in both locations showed a positive monotonic relationship, indicating that the assemblages in both locations are similarly

structured with respect to individual species abundances (Figure 9). No significant differences were found between the total abundance of oplophorids collected at each station in slope (mean =  $44 \times 10^{-5} \text{ m}^{-3}$ ) versus offshore (mean =  $34 \times 10^{-5} \text{ m}^{-3}$ ) locations ( $p > 0.5$ ) (Table 2.); however, intrastation variance was significantly higher ( $p < 0.01$ ) within the slope stations ( $2.11 \times 10^{-8} \text{ m}^{-3}$ ) than the offshore stations ( $1.27 \times 10^{-8} \text{ m}^{-3}$ ).

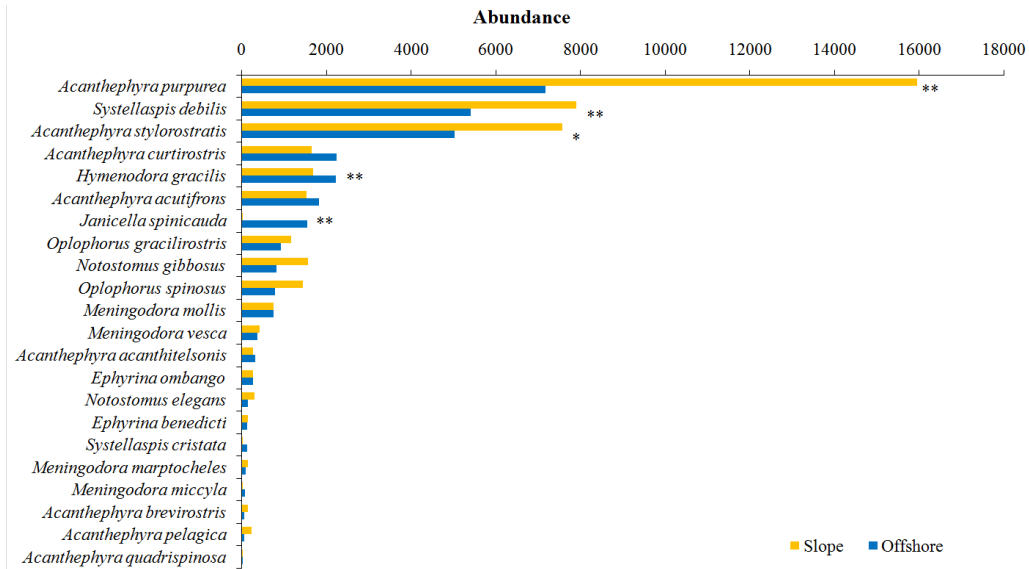

Figure 8. Abundance ( $10^{-7} \text{ m}^{-3}$ ) comparison of slope versus offshore oplophorids. Asterisks indicate species with significantly different abundances between the two locations. \* indicates p values between 0.05-0.01. \*\* indicates p values less than 0.01.

Figure 9. Positive monotonic relationship of oplophorid assemblages based on species abundance ( $10^{-7} \text{ m}^{-3}$ ) in offshore versus slope locations.

Table 2. Total abundance ( $10^{-5} \text{ m}^{-3}$ ) and variance of oplophorids by slope and offshore stations

| Slope    |                       | Offshore |                       |

Biomass trends reflected abundance trends, with biomass of the majority of observed oplophorid species higher at slope stations than at offshore stations (Figure 10). However, biomass did not closely reflect abundance trends for *Acantheephyra purpurea* and *Notostomus elegans*. Although *A. purpurea* was twice as abundant, its biomass was only ~50% greater in slope samples as in offshore samples, likely because offshore specimens had, on average, greater carapace lengths and, therefore, greater biomasses. Individuals of *N. elegans*, on the other hand, had greater average carapace lengths and biomass along the slope, resulting in a biomass that was five-fold greater in the slope samples, while abundance was only two-fold greater in slope versus offshore samples.

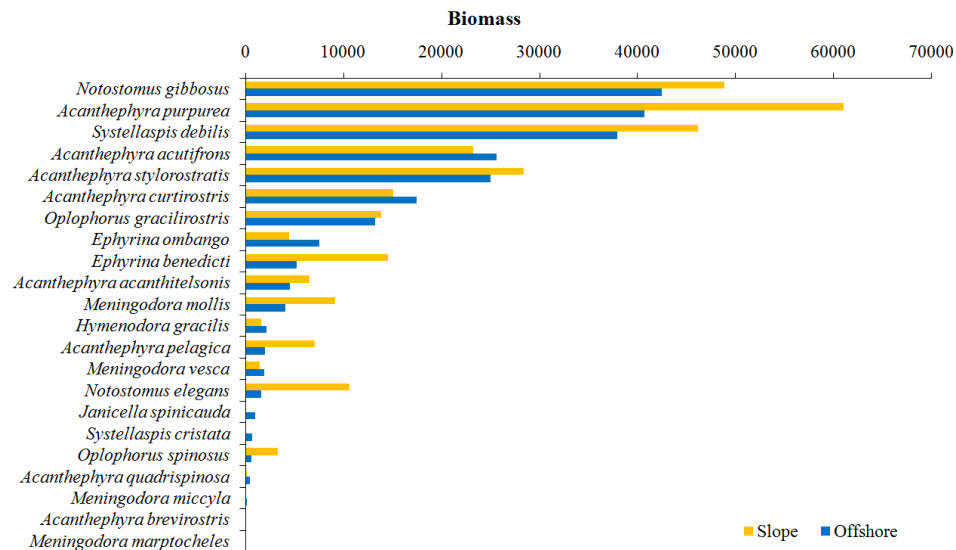

Figure 10. Biomass ( $10^{-9}$  g  $m^{-3}$ ) comparison of slope versus offshore oplophorid species.

*Notostomus gibbosus* had the highest biomass in offshore samples and the second-highest in slope samples, whereas *Acantheephyra purpurea* had the highest biomass in slope samples and the second-highest biomass offshore. *Systellaspis debilis*, *Acantheephyra acutifrons*, and *Acantheephyra stylostratis* accounted for the third-, fourth-, and fifth-highest biomass totals, respectively, in both locations. Although *A. acutifrons* had a higher biomass offshore, both *S. debilis* and *A. stylostratis* had higher biomasses in slope samples. *Ephyrina ombango* and *Janicella spinicauda* were the only other species with substantially higher biomasses offshore than in slope samples.

Slope and offshore assemblages of oplophorids were compared using Shannon Diversity ( $H'$ ) and Pielou's Evenness ( $J'$ ) Indices with respect to depth range and solar cycle (Tables 3, 4). Because bottom depth differed from station to station, precluding bathypelagic trawls at many stations, only the epipelagic (0-200 m), upper mesopelagic (200-600 m), and lower mesopelagic (600-1000 m) zones were compared. Diversity increased with depth, during the day and at night, for both slope and offshore locations; however, no significant differences were found when comparing the diversity of oplophorid assemblages in both locations ( $p > 0.5$  for all tests) (Tables 3, 4). Evenness of the oplophorid assemblage in both locations increased with depth during the day and night; however, as with  $H'$  values, no significant differences were seen among the slope and offshore locations ( $p > 0.5$  for all tests) (Tables 3,4).

Table 3. Average indices and equitability of nighttime slope and offshore assemblages of oplophorids.  $S$  = species richness,  $N$  = total number of shrimp  $10^{-5} \text{ m}^{-3}$  collected,  $H'$  = Shannon diversity index,  $J'$  = Pielou's evenness index.

|                     | Depth Range (m) | $S$  | $N$   | $H'$ | $J'$ |
|---------------------|-----------------|------|-------|------|------|
| Slope Assemblage    | 0-200           | 2.46 | 36.70 | 0.65 | 0.64 |
|                     | 200-600         | 3.33 | 62.90 | 0.81 | 0.66 |
|                     | 600-1000        | 5.27 | 42.20 | 1.23 | 0.80 |
| Offshore Assemblage | 0-200           | 2.87 | 37.40 | 0.71 | 0.70 |
|                     | 200-600         | 4.27 | 36.80 | 0.97 | 0.70 |
|                     | 600-1000        | 6.30 | 32.00 | 1.53 | 0.85 |

Table 4. Average indices and equitability of daytime slope and offshore assemblages of oplophorids.  $S$  = species richness,  $N$  = total number of shrimp  $10^{-5} \text{ m}^{-3}$  collected,  $H'$  = Shannon diversity index,  $J'$  = Pielou's evenness index.

### ***Vertical Distribution***

Of the 22 species of oplophorids collected, eight were strong vertical migrators (SVM), seven were non-vertical migrators (NVM), and one was a weak vertical migrator (WVM). Figures 11, 12, and 13 illustrate the vertical distribution patterns of the three dominant species, nine abundant species, and four uncommon species, respectively. Four of the SVM species - *Janicella spinicauda*, *Oplophorus gracilirostris*, *O. spinosus*, and *Systellaspis debilis* - migrated into the epipelagic zone at night, whereas *Acantheephyra purpurea*, *Meningodora vesca*, and *Notostomus elegans* were limited to diel migrations within the mesopelagic zone. *Ephyrina benedicti* was the only SVM species found to migrate within the bathypelagic zone. The migration pattern of *A. acanthitelsonis*, the only WVM, was restricted to within the mesopelagic zone over a 24-hour period. Most NVM specimens were collected from the lower mesopelagic or bathypelagic zone, or overlapped both zones.

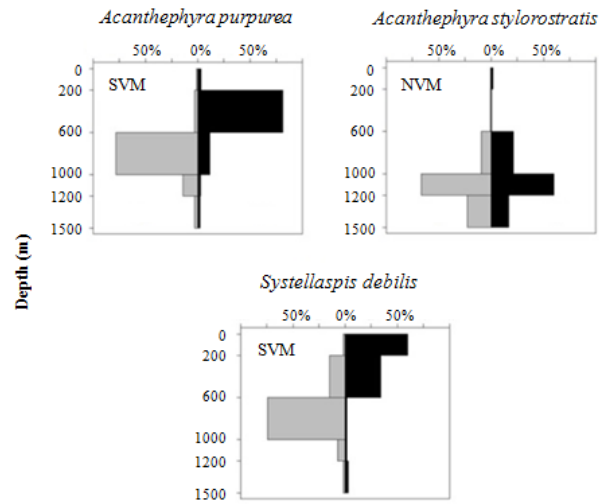

Figure 11. Vertical distribution patterns of dominant oplophorid species. SVM indicates a strong vertical migrator and NVM indicates a non-vertical migrator.

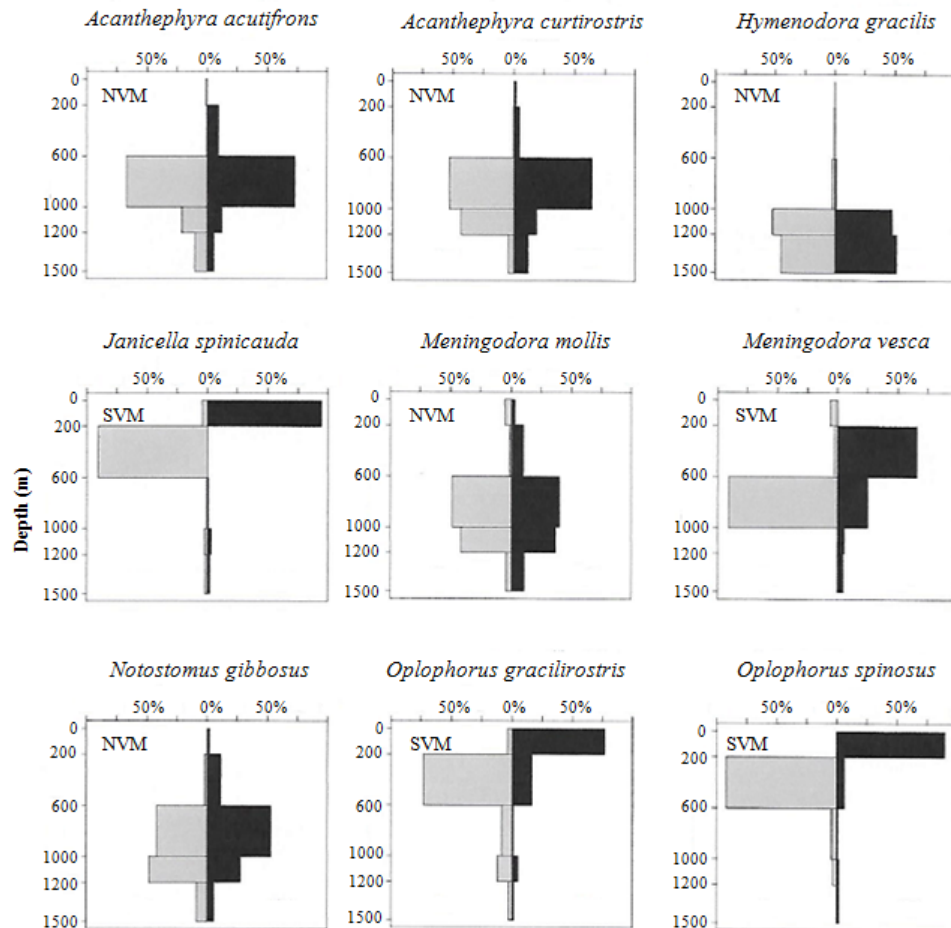

Figure 12. Vertical distribution patterns of abundant oplophorid species. SVM indicates a strong vertical migrator and NVM indicates a non-vertical migrator.

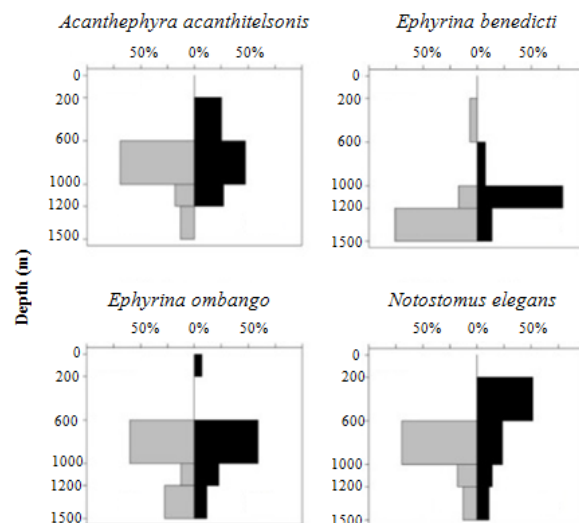

Figure 13. Vertical distribution patterns of uncommon oplophorid species. SVM indicates a strong vertical migrator, WVM indicates a weak vertical migrator, and NVM indicates a non-vertical migrator.

As stated above, too few individuals of the rare taxa were caught to draw any conclusions about their migratory behavior. Their abundance values corresponding depth ranges are shown in Table 5.

Table 5. Abundance and vertical distribution of rare species

| Species                           | Depth Range (m) | Abundance ( $10^{-7} \text{ m}^{-3}$ ) |       |
|-----------------------------------|-----------------|--|-------|
|                                   |                 | Day                                    | Night |
| <i>Acanthephyra brevirostris</i>  | 0-200           | 0                                      | 0     |
|                                   | 200-600         | 0                                      | 0     |

### ***Gravid Female and Ontogenetic Data***

At least one gravid female was noted in 13 of the 22 species of oplophorids in the study (Table 6). *Systellaspis debilis*, *Acanthephyra stylostratis*, and *Acanthephyra purpurea* were the three species with the greatest numbers of gravid females. *Oplophorus gracilirostris* and *S. debilis* were the two species with the highest percentage of gravid females (16.8% and 15.6%, respectively).

Table 6. Abundances ( $10^{-7} \text{ m}^{-3}$ ) per depth range and percent of total assemblage composed of gravid females of each species

| Species                             | Abundance ( $10^{-7} \text{ m}^{-3}$ ) |             |             |              |              | % of Total Assemblage |
|-------------------------------------|--|-------------|-------------|--------------|--------------|-----------------------|
|                                     | 0-200 m                                | 200 - 600 m | 600- 1000 m | 1000- 1200 m | 1200- 1500 m |                       |
| <i>Acanthephyra acanthitelsonis</i> | 0                                      | 0           | 2           | 0            | 0            | 2.2                   |
| <i>Acanthephyra acutifrons</i>      | 0                                      | 0           | 0           | 6            | 0            | 0.4                   |
| <i>Acanthephyra curtirostris</i>    | 5                                      | 6           | 15          | 12           | 0            | 3.9                   |
| <i>Acanthephyra purpurea</i>        | 0                                      | 28          | 50          | 0            | 4            | 2.6                   |
| <i>Acanthephyra stylostratis</i>    | 0                                      | 0           | 42          | 259          | 102          | 8.1                   |
| <i>Ephyrina benedicti</i>           | 0                                      | 0           | 0           | 0            | 4            | 4.8                   |
| <i>Ephyrina ombango</i>             | 0                                      | 0           | 7           | 0            | 0            | 7.5                   |

| <i>Meningodora vesca</i>            | 0                                      | 2           | 7           | 6            | 0            | 8.8                   |
| <i>Oplophorus gracilirostris</i>    | 27                                     | 30          | 10          | 6            | 0            | 16.8                  |
| <i>Oplophorus spinosus</i>          | 5                                      | 0           | 0           | 0            | 0            | 0.7                   |
| <i>Systellaspis cristata</i>        | 0                                      | 0           | 2           | 0            | 0            | 6.2                   |
| <i>Systellaspis debilis</i>         | 128                                    | 99          | 151         | 18           | 4            | 15.6                  |

Gravid female abundances were also examined with respect to sampling month (Table 7). The number of species with gravid females increased from April (n=6), to May (n=9), to June (n=11). However, three species, *A. purpurea*, *O. gracilirostris*, and *S. debilis*, which had gravid females in all three months, had substantially more in May than

in April or June. *Meningodora mollis* and *M. vesca*, on the other hand, had substantially more gravid females in April than May or June.

Table 7. Gravid female abundance ( $10^{-7} \text{ m}^{-3}$ ) by month for each species

| Species                             | Abundance ( $10^{-7} \text{ m}^{-3}$ ) |     |      |
|-------------------------------------|--|-----|------|
|                                     | April                                  | May | June |
| <i>AcanthePHYra acanthitelsonis</i> | 0                                      | 0   | 1    |
| <i>AcanthePHYra acutifrons</i>      | 0                                      | 3   | 0    |
| <i>AcanthePHYra curtirostris</i>    | 0                                      | 5   | 10   |
| <i>AcanthePHYra purpurea</i>        | 25                                     | 44  | 15   |
| <i>AcanthePHYra stylorostratis</i>  | 63                                     | 51  | 60   |
| <i>Ephyrina benedicti</i>           | 0                                      | 0   | 1    |
| <i>Ephyrina ombango</i>             | 0                                      | 3   | 2    |
| <i>Meningodora mollis</i>           | 13                                     | 0   | 3    |
| <i>Meningodora vesca</i>            | 25                                     | 3   | 2    |
| <i>Oplophorus gracilirostris</i>    | 13                                     | 41  | 7    |
| <i>Oplophorus spinosus</i>          | 0                                      | 3   | 0    |
| <i>Systellaspis cristata</i>        | 0                                      | 0   | 1    |
| <i>Systellaspis debilis</i>         | 63                                     | 189 | 57   |

For ontogenetic analyses, only the five species with the highest numbers of gravid females were used, with one exception (see below), as these included enough individuals to accurately separate immature (I) from mature shrimps (M). The carapace length of the smallest gravid female (Table 8) was used as the minimum length for sexually mature individuals of each species; smaller specimens were considered sexually immature per Hopkins *et al.*, (1989). The one exception was *Notostomus gibbosus*, which included no gravid females; however, size classes of carapace lengths based on Hopkins *et al.* (1989) made analysis of ontogenetic trends possible (Table 8). Specimens with carapace lengths  $\leq 20$  mm were considered immature, whereas specimens with carapace lengths  $\geq 35$  mm were considered mature.

Table 8. Carapace lengths (mm) of smallest gravid female used for ontogenetic analysis

| Species                            | Carapace length (mm) |
|------------------------------------|----------------------|
| <i>AcanthePHYra curtirostris</i>   | 13.62                |
| <i>AcanthePHYra purpurea</i>       | 10.85                |
| <i>AcanthePHYra stylorostratis</i> | 10.43                |
| <i>Notostomus gibbosus</i>         | 20.00                |
| <i>Oplophorus gracilirostris</i>   | 14.28                |
| <i>Systellaspis debilis</i>        | 10.54                |

More immature specimens of all six species were collected at shallower depths (Table 9). At night, M:I ratios had greater variation between depth ranges than during the day, likely due to the increased abundance of mature individuals of each species. Of the three species of vertical migrators, *Oplophorus gracilirostris* showed the greatest change in assemblage structure between depth zones at night, whereas *Notostomus gibbosus* exhibited the most prominent change of the three non-migrating species.

Table 9. Abundances ( $10^{-7} \text{ m}^{-3}$ ) and ratios of mature to immature individuals (M:I) for each species with respect to depth range and time of day

| Species                          | Depth Range (m) | Day   |   |           | Night   |   |           |
|----------------------------------|-----------------|---|---|-----------|---|---|-----------|

- indicates depth ranges with insufficient mature abundances to calculate ratio

+ indicates depth ranges with insufficient immature abundances to calculate ratio

## DISCUSSION

### *Hydrography*

Over 280 trillion gallons of freshwater flow into the GOM annually from over twenty major river systems, with over half of this influx coming from the Mississippi River alone (Moody, 1967). Jochens and DiMarco (2008) noted lower salinity concentrations in surface waters at stations sampled southeast and southwest of the Mississippi River Delta than in stations sampled further offshore. April and May are almost always the times of maximum discharge, whereas the least drainage tends to occur in September and October (Kourafalou and Androulidakis, 2013). Temperature and salinity data collected during this study, however, showed little variation between slope and offshore stations, suggesting that these parameters cannot explain differences in oplophorid distribution patterns between the slope and offshore locations.

### *Oplophorid Abundance*

The dominant species of oplophorids found in this study (*Acanthephyra purpurea*, *Acanthephyra stylostratis*, and *Systellaspis debilis*) accounted for approximately 62% of the total oplophorid catch. Hopkins *et al.* (1989) also found that *A. purpurea* and *S. debilis* were among the dominant species of oplophorids present at Standard Station in the northeastern GOM. They found *A. stylostratis* to be relatively rare, but this was because they only sampled at depths above 1000 m. At the same location, Burghart *et al.* (2007) recorded *A. stylostratis* as the second-most abundant oplophorid at depths between 1000 and 3000 m in the bathypelagic zone. In the current study, *Hymenodora*

*gracilis* was abundant in numbers but had a relatively low contribution to the total biomass due to smaller carapace sizes, backing up the previous findings by Burghart *et al.* (2007).

Since the current study only sampled the top 1500 m of the water column, several deeper bathypelagic oplophorid species, such as *Hymenodora glacialis* and *AcanthePHYRA gracilipes* were not collected. Burghart *et al.* (2007) recorded these two as the first- and fifth-most abundant oplophorids, respectively, caught in the bathypelagic zone. Burghart *et al.* (2007) also collected two rare species of bathypelagic oplophorids not seen in the current study: *Systellaspis braueri* and *Systellaspis pellucida*.

### ***Oplophorid Biomass***

Understanding the contributions of individual families is important, because pelagic decapod shrimp species play significant roles in pelagic food webs and make significant contributions to the total biomass in all deep-sea pelagic communities yet studied (Pearcy and Forss, 1966; Hopkins *et al.*, 1994). In this study, Oplophoridae contributed the most of any family to overall micronektonic crustacean biomass, highlighting its importance in the deep-sea ecosystem of the GOM. Oplophoridae accounted for approximately 31% of total crustacean biomass; Benthescymidae accounted for ~21%, the next highest total.

*AcanthePHYRA purpurea*, *Notostomus gibbosus*, *Systellaspis debilis*, *AcanthePHYRA acutifrons*, and *AcanthePHYRA stylorostratis* recorded the five highest biomass totals, in descending order. Hopkins *et al.* (1994) also found *S. debilis*, *A. purpurea*, and *A. stylorostratis* among their five highest biomass totals, but *A. curtirostris* and *A. acanthitelsonis* completed their top five list. *AcanthePHYRA curtirostris* was fourth in abundance in the current study, but its smaller size accounted for its lower total biomass.

As in the current study, Burghart *et al.* (2007) found *AcanthePHYRA acutifrons*, *Notostomus gibbosus*, and *AcanthePHYRA stylorostratis* to have three of the five highest biomass totals. However, as with Hopkins *et al.* (1994), they included *A. curtirostris* rather than *A. acutifrons* (in the current study) in the top five in terms of biomass.

### ***Slope vs. Offshore Assemblage Comparison***

Five species of oplophorids showed significant differences in assemblage abundance between slope and offshore locations. Of these, *Acanthephyra stylorostratis*, *A. purpurea*, and *Systemaspis debilis* were significantly more abundant at slope stations, with *A. purpurea* more than twice as abundant in slope stations as in offshore stations. *Hymenodora gracilis* was significantly more abundant offshore, and *Janicella spinicauda* was completely absent from slope samples except for one specimen collected from the lower mesopelagic zone during the day. Since *J. spinicauda* was collected from 11 offshore stations, these results appear to be real and not simply the result of more offshore sampling. Significantly higher variance in oplophorid abundance among slope stations relative to offshore was probably due to substantially fewer slope stations coupled with higher abundances in the former area (Table 2). Significantly higher slope variance is also a possible explanation for the observed differences of individual species abundances with respect to both locations.

Studies on relationships between slope and offshore fauna are relatively uncommon; however, Reid *et al.* (1991) discussed differences in the distributions of micronektonic crustacean assemblages along the Hawaiian Islands. *Oplophorus gracilirostris* showed a clearly distinct mesopelagic-boundary distribution, with few specimens in offshore tows. *Janicella spinicauda* was common in both inshore and offshore trawls and was thus considered a facultative member of the boundary community. Although Reid *et al.* (1991) collected only two oplophorid species, they identified 23 micronektonic species with distinct boundary zone assemblages. Differences in the spatial abundance of *J. spinicauda* between the current study and Reid *et al.* (1991) support the hypothesis that slope communities are unique to their respective local region, and as such, more studies need to be completed to understand their interactions with offshore ecosystems.

No significant differences were seen for diversity ( $H'$ ) and evenness ( $J'$ ) comparisons of slope assemblages versus offshore oplophorid assemblages. Species richness was greater in both the epipelagic and lower mesopelagic zones in the offshore regions during the day. Hopkins *et al.* (1994) noted that the eastern GOM is an oligotrophic environment, which facilitates more competition among micronektonic

species for food and resources than in more productive areas. However, thirteen more trawls were conducted in offshore stations than in slope stations, so that more rare species were collected offshore. Both of these factors likely contribute to the higher species richness values offshore.

The scatterplot of oplophorid abundances indicates a positive monotonic relationship between offshore and slope assemblages, meaning that the hierarchy of species found in both locations are similar. This relationship, along with species diversity, and evenness data suggest that these two assemblages are structured similarly, even though differences in abundances exist between the two areas for five oplophorid species.

### ***Vertical Distribution***

All oplophorid species were more abundant at night than during the day. Visual avoidance of collection gear by micronektonic organisms has been reported (Itaya *et al.*, 2007) and offers a possible explanation for the difference in catch rates in the current study.

The vertical distribution data found for many of the species of oplophorids in this study support the results of Hopkins *et al.* (1989) and Hopkins *et al.* (1994), so this discussion will emphasize new data for the GOM, highlighting differences between this location and others studied.

*Meningodora vesca* and *Oplophorus spinosus* were both strong vertical migrators, a pattern that has not been reported before for these species in the GOM, but has been reported for the north Atlantic (Foxton, 1970; Fasham and Foxton, 1979). *Meningodora vesca* migrated from the lower mesopelagic zone to the upper mesopelagic zone in the current study. Foxton (1970), working in the Canary Islands, collected only six specimens of *M. vesca*, but based on the collection depth of specimens, speculated that this species migrated within the mesopelagic zone during a 24-hour cycle. *Oplophorus spinosus* underwent diel migrations from the upper mesopelagic zone to the epipelagic zone, similar to what Fasham and Foxton (1979) found for this species in the eastern North Atlantic.

The vertical distributions of the non-vertically migrating species found in this study also back up the findings of previous mesopelagic and bathypelagic studies in the northeastern GOM (Hopkins *et al.*, 1989; Hopkins *et al.*, 1994; Burghart *et al.*, 2007).

Slight differences in vertical distribution descriptions of oplophorid species between the current and previous studies can be attributed to differences in sampling protocol. Hopkins *et al.* (1994) took samples every 50 m from the surface to 1000 m depth, giving more detailed information on the depth distributions of each species. Burghart *et al.* (2007) measured the bathypelagic zone from 1000-3000 by sampling in 500-m increments. This is a similar protocol to the current study, which, however, only sampled the upper 500 m of the bathypelagic zone. More discrete-depth sampling of the bathypelagic zone in the GOM is needed to get accurate depth of maximum occurrences for each bathypelagic oplophorid.

Table 10 provides the depth ranges of all oplophorid species found in the GOM, summarized from all previous studies conducted through the GOM together with data provided by the current study.

Table 10. Depth distributions of oplophorid species found in the Gulf of Mexico

| Species                               | Depth<br>Range (m) | Sources  |

\*indicates species caught in current study

### ***Gravid Female and Ontogenetic Data***

The carapace lengths of gravid females used to indicate the minimum size of mature individuals in this study are similar to those found by Hopkins *et al.* (1989) with *Acanthephyra purpurea* the sole exception. The smallest berried female of *A. purpurea* measured in the current study had a carapace length of 10.85 mm, considerably smaller than the smallest (16 mm) measured by Hopkins *et al.* (1989), and is the smallest gravid female of this species on record. As in the current study, Hopkins *et al.* (1989) found no berried females of *Notostomus gibbosus*; however, they did note that mature specimens ranged from 35-45 mm in carapace length and immature specimens ranged from 8-24 mm. The current study used similar size classes; although several immature specimens had carapace lengths < 5 mm, and the largest mature carapace length recorded was 53.19 mm. However, the true size at sexual maturity cannot be determined until berried females have been examined.

Ontogenetic depth patterns were observed in *Acanthephyra curtirostris*, *Acanthephyra purpurea*, *Acanthephyra stylostratis*, *Notostomus gibbosus*, *Oplophorus gracilirostris*, and *Systellaspis debilis*. More immature, smaller individuals of all six species were found at shallower depths than mature, larger specimens, supporting the hypothesis that smaller animals of pelagic species are found in shallower waters due to a decrease in size-dependent visual predation risk (De Robertis *et al.*, 2000). Hopkins *et al.* (1989) noted a similar ontogenetic pattern for *S. debilis* at night, but did not describe ontogeny for any other oplophorid species.

The gravid female and ontogenetic trends presented in this study will be especially beneficial when compared to data from future studies of oplophorids in providing a better understanding of whether seasonality in reproduction exists. In addition, comparisons of abundances of gravid females or juveniles with data from future studies are important to monitor ecosystem recovery.

## CONCLUSIONS

The results of this study indicate that there are no distinct differences between slope and offshore assemblages of oplophorids in the northeastern GOM, as indicated by the positive monotonic relationship of the two assemblages, as well as the results of diversity and evenness indices. However, three species of oplophorids had significantly higher abundances along the slope and two species had significantly higher abundances offshore. Based on the current study and previous studies in other locations, boundary communities and offshore communities, such as those in slope regions, are unique and should be treated on a local scale rather than a global one. The data presented here indicate that several species of oplophorids exhibit ontogenetic patterns in their vertical distributions, and provide a starting point for future studies on reproductive seasonality. Data such as these are critical for modeling potential impacts of anthropogenic perturbations, as well as recovery timelines.
