1 **Abstract**

2 **Background and Aims:** The effect of sarcopenic visceral obesity on risk of nonalcoholic fatty
3 liver disease (NAFLD) is uncertain. We investigated whether: a) the skeletal muscle mass to
4 visceral fat area ratio (SV ratio), as a measure of sarcopenic visceral obesity, is a risk factor for
5 NAFLD; and b) the SV ratio adds to conventional adiposity measures to improve prediction of
6 incident NAFLD.

7 **Methods:** Adults without NAFLD (n=151,017) were followed up for a median of 3.7 years.
8 Hepatic steatosis was measured using ultrasonography, and liver fibrosis scores were estimated
9 using the Fibrosis-4 index (FIB-4) and the NAFLD Fibrosis Score (NFS). Cox-proportional
10 hazards models were used to determine sex-specific adjusted hazard ratios (aHRs) [95%
11 confidence intervals (CIs)]. The incremental predictive performance was assessed using the
12 area under the receiver operating characteristic curve, net reclassification improvement, and
13 integrated discrimination improvement.

14 **Results:** Multivariable-aHRs (95% CIs) for incident NAFLD comparing the lowest versus the
15 highest quintile of SV ratio were 3.77 (3.56–3.99) for men and 11.69 (10.46–13.06) for women
16 (*P*-interaction by sex <0.001). For incident NAFLD with intermediate/high FIB4, aHRs were
17 2.83 (2.19–3.64) for men, and 7.96 (3.85–16.44) for women (similar results were obtained for
18 NFS). Associations remained significant even after adjustment for body mass index, waist
19 circumference, and time-varying covariates. These associations were also pronounced in non-
20 obese than obese participants (*P*-interaction <0.001). The addition of SV ratio to conventional
21 adiposity measures modestly improved risk prediction for incident NAFLD.

22 **Conclusions:** SV ratio was inversely associated with risk of developing NAFLD, with effect-
23 modification by sex and obesity. Low SV ratio is a complementary index to conventional
24 adiposity measures in the evaluation of NAFLD risk.

15

16

17

18 Nonalcoholic fatty liver disease (NAFLD) is the most prevalent chronic liver disease, with an

1 overall estimated global prevalence of 25%-30% in adults ¹. NAFLD is a multisystem disease
2 that increases the risk of liver-specific complications and extrahepatic diseases, such as cardio-
3 metabolic morbidity and mortality ²⁻⁵. Currently, there is no approved medical therapy for
4 NAFLD ⁶. Further research is needed to understand the heterogeneous factors that are involved
5 in the aetiology and pathogenesis of this complex liver condition, in order to give better insight
6 into how best to identify high-risk individuals and design effective treatments for the disease.

7 Obesity, specifically abdominal obesity, is a well-established risk factor for NAFLD ^{7, 8}.
8 Visceral fat area (VFA) is an accurate and reproducible measure of abdominal obesity and has
9 a stronger association with metabolic syndrome (MetS) and NAFLD risk than proxy measures
10 of adiposity, such as body mass index (BMI) and waist circumference (WC) ^{7, 9}. Along with
11 visceral obesity, reduced skeletal muscle mass, an essential component of sarcopenia, has been
12 reported as a novel risk factor for NAFLD ¹⁰. Skeletal muscle is a key tissue, given that glucose
13 disposal is facilitated by insulin, and reduced skeletal muscle mass may induce relative insulin
14 resistance ^{11, 12}. Visceral adipose tissue is also strongly associated with insulin resistance ⁴⁰;
15 thus, the combination of decreased muscle mass and increased visceral fat mass may markedly
16 perturb metabolism and increase NAFLD risk.

17 Recently, it has been reported that "sarcopenic visceral obesity" i.e. the coexistence of
18 sarcopenia and high visceral adiposity levels, is associated with higher levels of insulin
19 resistance and metabolic impairment; than either the presence of low muscle mass, or obesity
20 as individual risk factors ^{14, 15}. The skeletal muscle mass to visceral fat area ratio (SV ratio) is
21 a single integrated measure used to describe sarcopenic visceral obesity and the SV ratio is
22 generated by dividing the appendicular skeletal muscle mass (ASM) by VFA ¹⁶. Recent studies
23 have shown a close association between SV ratio and cardiometabolic diseases, including

1 T2DM, MetS and arterial stiffness, independent of conventional obesity measures^{16,17}. To the
2 best of our knowledge, no cohort studies to date have investigated the effect of SV ratio on the
3 risk of developing incident NAFLD in the general population.

4 This study aimed to test the hypothesis that people with a low SV ratio, as an indicator of
5 sarcopenic visceral obesity, have a greater risk of incident NAFLD (defined by liver fat) and
6 incident NAFLD with increased risk of liver fibrosis (defined by liver fat and increased liver
7 fibrosis scores) and then that addition of SV ratio to body mass index (BMI) or waist
8 circumference, as conventional adiposity measures, improves risk prediction for incident
9 NAFLD.

10 **MATERIALS AND METHODS**

11 *Study population*

12 The present study was performed in a subsample of the Kangbuk Samsung Health Study, a
13 large-scale cohort study of Korean adults who attended health check-ups annually or biennially
14 at the Kangbuk Samsung Hospital Total Healthcare Centers in Seoul and Suwon, South Korea
15¹⁸. 310,740 participants underwent an initial health check-up, including bioelectrical
16 impedance analyzer (BIA) measurements between 2011 and 2018 and at least one follow-up
17 examination until December 31, 2019. After excluding participants who met the exclusion
18 criteria (**Figure 1**), 151,017 participants were included in the current analysis. All procedures
19 involved in this study of human participants were in accordance with the the Ethical Principles
20 for Medical Research Involving Human Subjects outlined in the 2013 Declaration of Helsinki.
21 This study was approved by the Institutional Review Board of Kangbuk Samsung Hospital
22 (IRB No. KBSMC 2021-04-048), which waived the requirement for informed consent due to
23 the use of anonymized retrospective data that were routinely collected during the health
24 screening process.

1 ***Data collection***

2 Health screening examinations, including questionnaires, impedance analyses and liver
3 ultrasounds, were repeated every year or two years during the follow-up visits. Physical activity
4 levels were recorded using the validated Korean version of the International Physical Activity
5 Questionnaire short form and were converted to metabolic equivalents (METs; min/week)¹⁹.
6 They were classified into one of the following three categories: inactive, minimally active, or
7 health-enhancing physical activity (HEPA), meeting one of the following two standards: (i)
8 vigorous-intensity activity on ≥ 3 days per week totaling $\geq 1,500$ MET min/week, or (ii) 7 days
9 with any combination of walking, moderate-intensity, or vigorous-intensity activities,
10 achieving at least 3,000 MET min/week¹⁹.

11 ***Measurement and definition of SV ratio, a sarcopenic visceral obesity index***

12 A multi-frequency BIA (InBody 720; Biospace Inc., Seoul, Korea) was used to measure body
13 composition after all participants had fasted overnight (≥ 10 hours) prior to BIA measurement.
14 The BIA technique has been validated for body composition assessment, with a good
15 correlation with those obtained by dual-energy X-ray absorptiometry or abdominal computed
16 tomography (CT), including VFA and appendicular skeletal muscle mass (ASM)^{20, 21}. A
17 previous study of 200 Korean adults aged 20–69 years estimated the validity of lean body mass
18 (LBM) and percent body fat (PBF) measurements assessed using BIA and DXA²². The
19 correlation coefficients between DXA and BIA for LBM and PBF were high ($r=0.951$ and
20 $r=0.889$ for men and $r=0.956$ and $r=0.898$ for women, respectively)²². In addition, in a study
21 of children with obesity and NAFLD in the United States, total fat mass and skeletal muscle
22 mass determined using BIA and MRI were strongly correlated ($r =0.813$ and $r=0.701$,
23 respectively)²³. It has also been reported that visceral fat mass measured using BIA is highly

1 correlated with visceral fat mass measured using abdominal CT scan ($r=0.759$)²⁴. In our study,
2 ASM was defined as the sum of the lean tissue mass in the arms and legs and SV ratio (kg/cm^2)
3 was calculated as ASM (kg) divided by VFA (cm^2)^{16, 25}.

4 ***Liver ultrasound measures and definition of fatty liver and its severity***

5 Abdominal ultrasound was performed by experienced radiologists who were unaware of the
6 study's aims. Hepatic steatosis (HS) was diagnosed based on the standard criteria: a diffuse
7 increase in fine echoes in the liver parenchyma compared with the kidney or spleen
8 parenchyma, deep beam attenuation, and bright vessel walls²⁶. The inter-observer and intra-
9 observer reliability values for HS diagnosis were substantial (kappa statistic of 0.74) and
10 excellent (kappa statistic of 0.94), respectively¹⁸. We used the Fibrosis-4 (FIB-4) and NAFLD
11 fibrosis score (NFS), two validated non-invasive indices of advanced fibrosis, to evaluate HS
12 severity^{27, 28}. The FIB-4 cut-off points were defined as <1.30 (low risk), $1.30-2.67$
13 (intermediate risk), and ≥ 2.67 (high risk) for predicting probability of advanced fibrosis^{27, 28}.
14 The NFS cut-off points were <-1.455 for a low risk, 0.676 to -1.455 for an intermediate risk,
15 and >0.676 for a high probability of advanced fibrosis^{27, 28}. Since the number of the study
16 participants who progressed to high fibrosis score category (FIB-4 ≥ 2.67 or NFS >0.676)
17 during a median follow-up of 3.7 years was too small to obtain a reliable estimate, we combined
18 the individuals with an intermediate and high risk of HS severity for FIB-4 and NFS scores.

19 ***Statistical analysis***

20 No standard cut-off points have been established for SV ratio to define sarcopenic visceral
21 obesity. To assess the relationship between the SV ratio as a continuous factor and NAFLD risk,
22 we modelled the SV ratio as restricted cubic splines with knots at the 5th, 27.5th, 50th, 72.5th,
23 and 95th percentiles of the sample distribution to provide a flexible estimate of the

1 concentration-response relationship between the SV ratio and incident NAFLD. Then, we
2 defined sex-specific quintiles of SV ratio within the study population as follows: 0.09-0.26,
3 0.26-0.31, 0.31-0.36, 0.36-0.45 and 0.45-8.04 for men; and 0.06-0.18, 0.18-0.22, 0.22-0.25,
4 0.25-0.30 and 0.30-6.34 for women. The fifth quintile representing the highest SV ratio was
5 used as the reference group. The primary endpoints for the study were a) incident HS, and b)
6 incident HS with intermediate/high probability of advanced fibrosis at follow-up, assessed by
7 two noninvasive fibrosis markers (FIB-4 and NFS levels). The incidence rate was presented as
8 the number of cases per 1000 person-years. Cox-proportional hazard models were used to
9 estimate the adjusted hazard ratios (aHR) with 95% confidence intervals (CI) for incident HS
10 by comparing the highest (reference) to each of the other four SV ratio quintiles.

11 The models were adjusted incrementally as follows: Model 1 was adjusted for age, center
12 (Seoul or Suwon), year of the screening exam, education level (below college graduate, college
13 graduate or higher, or unknown), alcohol consumption (<10 g/day or \geq 10 g/day), smoking
14 (never, former, current smoking and unknown), physical activity (inactive, minimally active,
15 health-enhancing physical activity or unknown), total energy intake (quintiles, or unknown),
16 medication for hyperlipidemia, history of diabetes and history of hypertension. Model 2 was
17 adjusted for all covariates in Model 1, plus BMI as a continuous variable. To incorporate change
18 in SV ratio and change in covariates during the follow-up period, we conducted time-dependent
19 analyses, wherein updated status of SV ratio and other covariates were treated as time-varying
20 covariates.

21 We performed further analyses to compare the predictive ability of the SV ratio (and its
22 individual components) using Harrell's C-index (the area under the receiver operating
23 characteristic curve [AUROC]) and also calculated net reclassification improvement (NRI),
24 and integrated discrimination improvement (IDI) to quantify the incremental predictive ability

1 by adding the SV ratio relative to BMI or waist circumference.

2 Furthermore, to assess whether SV ratio provides additional information beyond BMI, an
3 indicator of overall obesity, we performed stratified analyses based on obesity status (BMI of
4 <25 vs. ≥ 25 kg/m²²⁹).

5 All analyses were conducted using STATA version 16.0 (StataCorp LP, College Station, TX,
6 USA), and we defined the *p*-value for statistical significance as a two-sided $p < 0.05$.

7

8 **RESULTS**

9 *Baseline Characteristics*

10 The baseline characteristics of 59,699 men and 91,318 women are presented according to SV
11 ratio quintiles (**Table 1, and Supplementary Tables 1-2**). Individuals in the lowest quintile of
12 the SV ratio had the least appendicular skeletal muscle mass with the highest fat mass and
13 greatest visceral fat area. Individuals in the lowest SV ratio (first quintile) tended to be older,
14 consumed more alcohol, and had higher HOMA-IR and hs-CRP levels than those in the fifth
15 quintile. Moreover, there were a higher proportion of subjects with hypertension,
16 hyperlipidemia, and physical inactivity in this quintile compared to the highest SV ratio quintile.
17 There was a modest inverse association between both obesity and abdominal obesity with SV
18 ratio quintile; the correlation coefficients between SV ratio and BMI were -0.53 for women
19 and -0.43 for men, while coefficients between SV ratio and WC were -0.49 for women and $-$
20 0.43 for men. The baseline characteristics of the participants are presented according to the
21 presence of missing data (Supplementary Table 3–4). Although most baseline characteristics
22 were different between the two groups, main exposure and other anthropometric measures,
23 including body composition, BMI, and waist circumference, after adjusting for age and sex
24 were similar between the two groups.

1 *Development of NAFLD according to SV ratio*

2 During 523145.8 person-years of follow-up, 26,543 cases of incident NAFLD were identified
3 (27.0 per 10³ person-years for women; and 91.7 per 10³ person-years for men), and the median
4 follow-up duration was 3.7 years (interquartile range: 2.0–4.8 years; maximum: 7.3 years). In
5 the spline regression models, the NAFLD risk decreased across the range of the SV ratios in
6 men (**Figure 2**). In women, the SV ratio showed an inverted J-shaped association with the
7 incidence of NAFLD, while the overall trend tended to be inverse between the SV ratio and
8 NAFLD risk. SV ratio quintile was inversely associated with the risk of incident NAFLD (*P*-
9 trend <0.001) and this association differed by sex (*P*-interaction <0.001) (**Table 2**). After
10 adjustment for confounders, multivariable-adjusted HRs (95% CIs) for incident NAFLD,
11 comparing the lowest to the highest SV ratio quintile, were 3.42 (3.24–3.61) for men and 11.27
12 (10.10–12.58) for women. These associations were attenuated after adjusting for BMI, but
13 values remained highly statistically significant. Importantly, all of these associations were
14 similarly observed in time-dependent analyses; wherein, the updated status of SV ratio and
15 other confounders were incorporated as time-varying covariates. These data indicated that
16 change in SV ratio or other key covariates between baseline and follow up, did not materially
17 affect the results. After adjusting for WC instead of BMI, this association persisted
18 (**Supplementary Table 5**).

19 In the analyses to evaluate the predictive ability of the SV ratio (and its individual
20 components), a significant but modest increase in category-based NRI and IDI were observed
21 when the SV ratio was added to the BMI-based model or WC-based model (**Table 3**,
22 **Supplementary Table 6**). The improvement was greater than that observed with the individual
23 components (**Supplementary Table 6**). The predictive performance of the SV ratios was not
24 superior to that of BMI or WC-based on the AUROC (**Supplementary Table 7**). Although in

1 our study, the predictive performance of BMI, waist circumference, and SV ratio was
2 inadequate to predict incident NAFLD on an individual level (**Supplementary Table 7**),
3 adding the SV ratio improved the net reclassification improvement (NRI) and integrated
4 discrimination improvement (IDI) (**Table 3**). Thus, the SV ratio may be a complementary index
5 to conventional adiposity measures for evaluating NAFLD risk.’

6 ***Development of NAFLD with intermediate/high fibrosis score according to SV ratio***

7 During follow-up, 1,329 cases of incident NAFLD with intermediate/high FIB4 score were
8 identified (0.9 per 10³ person-years for women; and 4.3 per 10³ person-years for men), while
9 1,986 cases of incident NAFLD with intermediate/high NFS score were identified (1.3 per 10³
10 person-years for women; and 6.5 per 10³ person-years for men). The risk of incident NAFLD
11 with increased fibrosis scores decreased as SV ratio increased (P -trend <0.001) and this
12 association was stronger in women than in men (P -interaction <0.001) (**Table 4**), although the
13 age-standardized incidence of NAFLD was much lower in women than in men
14 (**Supplementary Table 8**). Comparing the lowest to the highest SV ratio quintile, the
15 multivariable-adjusted HRs (95% CIs) for incident NAFLD with intermediate/high FIB4 were
16 2.83 (2.19–3.64) for men and 7.96 (3.85–16.44) for women. These associations were attenuated
17 after adjustment for either BMI or WC (**Supplementary Table 3**) but remained statistically
18 significant. These associations were also consistently observed in time-dependent analyses,
19 again indicating that change in status of SV ratio or other covariates between baseline and
20 follow up did not materially affect the results. The results were also more pronounced when
21 NFS was used instead of the FIB-4 score. Further adjustment for HOMA-IR and hs-CRP also
22 did not materially change the results (**Supplementary Table 9**).

23 The risk of developing NAFLD with a high fibrosis score, either high FIB-4 or high NFS, was

1 significantly higher in the lowest SV ratio quintile than in the highest SV ratio quintile among
2 men although a similar tendency was observed among women, this did not reach statistical
3 significance (**Supplementary Table 10**).

4 ***Subgroup analysis***

5 The associations between SV ratio quintiles and incident NAFLD differed by obesity status
6 defined as BMI ≥ 25 kg/m² (p -interaction < 0.001), in which the association was considerably
7 stronger in non-obese individuals than obese individuals (**Table 5**). For men, the HR (95% CI)
8 for NAFLD comparing the lowest to the highest SV ratio quintile was 2.92 (2.73–3.13) for
9 non-obese participants and 1.72 (1.42–2.07) for obese participants. In contrast to men, women
10 with the lowest SV ratio had a markedly increased risk of NAFLD in non-obese subjects (HR:
11 7.97, 95% CI: 7.10–8.94). In obese women in the lowest SV ratio quintile, there was a trend
12 towards increased risk of incident NAFLD (HR: 1.87, 95% CI: 0.47–7.48).

13 The inverse association between SV ratio and NAFLD was much stronger in non-obese
14 women than in obese women (p -interaction < 0.001). Importantly, all of the associations
15 described above were consistently observed when BMI was replaced by WC, as a measure of
16 abdominal obesity (**Supplementary Table 11**). In additional analyses stratified using re-
17 categorization including ‘lean,’ ‘overweight,’ and ‘obese,’ the association between the low SV
18 ratio and risk of NAFLD was most pronounced in lean individuals with BMI of < 23 kg/m²
19 (**Supplementary Table 12**).

20 The association between SV ratio and the risk of incident NAFLD with intermediate/high
21 FIB-4 (or NFS score) was statistically significant only in non-obese participants and the
22 associations were consistently observed in in non-obese participants grouped by WC instead
23 of BMI (**Supplementary Tables 13-16**). Due to a small number of outcomes within the highest

1 (fifth) SV ratio quintile in women with obesity or abdominal obesity, the fourth quintile was
2 used as the reference group. Among women, the association between SV ratio and NAFLD
3 tended to be stronger in premenopausal women than in postmenopausal women but without
4 significant interaction by menopausal status (**Supplementary Table 17**).

5

6 **DISCUSSION**

7 Our novel findings show that in a retrospective cohort study of >150,000 adults with over half
8 a million person-years of follow-up, low SV ratio was an independent risk factor for developing
9 incident NAFLD during the follow-up period (both overall NAFLD, and NAFLD with
10 increased levels of liver fibrosis markers). Interestingly, our data show that the inverse
11 association between SV ratio and NAFLD was stronger in women than in men, and in non-
12 obese than in obese participants, and the association between SV ratio and NAFLD was
13 significantly modified by sex and obesity. Low SV ratio is a complementary index to
14 conventional adiposity measures in the evaluation of NAFLD risk. These associations persisted
15 even after adjustment for either BMI or WC or when adjusted for changes in potential
16 confounders during follow-up, as time-varying covariates. Importantly, the time dependent
17 analyses take account of any potential change in status of SV ratio or other key covariates,
18 between baseline and follow up.

19 In analyses assessing the incremental predictive ability after adding the SV ratio to
20 conventional adiposity indices (either BMI or WC), the addition of the SV ratio consistently
21 showed a significant, although modest, improvement in the AUROC, NRI and IDI, compared
22 to the base model based on age and conventional adiposity measures. Thus, the SV ratio may
23 be a complementary index that adds to conventional adiposity measures in the evaluation of
24 NAFLD risk and this finding needs to be tested further in other cohorts and in different ethnic

1 groups.

2 Recent cross-sectional and longitudinal studies have shown a positive association between
3 low skeletal muscle mass and NAFLD risk^{10, 30, 31}, focusing on ASM adjusted for proxy
4 indicators of obesity, such as BMI or body weight, without considering visceral adiposity.

5 SV ratio combines two body composition measures, ASM and VFA, and can be used to
6 identify sarcopenic visceral obesity. Several studies have evaluated the association between SV
7 ratio and NAFLD^{25, 32-34}. However, previous studies have had at least one of the following
8 limitations: cross-sectional study design; use of proxy measures for diagnosing NAFLD, such
9 as fatty liver index or hepatic steatosis index (rather than liver biopsy or liver imaging); lack
10 of adjustment for potential confounders, including BMI or WC; or lack of consideration of
11 effect modification by sex or obesity.

12 In our study, the relative impact of the SV ratio on the risk of NAFLD was more pronounced
13 in women than in men although the absolute incidence of NAFLD was much lower in women
14 than in men. Women, especially pre-menopausal women, tend to have metabolically more
15 favorable fat distribution, such as more fat in the gluteofemoral region and subcutaneous area,
16 while fat is predominantly stored in the visceral area in men.^{36, 37} Additionally, the amount of
17 skeletal muscle mass in women was lower than that in men.³⁸ Proxy measures of overall
18 adiposity, such as BMI, may not be particularly useful as a measure of metabolic risk in women.
19 We suggest that better differentiation between fat and lean mass is needed in women. Measures
20 such as sarcopenic visceral obesity may be helpful as a measure of metabolic risk in women.
21 Further research using detailed phenotyping of fat distribution and measurement of skeletal
22 muscle mass will help understand the differential effect of SV ratio on NAFLD risk between
23 men and women.

1 Furthermore, in our study, the independent and inverse association between SV ratio and
2 NAFLD risk was much stronger among non-obese participants than among obese participants
3 with the strongest association seen in lean individuals with BMI of $<23 \text{ kg/m}^2$. These findings
4 were consistently observed even when the changes in SV ratio, BMI, and other confounders
5 over time were treated as time-varying covariates, suggesting that obesity is an effect modifier
6 of the association between the SV ratio and NAFLD risk. Potential contributory factors include
7 that lean NAFLD subjects who have been identified by BMI might also include people with an
8 unfavorable combination of excess abdominal adipose tissue, decreased protective fat tissue,
9 and low levels of skeletal muscle mass. Indeed, although NAFLD is strongly associated with
10 overall and central obesity, it also occurs in non-obese subjects, with approximately 40% of the
11 global NAFLD population being classified as non-obese ³⁹. Non-obese subjects with NAFLD
12 also show higher all-cause mortality, and mortality due to CVD and liver disease, than obese
13 NAFLD individuals ³⁹. Further research using detailed fat distribution phenotyping and skeletal
14 muscle mass measurement will be helpful in understanding the differential effect of SV ratio
15 on risk of NAFLD in men and women, and between non-obese and obese individuals.

16 Several plausible mechanisms may explain the concurrent roles of skeletal muscle and
17 visceral fat mass in the risk of NAFLD, including insulin resistance, previously described, and
18 inflammation. The skeletal muscle is capable of secreting myokines, such as myostatin and
19 irisin, which are involved in oxidative stress and inflammation ¹². Dysregulation of these
20 myokines may promote liver injury by increasing insulin resistance and oxidative stress ⁴¹.
21 Visceral adipose tissue macrophages produce proinflammatory cytokines, such as interleukin-
22 6 (IL-6), and tumor necrosis factor α , which are correlated with muscle atrophy, and may
23 increase the risk of NAFLD progression ⁴². Moreover, cytokines such as IL-6, which are
24 produced by inflamed adipose tissue, may further increase muscle wasting and exacerbate the

1 situation in chronic inflammatory states⁴³.

2 Despite these findings, our study has certain limitations. First, BIA could overestimate fat-
3 free mass (FFM) and underestimate fat mass in obese elderly populations²⁰. BIA may also be
4 affected by certain factors, such as fluid status, pregnancy, and malnutrition.⁴⁴ The hydration
5 status of the study participants was not determined before the body composition assessment.
6 All participants performed an overnight fast of ≥ 10 h prior to the BIA measurements because
7 fasting blood samples were collected at this time. Women in our study were supposed to be
8 non-pregnant to be eligible for a comprehensive health screening test that included imaging
9 studies. However, any inaccuracy in the BIA assessment would be universally applicable to all
10 participants in the study. The results of this study might not be generalizable to other adult
11 populations with extreme bodyweight and abnormal hydration status. Second, we used liver
12 ultrasound and liver fibrosis index (NFS and FIB-4) in our analyses. It was neither feasible nor
13 ethical to obtain histological data on liver steatosis and fibrosis from liver biopsies of this
14 occupational cohort of relatively healthy participants. The non-invasive diagnosis of the fatty
15 liver using ultrasonography and liver fibrosis indices has been validated with acceptable
16 accuracy and reproducibility and has been widely used in population-based studies^{28,45}. Third,
17 the relatively short follow-up time (median of 3.7 years) precluded an evaluation of advanced
18 fibrosis (FIB-4 ≥ 2.67 or NFS > 0.676) due to small case numbers. Considering the natural
19 history of fibrosis progression in patients with NAFLD has a long duration of 14.3 (95% CI,
20 9.1–50.0) years in one stage of fibrosis progression for patients with NAFLD³⁵, future studies
21 with longer follow-up durations are needed to determine the risk of NAFLD with high fibrosis
22 score, a more severe form of NAFLD, according to the SV ratio. Fourth, in our study, dietary
23 intake was assessed using a 103-item self-administered food frequency questionnaire (FFQ)
24 reflective of usual food intake over the past year that was developed and validated for use in

1 South Korea ⁴⁶. Additionally, seasonings and oils, typically included in Korean diet, are not
2 considered in this FFQ, which tends to underestimate total calorie intake compared to that in
3 dietary records, the reference standard ⁴⁶; thus, we cannot exclude measurement errors in the
4 dietary assessments. Fifth, data on myokine and adipokine levels were not available, although
5 dysregulation of the myokines and adipokines may contribute to liver injury by chronic
6 inflammation.^{40, 41} Future studies with a detailed assessment of myokine and adipokine levels
7 may help elucidate the mechanism underlying the association between SV ratio and NAFLD.
8 Finally, our study population comprised healthy middle-aged adults of Korean ethnicity, who
9 had good access to health care facilities; therefore, the generalizability of our findings to other
10 ethnic groups needs to be tested.

11 In conclusion, we have identified that low SV ratio is an independent risk factor for
12 developing NAFLD. Notably, low SV ratio was a stronger risk factor for NAFLD in women
13 than in men and was a much stronger risk factor in non-obese (especially, lean) than in obese
14 participants. This association was independent of BMI, WC, time-varying covariates (that take
15 account of change in status between baseline and follow up), and other potential confounders,
16 such as physical activity, in a large Korean cohort. Low SV ratio is a complementary index that
17 adds to conventional adiposity measures in the evaluation of NAFLD risk. Future studies with
18 consideration of effect modification by sex and obesity are needed to examine whether similar
19 findings exist in other ethnic groups.

20 **Acknowledgements**

21 We thank our staff members at the Kangbuk Samsung Health Study for their hard work,
22 dedication, and continuing support. This study was supported by SKKU Excellence in
23 Research Award Research Fund, Sungkyunkwan University, 2020, and by the National

1 Research Foundation of Korea, funded by the Ministry of Science, ICT, & Future Planning

Graphical Abstract

Skeletal muscle mass to visceral fat area ratio as a predictor of nonalcoholic fatty liver disease in lean and overweight men and women with effect modification by sex

Running title: SV ratio and fatty liver

Yoosun Cho, MD, PhD¹; Yoosoo Chang, MD, PhD^{2,3,4*}; Seungho Ryu, MD, PhD^{2,3,4*}; Hyun-Suk Jung, MD¹; Chan-won Kim, MD, PhD¹; Hyungseok Oh, MD¹; Mi Kyung Kim, PhD⁵; Won Sohn⁶; Hocheol Shin, MD, PhD^{2,7}; Sarah H. Wild, MB, BChir, PhD⁸; and Christopher D Byrne, MB, BCh, PhD^{9,10}

^a Base model adjusted for age and BMI.

^b Base model adjusted for age and waist circumference.

Risk cut-offs of 10% and 30% were used.

Abbreviations: AUROC, area under the receiver operating characteristic curve; BMI, body mass index; CI, confidence intervals; IDI, integrated discrimination improvement; NRI, net reclassification improvement; SV ratio, skeletal muscle mass; visceral fat area ratio.

Supplementary Table 7. Overall accuracy for non-alcoholic fatty liver disease by adiposity indices

	AUROCs (95% CI) ^a	
	Men	Women
BMI	0.640 (0.636–0.644)	0.769 (0.765–0.774)
Waist circumference	0.647 (0.643–0.651)	0.759 (0.754–0.764)
SV ratio	0.619 (0.614–0.623)	0.729 (0.724–0.734)

^a Values are presented as AUROCs with 95% CIs for NAFLD.

Abbreviations: ASM, appendicular skeletal muscle mass; AUROC, area under the receiver operating characteristic curve; BMI, body mass index; CI, confidence interval; SV ratio, skeletal muscle mass and visceral fat area ratio; BMI, body mass index.

Supplementary Table 8. Age-standardized incidence density of hepatic steatosis (HS) and HS plus intermediate/high probability of advanced fibrosis by sex

	Age-standardized incidence density (/ 10 ³ PY)		
	For HS	For HS plus intermediate-to-high FIB-4	For HS plus intermediate-to-high NFS
Men	90.5 (89.1–91.8)	4.0 (3.8–4.3)	6.1 (5.8–6.4)
Women	27.1 (26.6–27.7)	0.9 (0.8–1.0)	1.4 (1.3–1.5)

Supplementary Table 9. Hazard ratios^a (95% CI) of non-alcoholic fatty liver disease, and NAFLD with intermediate-to-high probability of advanced fibrosis according to skeletal muscle mass to visceral fat area ratio quintiles after further adjustment for HOMA-IR and hs-CRP

SV ratio (kg/cm ²) quintiles	NAFLD	NAFLD+ intermediate-to-high Fib4	NAFLD+ intermediate-to-high NFS
Men

<i>Per 0.1 decrease in SV ratio</i>	1.29 (1.03-1.62)	1.44 (1.09-1.90)	3.87 (3.11-4.82)

^a Estimated from Cox proportional hazard models. Multivariable model was adjusted for age, centre, year of screening exam, alcohol consumption, smoking, physical activity, total energy intake, education level, medication for hyperlipidaemia, history of diabetes (not for HS plus intermediate-to-high NFS), history of hypertension, HOMA-IR and hs-CRP.

The mean SV ratio in each quintile among men: Q1, 0.23; Q2, 0.29; Q3, 0.33; Q4, 0.40 and Q5, 0.63.

The mean SV ratio in each quintile among women: Q1, 0.17; Q2, 0.21; Q3, 0.25; Q4, 0.29 and Q5, 0.40.

Abbreviations: FIB-4, Fibrosis-4 score; NFS, non-alcoholic fatty liver disease fibrosis score; CI, confidence interval; HR, hazard ratio; SV ratio, skeletal muscle mass to visceral fat area ratio.

Supplementary Table 10. Development of hepatic steatosis (HS) and a high probability of advanced fibrosis by skeletal muscle mass to visceral fat area ratio quintiles

5 *Hepatology Communications*

6

7 Dear Prof. Gyongyi Szabo and Kymberly Watt,

8 Thank you for your constructive suggestions regarding our manuscript (HEP4-22-0037.R1) titled '**Skeletal**
9 **muscle mass to visceral fat area ratio as a predictor for nonalcoholic fatty liver disease in lean and**
10 **overweight men and women with effect modification by sex.**' We have revised the manuscript according to the
11 reviewers' recommendations and comments as requested. As recommended, we amended our manuscript while
12 reorganizing the Discussion section.

13

14 In addition to the revised version of the manuscript, we have uploaded a version with the changes marked in red,
15 reflecting the modifications to the manuscript as well as our point-by-point responses to the reviewers' comments,
16 which detail the changes made in response to these comments.

17

18 We are pleased to submit the revised version of the manuscript for publication in *Hepatology Communications*.

19

20 The authors declare no conflicts of interest related to this manuscript, including financial conflicts. This paper has
21 not been submitted for publication elsewhere and is not under consideration by any other journal.

22

23 Thank you for your consideration of our manuscript. Please feel free to contact me if you have any questions
24 related to our manuscript. I look forward to hearing from you.

25

26 Sincerely,

Seungho Ryu, MD, PhD

2 **Reviewer(s)' Comments to Author:**

3

4 **Reviewer: 1**

5

6 **I agree with the reviewer that the discussion needs reorganization as described.**7 **Response:**

8 Thank you for valuable comments. We agree that our Discussion section needs to be
9 reorganized and we amended our manuscript as your suggestions. Our point-by-point responses
10 are provided below.

11

12 **consider moving the paragraph " There are several plausible mechanisms that may
13 explain the concurrent roles of skeletal muscle and visceral fat mass in the
14 pathophysiology of NAFLD. Skeletal muscle is a key tissue, given that glucose disposal
15 is facilitated by insulin, and reduced skeletal muscle mass..." to the introduction.**

16 **Response:**

17 Thank you. As recommended, we moved the paragraph to the Introduction section and revised
18 the mechanism section below.

19

20 ***Introduction, page 5, last part of 2nd paragraph;***

21 'Skeletal muscle is a key tissue, given that glucose disposal is facilitated by insulin, and
22 reduced skeletal muscle mass may induce relative insulin resistance^{11, 12}. Visceral
23 adipose tissue is also strongly associated with insulin resistance⁴⁰; thus, the combination
24 of decreased muscle mass and increased visceral fat mass may markedly perturb
25 metabolism and increase NAFLD risk.'

26 ***Discussion, page 16, last paragraph to page 17, 1st paragraph;***

27 'Several plausible mechanisms may explain the concurrent roles of skeletal muscle and
28 visceral fat mass in the risk of NAFLD, including insulin resistance, previously
29 described, and inflammation. The skeletal muscle is capable of secreting myokines, such
30 as myostatin and irisin, which are involved in oxidative stress and inflammation¹².
31 Dysregulation of these myokines may promote liver injury by increasing insulin

1 resistance and oxidative stress ⁴¹. Visceral adipose tissue macrophages produce
 2 proinflammatory cytokines, such as interleukin-6 (IL-6), and tumor necrosis factor α ,
 3 which are correlated with muscle atrophy, and may increase the risk of NAFLD
 4 progression ⁴². Moreover, cytokines such as IL-6, which are produced by inflamed
 5 adipose tissue, may further increase muscle wasting and exacerbate the situation in
 6 chronic inflammatory states ⁴³.

7 **"Since the number of the study participants who progressed to high fibrosis score**
 8 **category 3 (FIB-4 ≥ 2.67 or NFS > 0.676) during a median follow-up of 3.7 years was too**
 9 **small to obtain a reliable estimate, we combined the individuals with an intermediate**
 10 **and high risk of HS severity for FIB-4 and NFS scores, possibly indicating the**
 11 **development of NAFLD with a worsening of fibrosis score rather than NAFLD with**
 12 **advanced fibrosis.".. to the methods section.**

13
 14 **Response:**

15 Thank you. As recommended, we moved the paragraph to the Method section.

16
 17 *Materials and Methods, page 8, last part of 2nd paragraph;*

18 'Since the number of the study participants who progressed to high fibrosis score
 19 category (FIB-4 ≥ 2.67 or NFS > 0.676) during a median follow-up of 3.7 years was too
 20 small to obtain a reliable estimate, we combined the individuals with an intermediate
 21 and high risk of HS severity for FIB-4 and NFS scores.'

22
 23 **and.. "Considering the natural history of fibrosis progression in patients with NAFLD**
 24 **has a long duration of 14.38 (95% CI, 9.1–50.0) years in one stage of fibrosis progression**
 25 **for patients with NAFLD 35, future studies with longer follow-up durations are needed**
 26 **to determine the risk of NAFLD with high fibrosis score, a more severe form of NAFLD,**
 27 **according to the SV ratio."... to the limitations paragraph**

31
 32 *Discussion (limitation), page 17, last part to page 18, 1st sentence;*

1 'Third, the relatively short follow-up time (median of 3.7 years) precluded an evaluation
2 of advanced fibrosis (FIB-4 ≥ 2.67 or NFS > 0.676) due to small case numbers.
3 Considering the natural history of fibrosis progression in patients with NAFLD has a
4 long duration of 14.3 (95% CI, 9.1–50.0) years in one stage of fibrosis progression for
5 patients with NAFLD ³⁵, future studies with longer follow-up durations are needed to
6 determine the risk of NAFLD with high fibrosis score, a more severe form of NAFLD,
7 according to the SV ratio.'

8
9
10
11
12
13 **Reviewer: 2**

14
15 **The authors have addressed each of the many individual criticisms I submitted in my**
16 **initial review and this version of the paper is much strengthened and the methods are**
17 **more granular. With that said, the organization of the discussion needs to be re-worked**
18 **with the change in title and the new focus on lean and overweight individuals and also**
19 **sex-based differences.**

20
21 **Response:**

22 Thank you for constructive comment. As recommended for the previous revision, we have
23 changed the title to '**Skeletal muscle mass to visceral fat area ratio as a predictor for**
24 **nonalcoholic fatty liver disease in lean and overweight men and women with effect**
25 **modification by sex**'. We have now added information on effect-modification to the Abstract.
26 We have revised our Discussion to emphasize differences between lean and overweight
27 individuals and also effect-modification by sex. We have also reorganized the Discussion
28 section.
