AUTOMATED METHODS FOR FIBER DIAMETER MEASUREMENT OF FIBROUS
SCAFFOLDS

A thesis submitted in partial fulfillment of the requirements for the degree of Master of
Science in Biomedical Engineering at Virginia Commonwealth University.

by

ANNA ALEXANDRA BULYSHEVA
B.S., University of North Carolina at Chapel Hill, 2006

Director: GARY L. BOWLIN, PH.D
PROFESSOR, BIOMEDICAL ENGINEERING

Virginia Commonwealth University
Richmond, Virginia
December 2009

Acknowledgements

I would like to thank the many people who have helped me advance through this laborious process. Although at times it was a lonely road, I could not have accomplished this without the support and advice from my family, advisor, friends, and lab-mates.

I am dedicating this work to my parents, Drs. Larissa and Alexander Bulyshev as a tribute to your unconditional guidance, love and support. I would not be here today; if it was not for the many daily sacrifices that you have made on my behalf. I cannot thank you enough for a life and education that you have made possible. Your faith in my abilities has made me strive to achieve more than I thought possible. Thank you.

I would like to thank my advisor, Dr. Gary Bowlin for providing the motivation to initiate and complete this work.

My lab-mates have started out as guides and many became close friends in the process. Thank you for providing support with kind words and technical advice. I especially would like to thank Koyal Garg and Yas Maghdouri, for the many stimulating and insightful end-of-the-day discussions that have brought joy and laughter during the good and better grad-school days.

To all who are not mentioned by name, you have brought me closer to this day in small and large ways, which are all remembered and highly valued.

Abstract

AUTOMATED METHODS FOR FIBER DIAMETER MEASUREMENT OF FIBROUS SCAFFOLDS

By Anna Alexandra Bulysheva, B.S.

A Thesis submitted in partial fulfillment of the requirements for the degree of Master of Science in Biomedical Engineering at Virginia Commonwealth University.

Virginia Commonwealth University, 2009

Major Director: Gary L. Bowlin, Ph.D.
Professor, Biomedical Engineering

The purpose of this work was to develop an automated method of measuring fiber diameters of electrospun scaffolds from scanning electron microscopy images of these scaffolds. Several automated methods were developed and evaluated by comparison to known values and data obtained via the standard manual method. Simulated images with known diameters were used as test images to evaluate the accuracy of each measurement technique. Eight scanning electron microscopy images were also used for the evaluation of the automated methods compared to the standard manual method. All diameter measurements were made in pixels. Five new automated methods coded in MATLAB were developed. The five methods varied the approach of identifying edges of fibers as well as assigning edges to single fibers and calculating the distance between edges assigned to the

same fiber. One-way analysis of variance and the Tukey-Kramer tests were performed for comparison of all methods per image. The Custom Canny Slopes automated method was shown to accurately approximate the mean diameters in ten simulated images as well as microscopy image of real scaffolds ($p < 0.05$)

Introduction

Tissue engineering is a rapidly evolving field with the main goal of constructing living tissues *in vitro* for *in vivo* applications. One area of research towards this goal is the development of scaffolds for mimicking micro-cellular environments for cell proliferation outside of the body. Such scaffolds are carefully characterized based on cell-scaffold interactions, mechanical strength of the scaffolds, topography, immune-compatibility, diffusion permeability, etc. Depending on the manufacturing techniques, the characterization parameters can vary. One popular manufacturing technique of scaffolds is electrospinning. Electrospinning is a technique for creating non-woven mats of fibers on a nano to micro-scale in terms of fiber diameters. This technique closely simulates the natural fibrous three-dimensional morphology of the extra-cellular matrix, which normally supports cells within various tissues. This technique can be applied to a large variety of natural and synthetic polymers in order to create a favorable scaffold. The versatility in terms of materials and morphological similarity to natural extra-cellular matrices makes electrospinning a highly promising area of research. A very fundamental characteristic of electrospun scaffolds is the mean fiber diameter. It has influence over many other properties the scaffold may exhibit, such as allowing cell adhesion, cell migration and diffusion of nutrients. Therefore, average fiber diameter is always measured and reported for electrospun scaffolds. Various parameters for a given polymer or even blends of

polymers can be altered in order to produce favorable fiber dimensions for cellular proliferation (1-3).

Fiber diameter measurement is usually performed manually by measuring the diameters of multiple fibers within one microscopy image. This is a laborious process which requires the operator to draw a segment orthogonal to the direction of each fiber approximating its borders. Specialized software calculates the distance between the endpoints of the segment, the operator then draws the next segment and the process is repeated 20-100 times. An automated, operator independent method can significantly reduce the time and effort spent on characterization of electrospun scaffolds especially for processing multiple scaffolds as well as reducing variability in results.

Project Synopsis

The focus of this study is to develop an automated method for measuring the fiber diameters of electrospun scaffolds. This work employs image processing techniques to extract diameter information from the Scanning Electron Microscopy (SEM) images of the scaffolds. The goal is to develop an operator independent method which can process the images and accurately measure fiber diameters. Two different implementations of Canny edge detection method were used to determine the location of the fiber borders. The Canny method was chosen for its superior accuracy compared to other edge detection methods (4,5). Once the edges were found, three different approaches were used to assign two edges to single fibers. The distance between the selected edges was then computed for each recognized fiber.

The author has found no literature regarding validation studies of a standard method compared to known values; therefore test images were created to simulate scanning electron microscopy images of electrospun scaffolds. The diameter of each fiber within these images was predetermined and known. Images with a narrow distribution of fiber diameters, and a wide distribution of fiber diameters with approximately 100 fibers per image were created.

Data was collected from five volunteers processing each image using the conventional manual method. Each image was displayed in image processing software such as ImageJ or UTHSCSA ImageTool, and the distance measurement tool of the

software was used to measure one hundred diameters. Every image was also processed with each of the five developed automated techniques.

Background Information

Fibrous ECM Analogues in Tissue Engineering

Tissue engineering is a growing field involving a diverse set of disciplines ranging from biological sciences, to engineering and physical sciences. Engineering tissues *in vitro* can have either therapeutic applications for *in vivo* implantation or treatment development applications for *in vitro* disease models. Developing tissues *in vitro* entails mimicking the micro and macro-scale cellular environment to allow for native cells of the tissues to perform their usual functions. There are various factors to be considered for manipulating cellular environment. Soluble cell-cell signals, nutrients, oxygen and carbon dioxide exchange, temperature, salinity and pH balance are all vital aspects of tissue culturing. Another critical aspect to closely mimicking the micro-environment of tissues is mimicking the extra-cellular matrix (ECM). The ECM not only functions to physically support the cells via cell adhesion, but it also regulates their proliferation and migration rates as well as other vital metabolic functions. The cell-matrix interactions occur in all three dimensions, which is difficult to replicate outside of the body. An ideal ECM analogue would provide cells of a particular tissue with the same cues that they would receive from their native ECM *in vivo*, but would do so *in vitro*.

The natural ECM of various tissues is often fibrous in nature with nano-scale diameters. Although this fibrous structure is very complex and is composed of numerous types of macromolecules and varies in structure and composition from tissue to tissue, the idea of creating fibrous scaffolds for the ECM analogues has gained tremendous momentum. The morphology of native ECM is primarily a network of long protein nano-fibers linked together with various glycoproteins. This fibrous morphology is the driving factor for creating fibrous scaffolds for ECM analogues (6-8). It has been experimentally determined that compared to two-dimensional smooth surfaces and three-dimensional porous films, fibrous networks of the same material provide better support for adhesion and migration of various cells (9).

Common methods for creating small fiber diameter webs include self-assembly, phase separation and electrospinning. Amphiphilic peptides with a hydrophobic and hydrophilic regions are known to self assemble into structures such as vesicles, micelles and tubules when dissolved in an aqueous solution. The structure of these peptides dictates the shape of the three-dimensional network formed in solution depending on temperature, pH and salinity of the aqueous solution. Various peptides have been fabricated to exploit their properties for self-assembling into three-dimensional nanofibrous networks with usage in tissue engineering and drug delivery applications. The fiber diameters for scaffolds created with this method are on the order of 30-50 nm (7,10,11).

Phase separation can either be non-solvent induced separation or thermally induced separation. Non-solvent induced separation can be accomplished by dissolving the polymer in a solvent and then introducing a non-solvent to the surface of the solution. The non-

solvent displaces the solvent in the solution making the solution unstable and causing the polymer to precipitate out of solution and therefore forming a porous scaffold (7,12).

Thermally induced phase separation is more common and involves dissolving the polymer in a solvent at high temperatures, and then quickly lowering the temperature to cause rapid precipitation, at which point the scaffold forms and the solvent is removed via sublimation or extraction (7,12,13). The fiber diameters fall into the range of 50-500 nm, when this method is implemented (7).

The most well studied method for preparation of fibrous scaffolds is electrospinning. This is a fairly simple process of utilizing electrostatic forces to produce non-woven fibrous mats. As one example, a polymer solution is drawn up into a syringe with a blunt needle. The needle is positively charged and a negatively charged collecting plate is placed at a predetermined distance from the needle. The resulting electrostatic field between the needle and the collecting plate causes a force to act on the polymer solution in the direction of the collecting plate. If the force is sufficiently high, the surface tension of the solution breaks and a jet of polymer solution moves from the tip of the needle to the collecting plate. While the jet travels to the collecting plate, the solvent evaporates leaving only the polymer fibers in the newly generated scaffold. This method can be use for a large range of natural and synthetic polymers and a large range of solvents. The fiber diameters for this method fall into the range of 200nm-10 μ m, depending on the polymer and solvent chosen as well as parameters such as concentration, air gap distance, and electric field strength (2,3,6,7,11).

It has been experimentally determined that scaffold diameters of the same material have a great impact on cell migration and proliferation. Smaller fiber diameter scaffolds have been shown to promote better cellular adhesion and migration than larger diameter scaffolds (1). It is therefore important to be able to measure the fiber diameter in an efficient accurate way. This measurement would become even more important if any of these scaffolds reach clinical applications and mass production. It is unlikely that a manual measurement can be performed efficiently on a large scale. The author is therefore proposing automated methods for performing fiber diameter measurements from SEM images of fibrous scaffolds.

Manual Method for Fiber Diameter Measurement

Although there is no validated standard manual method for measurement of fiber diameters from SEM images of scaffolds, there is a generally accepted manual method, which is frequently used to quantify fiber diameters. The image of the scaffold is opened in image processing software such as ImageJ (NIH) or UTHSCSA ImageTool. The scale is set based on the pixel/scale bar ratio, which is obtained by measuring the scale bar in pixels and providing length of the scale bar in metric units. The distance tool of the software is then used to acquire 20-100 measurements of fiber widths. In each measurement, an orthogonal segment is drawn beginning and ending on the edges of the fiber. The angle of the segment is determined qualitatively by visual inspection. The placement of the end points on the edges of the fibers is also determined by visual

inspection. The software then calculates the distance between the endpoints in pixels and converts it to metric units previously specified. The average diameter and the standard deviation from that average are reported for each scaffold (2,14-16).

Automated Method for Fiber Diameter Measurement

There is one published, image processing based method for fiber diameter measurement of electrospun scaffolds by Ziabari and coworkers. The grey scale images are converted to black and white images via local thresholding. A distance transform image is constructed from the black and white image with intensity values indicating the distance each white pixel is from the nearest edge. The distance transform image is then thinned and pruned to produce a skeleton of the fiber network with white lines corresponding to the location of the center of each fiber. The intersections of these skeletons are then removed. The four images can be seen consecutively in Figure 1. The new skeleton is used with correlation to the distance transform image to choose only the diameters from the distance transform matrix that do not correspond to intersections. This method was tested on a simulated image with known fiber distribution and an image of a micrograph of the real electrospun web (17).

Figure 1 Sequence of image processing steps of the Ziabari method. a) black and white simulated image, b) distance transform image, c) skeleton, d) skeleton with intersections removed (17)

The main drawback of this method is the difficulty of obtaining a black and white image that accurately represents the boundaries of the fibers when the background is not very well defined or cluttered with more fibers, which is often the case for real fibrous scaffolds. This method works well for networks that do not have many overlapping fibers. The black and white conversion, even with local thresholding, does not work accurately for densely sited fibers in scaffolds. The black and white image ends up with some fibers fused together into one wide fiber, or the border region is placed well outside of the actual edge of the fiber. Therefore the remaining manipulations introduced with this method result in inaccurate measurements of the fiber size from the original grey scale image.

Edge Detection Methods in Image Processing

Edge detection can be accomplished by first or second order derivatives in order to extract meaningful information from changes in intensity values in images. The first order gradient equation is most commonly used for convenience.

$$\nabla F = \begin{bmatrix} G_x \\ G_y \end{bmatrix} = \begin{bmatrix} \frac{\partial F}{\partial x} \\ \frac{\partial F}{\partial y} \end{bmatrix}$$

Since images are discrete sets of values, the derivatives must be approximated by numerical solution. There are many different approaches to finding a numerical solution in order to identify a meaningful discontinuity in an image, which can be labeled as an edge. The most commonly used methods are methods developed by Sobel, Prewitt, Roberts and Canny (4,5). For an image neighborhood in Figure 2, the Sobel approximation is

$$G_x = (a_7 + 2a_8 + a_9) - (a_1 + 2a_2 + a_3)$$

$$G_y = (a_3 + 2a_6 + a_9) - (a_1 + 2a_4 + a_7)$$

a_1	a_2	a_3
a_4	a_5	a_6
a_7	a_8	a_9

Figure 2 Image neighborhood representation (4)

The Prewitt approximation of the gradient is:

$$G_x = (a_7 + a_8 + a_9) - (a_1 + 2a_2 + a_3)$$

$$G_y = (a_3 + a_6 + a_9) - (a_1 + 2a_4 + a_7)$$

The Roberts approximation is simply:

$$G_x = a_9 - a_5$$

$$G_y = a_8 - a_6$$

The Canny method is more complex than taking a maximum gradient as a meaningful edge. A Gaussian filter is employed in order to make method less sensitive to noise. Once the noise is minimized, a derivative in the form of a numerical approximation of the gradient is generated with the local maxima taken as the possible edges. A high and low threshold value is used to determine the strong and weak discontinuities which can be edges. The weak edges are only used if they are connected to a strong edge. Of the above methods, the Canny method is considered to be the most accurate and is often used for various image processing applications (4,5).

Hough Transform

It is often desired not only to identify edges, but also to detect line segments within the image. This can be accomplished by first detecting edges with the methods above and then using the Hough transform to identify lines. The Hough transform can be used to link a set of points to a meaningful segment. A straight line is the simplest of the possible

equations that can be represented using the Hough transform. The familiar equation of a line $y_i = mx_i + b$ can be represented parametrically in the form of $b = -x_i m + y_i$, where in the parameter space (m - b space), there is only one line that corresponds to the specific pair (x_i, y_i) . Therefore, intersections of lines in the m - b space signify that pairs (x_i, y_i) and (x_j, y_j) are on the same line in the x - y plane. Parametric representation in the m - b space can be useful in counting the number of intersections in the m - b plane to represent lines in the original image, however it becomes computationally difficult, when m approaches infinity with vertically sloped lines (4,5).

The linear Hough transform allows for a finite representation of lines in the parametric space. The following equation can be used

$$x \cos \theta + y \sin \theta = \rho$$

where θ is the angle between the x -axis and a normal segment to the line in x - y space passing through the origin, ρ is the length of that segment, or the distance the line is away from the origin in the x - y space. In the θ - ρ space each (θ_i, ρ_i) pair corresponds to a single line in the x - y space. The intensity value in the θ - ρ space corresponds to how many points fall on that line from the x - y space. The local maxima in the θ - ρ space can then be used to identify meaningful lines in the original image by setting a reasonable threshold for how many points should be on a line in order to detect a line (4,5).

Materials and Methods

Test Images

There were multiple types of test images generated for evaluating the accuracy of various methods of fiber diameter measurements. All test images were created via code written in MATLAB. The images have randomly oriented fibers with 10% white noise incorporated into the fiber intensities and into the background intensities. The orientation of the fiber is also random. Each fiber has intensity values increasing towards the central axis of the fiber and decreasing intensity towards the edges. The peak intensity varies randomly from fiber to fiber within a specified range. The flowchart in Figure 3 illustrates the algorithm used to create the test images. The algorithm was implemented in MATLAB.

There were two possible fiber diameter distributions. Narrow distribution restricted the fiber diameters from 0.85-1% of the maximum fiber diameter for that image. Wide distribution restricted the fiber diameters from 2 pixels to the maximum fiber diameter for that image. The maximum diameters ranged from 10-35 pixels. For each fiber the width was calculated randomly within the specified range. There were six images generated with a narrow distribution of fiber diameters and six images with a wide distribution of fiber diameters. The diameters of each fiber in every image were recorded.

Figure 4 shows the wide fiber diameter distribution test images used for testing with maximum fiber diameters ranging from 10-35 pixels. Figure 5 shows the narrow fiber diameter distribution test images, with maximum fiber diameters ranging from 10-35 pixels. The size of each image was set to 1020×650 pixels which is the typical image size used for creating real SEM images of electrospun scaffolds. Magnification and pixel resolution is usually adjusted so the fiber diameter is within the range chosen for test images in this study.

The real SEM images were generously donated by Koyal Garg and Scott Sell from their own research on electrospun scaffolds. Figure 6 shows the eight SEM images used for this study.

Human Data

Five volunteers measured each test image using the conventional manual technique. One hundred diameters were measured per image. Each volunteer was provided with all electronic test images and was directed to use either ImageJ or ImageTool software to view the images and employ the provided distance tool to measure diameters. The data was then collected from each volunteer and used for comparison with other measurement methods. No personal information about the volunteers was collected or recorded.

Overview of Automated Fiber Diameter Measurements

The main challenges in utilizing automated methods for fiber diameter measurement are identifying the boundaries or edges of individual fibers and correctly pairing two edges from the same fiber. Alternate solutions to the identification and pairing problems are presented in each of the five automated methods.

There are two methods that were explored for identifying edges. Both methods are implementations of the Canny edge detection method. The default MATLAB Canny edges detection was used initially, but was then replaced by a custom Canny implementation for improved accuracy of edge detection.

There are three methods that were explored for pairing edges. The first method creates a skeleton of the electrospun web in the image. This skeleton is compared with the edges that were found independently using the edge detection method to identify individual fiber segments. The fiber segments are considered valid if the skeleton and two edges around the skeleton have the exact same slope. The second method uses the sign of gradient to the original picture to assign left or right edges from independently found edges. The left and right edges are then paired if their slope is identical. The final method for pairing valid edges uses the sign of the gradient to assign left and right edges as in the previous method. However, in order to address the existence of numerous discontinuities in fiber edges due to intersections, the Hough transform is used. The descriptions of each complete measurement algorithm are presented in the following sections.

Skeleton Slopes Fiber Diameter Measurement

The first method developed by the author uses elements from the previously described Ziabari method, but varies in the determination of valid fiber edges portion of the method. In order to identify fibers from the background, a black and white image is created via a local threshold algorithm. A skeleton of the black and white image is created by thinning the white/fiber areas of the images and removing the intersections. The skeleton is used to define fibers, but the black and white image is not used to calculate the actual diameters. The binary image does not accurately represent the location of the edges of the fibers; therefore a distance transform would only perpetuate the error. Therefore a standard MATLAB Canny edge detection function was used to determine the location of the edges. Once a fiber is defined with a skeleton and two edges with identical slopes the distance between the two edges is recorded taking into account the inclination of the fiber. Figure 7 illustrates the algorithm developed for this portion of the experiments. The algorithm was implemented in MATLAB. All test images were processed with this method, and the collected data was compared to data from the manual measurements, as well as known diameters for the synthesized images. A simple sample image has been processed with this method to demonstrate the various steps involved. Figure 8 illustrates the various stages of processing this image.

Canny Slopes Fiber Diameter Measurement

This method uses a different principle to define valid left and right edges than the previous method, but uses a similar idea of slope determination to define valid pairs of edges to determine diameters of fibers. The original image is first filtered with a Gaussian filter to minimize noise. A numerical gradient is then taken of the filtered image and used to determine the approximate left and right borders of the fibers in the image, while the MATLAB Canny edge function was used to determine the edges. Positive gradient signifies a left border, while a negative gradient signifies a right border. This combined information is used to define single pixel wide left and right edges of fibers inside the images. Slopes of the left and right edges and their proximity were used to determine corresponding left and right edges of single fibers. The distance between them was calculated using their calculated inclination. Figure 9 illustrates the different stages of this algorithm. The sample image was processed with this method, and the various stages of processing this image with this method are shown in Figure 10. All test images were processed with this method and the resulting data was compared to the know diameters (when possible) and to the data collected from manual measurements as well as the other developed methods. The algorithm was implemented in MATLAB.

Canny Hough Fiber Diameter Measurement

This method uses the same strategy as the previous method to determine where the left and right edges are located, but uses the linear Hough transform to identify individual fibers to calculate their diameters. The left and right edge matrices are created as in the previous method. The Hough transform is applied to each edge matrix. The left edges are not necessarily visible in the same part of the fiber as are the corresponding right edges. Performing the Hough transform allows to choose left and right pairs of edges from the same fiber, without having the pairs to be in the exact same horizontal position as is required by the Slopes method. This method assumes that the fibers are linear and that edges found along the same line in left edges matrix belong to the same edge of the same fiber. Lines with identical inclination from the left and right edges matrices with no lines between them are assumed to belong to the two edges of the same fiber. The diameters are then measured once for each fiber found. Intersections of fibers do not introduce limitations to fiber diameter measurement when this method is applied.

The algorithm for this method, illustrated in Figure 11, was implemented in MATLAB. All test images were processed with this method. The collected data was compared to data from the manual measurements, as well as known diameters for the synthesized images. The sample image was processed with this method. Figure 12 shows the different image processing stages. The gradient images were omitted in this figure since they already appear in Figure 10 (c-d).

Custom Canny Slopes Fiber Diameter Measurement

Determining the location for the edges of each fiber is the most critical element in accurately measuring the fiber diameters. A custom edge function based on the Canny method was written in MATLAB for the purpose of accurate fiber diameter determination. A Gaussian filter is applied to the original image. The gradient is taken of the filtered image. The magnitude of the gradient is thinned to only contain one local maximum, effectively making the edges one pixel wide. The left and right edges are defined by existence of an edge and positive x-direction gradient or existence of an edge and negative x-direction gradient respectively. The pairs of edge segments from the same fiber are then determined. The following steps are the same as in the Canny Slopes fiber diameter measurement algorithm. Moving along each row of the left edges matrix, an edge is paired with a corresponding right edge. The slopes of both are calculated and if identical, a diameter measurement is taken from that segment of the fiber. Figure 13 illustrates the various stages of this algorithm.

This algorithm was implemented in MATLAB and all test images were processed with this method. Recorded data for each image was compared to the known diameters for the simulated images and to human data when known diameters were not available. A sample image was also processed to demonstrate the various stages of this method. Figure 14 shows the resulting stages of processing the sample image with this method.

Custom Canny Hough Fiber Diameter Measurement

This method combines the custom edge detection of the previous method with Hough transform for defining valid fibers and their diameters. The original image is filtered with a Gaussian filter. The numerical gradient approximation is taken of the filtered image. The magnitude of the gradient matrix is thinned to one pixel width by suppressing all non-maxima points. The left and right edges are determined by using the thinned matrix of edges and the x-direction gradient matrix. Every edge corresponding to a positive gradient defines the left edge, while every edge corresponding to a negative gradient defines the right edge.

The linear Hough transform is taken of each edge image. The local peaks within the Hough transform space are taken to define edge lines within the original image. Corresponding line pairs from left and right edges with the same slope are taken to define a fiber if there are no other lines of the same inclination in between the lines of the selected pair. The diameters are calculated between the selected edges.

The algorithm for this method is shown in Figure 15. The method was implemented in MATLAB. All test images were processed with this method and resulting fiber diameters were compared to known and manually measured diameters. Figure 16 shows the various outputs of this method on the sample image, the gradient pictures are not included in this figure since they already appear in Figure 14 (c-d).

Statistical Analysis

Data sets from different methods for each image were compared to determine if differences existed between the different methods and if so which methods were statistically different. One-way analysis of variance (ANOVA) was performed on all data sets from each image to determine whether there were differences. If statistically significant differences existed, the Tukey-Kramer test was performed on data from images with statistical differences between data sets ($\alpha = 0.05$). The MATLAB statistical package was used to perform the statistical analysis. Statistical analysis results such as ANOVA tables and multiple comparison figures can be found in Appendix A.

Results and Discussion

Overview

The graphs in Figures 17-36 demonstrate the resulting average fiber diameters \pm standard deviation for all data sets per each image. Figures 37-55 show the histograms for each data set per test image. One-way ANOVA and Tukey-Kramer multiple comparison test results are summarized in Table 1, Table 2 and Table 3 for narrow fiber diameter distribution, wide fiber diameter distribution and real SEM images respectively. The names of images indicate a statistically significant difference for the pair of data acquisition methods when both methods were applied to that test image.

Manual Method Results

The accuracy of the manual method was quantitatively evaluated by manually measuring fiber diameters of simulated SEM images with known fiber diameters. As can be seen in Table 1, data sets acquired by person 1, 3, 4 and 5 were not statistically different from the known fiber diameters for any of the narrow fiber diameter distribution images. Person 2 collected data sets that were statistically different from the known fiber diameters

for images narrow10 and narrow30. For wide fiber diameter distribution, variation from the known fiber diameters was more notable, since only person 1 and person 5 collected data sets with no statistically significant differences from the known mean diameters. Persons 2 and 4 collected data sets that varied from the known for images wide15 and wide30 respectively, while person 3 collected data varying from the known for images wide10, wide25, and wide20. The variation between the accuracy of the manual method for narrow distribution fibers as opposed to wide distribution fibers can be related to the larger variation in available fiber dimensions to measure. Personal preference plays a role in which fibers are chosen for measurement, and it is possible that different people choose different fibers for measurement, resulting in differences in mean fiber diameter. This difference is not observed while processing the narrow distribution fibers due to a relative lack of choice in fiber diameters. Other sources of error include qualitatively assessing the angle of the fiber and the edges of the fiber via visual inspection instead of quantitative measures.

Tables 1, 2 and 3 also demonstrate that there are considerable statistically significant differences between measurements made by different people of the same test images. Tables 1 and 2 show that although data collected by different people may be statistically accurate compared to the known diameters, it does not mean that there is no significant difference between measurements by different people. For example person 3 and person 4 have both accurately measured the mean fiber diameters from all narrow distribution test images, but their data sets have a statistically different means for narrow15, narrow20 and narrow25.

Skeleton Slopes Fiber Diameter Measurement Results

This method showed consistent underestimation of the fiber diameters for the narrow distribution images as can be seen in Figures 17-22. It is also considerably inconsistent with the known diameters for those images as can be seen in Table 1. This method was more successful at processing the wide distribution test images than the narrow distribution images as can be seen in Table 2. Only images wide10 and wide30 were not accurately measured with this method. The sources of error for this method include the creation of the skeleton to identify the relative position of the fibers, and the accuracy of the location of the edges found for each fiber. Due to the conversion to a binary image, some fibers fuse into one, and the skeleton only reflects the position of one of the fibers, therefore some fibers are not measured even if their edges were found during edge detection. This method is very sensitive to accurate conversion to a binary image, which cannot be accurately standardized for all images. The binary conversion parameters can vary from image to image increasing the need for user input and rendering this method impractical.

When compared to the manually obtained data for real SEM images, this method yielded some statistically significant differences. It is difficult to assess the validity of such comparison, since there are no known fiber diameters for these images, and inconsistencies with some of the people data does not necessarily translate to inaccurate measurements.

Canny Slopes Fiber Diameter Measurement Results

This method was shown to process a larger number of fibers compared to the previous method. However the accuracy of this measurement does not appear to surpass the accuracy of the previous method as can be seen in Table 1 and Table 2, when comparing this method (DCS) with the known (act) diameters. Table 2 does show a considerable reduction in error, since there was a significant error in processing only two images. The major source of error is therefore the detection of the location of the edges of the fibers as opposed to fiber selection bias. As can be seen in Table 3, this method found statistically different mean fiber diameters from all manually acquired measurements of almost all real SEM images. This result in combination with the inaccurate measurements of known fiber diameter data, indicates that this method is not ideal for fiber diameter measurement of electrospun scaffolds.

Canny Hough Fiber Diameter Measurement Results

The results of this method also show significant inaccuracies based on comparison to known fiber diameters with narrow distribution, which is illustrated in Table 1 while comparing this method (DCH) with known (act) diameters. This measurement method applied to wide fiber diameter distribution test images yielded only two statistically

different results for wide10 and wide15. The differences between this method and manually acquired data for real SEM images can be seen in Table 3. It is highly likely that this method produced an inaccurate measurement for SEM5, SEM6 and SEM7 since it did not agree with any of the manually acquired data sets for these images. It is unlikely that all manually acquired data sets for these images are inaccurate. Since the previous two methods and this method differ in the way they find pairs of valid edges, but are the same in the way they determine the edge locations, the major source of error for this method is the same as the previous two methods. The edge location it appears to be inaccurate, rendering any methods using this edge location technique, impractical. An added source of error for this method is the requirement that the fibers be linear, since a straight line equation is fitted to the points on edges found. The real SEM images that had many curved fibers yielded fewer measurements with this method, since fewer long straight segments existed in the image.

Custom Canny Slopes Fiber Diameter Measurement Results

The accuracy of the Custom Canny Slopes (CCS) method has been validated by comparison to the known mean diameters, which can be seen in Table 1 and Table 2. The mean diameters acquired with this method were not statistically different from any of the known diameters for the narrow and wide distribution test images. As can be observed in Table 3, when this method was applied to real SEM images of electrospun scaffolds, the

mean diameters measured with this method were consistent with at least one or more manually obtained fiber diameter means for the corresponding images. This method is therefore considered to be an equivalent alternative to the manual measurement of fiber diameters from processing of SEM images.

Custom Canny Hough Fiber Diameter Measurement Results

This method performed in a similar way to the Custom Canny Slopes Method, as can be seen in Table 1 and Table 2 when comparing this method (CCH) to the known fiber diameters (act). There was a considerable drawback to this method, when it was applied to real SEM images. It performed reasonably well, when processing images with straight fibers, however due to its inherent feature of linear fit to edges for the selection of valid edge pairs; it was not able to process SEM images with a large proportion of curved fibers as can be seen in Table 3 for SEM5 and SEM7. The SEM images that had relatively straight fibers were processed with statistically equivalent results to three or more manually obtained fiber diameter means for corresponding images. This method is therefore considered to be equivalent to the manual measurement of fiber diameters of electrospun scaffolds with straight fibers.

Table 3 Multiple comparison of the means for real SEMs ($\alpha=0.05$)

Conclusion

Five automated methods and the manual method for measuring fiber diameters of electrospun scaffolds were evaluated for accuracy by processing simulated images with known fiber diameters via all methods. It was determined that the manual method does provide accurate measurements of the mean fiber diameter with $p < 0.05$. The Skeleton Canny Slopes, Default Canny Slopes, and Default Canny Hough methods were shown to provide inaccurate measurements. The primary reason for these inaccuracies was determined to be the inaccurate determination of fiber edge locations. All three methods use the default Canny function to determine the fiber edge location. The methods vary in terms of identifying valid pairs of edges, however there did not appear to be an appreciable instance of wrong pairs of left and right edges, therefore the only appreciable source of error is the edge detection.

The Custom Canny methods did not show the same inaccuracies. The Custom Canny Slopes method was found to be accurate when applied to the simulated images ($p < 0.05$), and it was also determined to be equivalent to the manual method when applied to real SEM images of electrospun webs. The Custom Canny Hough method produced statistically equivalent mean fiber diameters to known values when applied to the simulated images. It also provided statistically equivalent mean fiber diameters to the manual method values for real SEM images of scaffolds with straight fibers. This method is not applicable for scaffolds with curved fibers. The optimal method is the Custom Canny

method, since it produced statistically accurate measurements, which are equivalent to the manual method

Future work will focus on improvements in the implementation of the Custom Canny Slopes method, potentially using C or C++ for coding the program, since MATLAB is not ideal for speedy computational tasks. Another direction that can be pursued is developing a non-linear generalized Hough transform to choose individual fibers. Fitting a curve to a fiber edge would eliminate the problem of the Custom Canny Hough method, since non-linear stretches of fibers could be identified. It would also eliminate the problem of counting the same fiber multiple times as is done in the Custom Canny Slopes method. Parametrically expressing a non-linear curve equation is a very difficult computational problem. Each additional parameter to the Hough transform, adds another dimension to the parametric representation of Hough space. For example the equation of the circle would have three parameters (center coordinates and radius) and therefore three-dimensional Hough Space. Ideally a generalized Hough transform would be used with different parameters, but even with just four parameters (for example a parabola) the computational problem becomes overwhelming for practical applications at this time.

APPENDIX B: Resulting Images for Skeleton Slopes Method

The following images were processed with the Skeleton Slopes fiber diameter measurement method. The fiber diameters per image can be found in the results section. The following figures, the determined valid edges per image were superimposed over the corresponding original image. Red and blue segments respectively represent the left and right edges of the valid edge pairs found with this method.

APPENDIX E: Resulting Images for Custom Canny Slopes Method

The following images were processed with the Custom Canny Slopes fiber diameter measurement method. The fiber diameters per image can be found in the results section. In the following figures, the determined valid edges per image were superimposed over the corresponding original image. Red and blue segments respectively represent the left and right edges of the valid edge pairs found with this method.

APPENDIX F: Resulting Images for Custom Canny Hough Method

The following images were processed with the Custom Canny Hough fiber diameter measurement method. The fiber diameters per image can be found in the results section. In the following figures, the determined valid edges per image were superimposed over the corresponding original image. Red and blue segments respectively represent the left and right edges of the valid edge pairs found with this method.

VITA

Anna Alexandra Bulysheva was born on July 11th, 1984 in Novosibirsk, Russia. She moved to Charlotte, NC in her teens and graduated from Charlotte Country Day School in 2002. She attended and graduated in 2006 from the University of North Carolina at Chapel Hill with a Bachelor of Science degree in Biology with a minor in Physics. After graduating with an undergraduate degree, Anna Bulysheva conducted radiofrequency ablation research as a research associate in the Computer Science Department of UNC-Chapel Hill. In 2007 she matriculated at the Virginia Commonwealth University to pursue her graduate education in Biomedical Engineering.
