Abstract. The attribute selection techniques for supervised learning, used in the preprocessing phase to emphasize the most relevant attributes, allow making models of classification simpler and easy to understand. The algorithm (SOAP: Selection of Attributes by Projection) has some interesting characteristics: lower computational cost ($O(m n \log n)$ m attributes and n examples in the data set) with respect to other typical algorithms due to the absence of distance and statistical calculations; its applicability to any labelled data set, that is to say, it can contain continuous and discrete variables, with no need for transformation. The performance of SOAP is analyzed in two ways: percentage of reduction and classification. SOAP has been compared to CFS [4] and ReliefF [6]. The results are generated by C4.5 before and after the application of the algorithms.

1 Introduction

The data mining researchers, especially those dedicated to the study of algorithms that produce knowledge in some of the usual representations (decision lists, decision trees, association rules, etc.), usually make their tests on standard and accessible databases (most of them of small size). The purpose is to independently verify and validate the results of their algorithms. Nevertheless, these algorithms are modified to solve specific problems, for example real databases that contain much more information (number of examples) than standard databases used in training. To accomplish the final tests on these real databases with tens of attributes and thousands of examples is a task that takes a lot of time and memory size.

It is advisable to apply to the database preprocessing techniques to reduce the number of attributes or the number of examples in such a way as to decrease the computational time cost. These preprocessing techniques are fundamentally oriented to either of the next goals: feature selection (eliminating non-relevant attributes) and editing (reduction of the number of examples by eliminating some of them or calculating prototypes [1]). Our algorithm belongs to the first group.

^{*} This work has been supported by the Spanish Research Agency CICYT under grant TIC2001-1143-C03-02.

In this paper we present a new method of attribute selection, called SOAP (Selection of Attributes by Projection), which has some important characteristics:

- Considerable reduction of the number of attributes.
- Lower computational time $O(m \cdot n \log n)$ than other algorithms.
- Absence of distance and statistical calculations: correlation, information gain, etc.
- Conservation of the error rates of the classification systems.

The hypothesis on which the heuristic is based is: “place the best attributes with the smallest number of label changes”. The next section discusses related work. Section 3 describes the SOAP algorithm. Section 4 presents the results. Which deal with several databases from the UCI Repository [3]. The last section summarizes the findings.

2 Related Work

Algorithms that perform feature selection as a preprocessing step prior to learning can generally be placed into one of two broad categories: wrappers, Kohavi [7], which employs a statistical re-sampling technique (such as cross validation) using the actual target learning algorithm to estimate the accuracy of feature subsets. This approach has proved to be useful but is very slow to execute because the learning algorithm is called upon repeatedly. Another option called filter, operates independently of any learning algorithm. Undesirable features are filtered out of the data before induction begins. Filters use heuristics based on general the characteristics of the data to evaluate the merit of feature subsets. As a consequence, filter methods are generally much faster than wrapper methods, and, as such, are more practical for use on data of high dimensionality. FOCUS [2], LVF [14] use class consistency as an evaluation meter. One method for discretization called Chi2 [13]. Relief [6] works by randomly sampling an instance from the data, and then locating its nearest neighbour from the same and opposite class. Relief was originally defined for two-class problems and was later expanded as ReliefF [8] to handle noise and multi-class data sets, and RReliefF [12] handles regression problems. Other authors suggest Neuronal Networks for an attribute selector. In addition, learning procedures can be used to select attributes, like ID3 [10], FRINGE [9] and C4.5 [11]. Methods based on the correlation like CFS [4], etc.

3 SOAP: Selection of Attributes by Projection

3.1 Description

To describe the algorithm we will use the well-known data set IRIS, because of the easy interpretation of their two-dimensional projections.

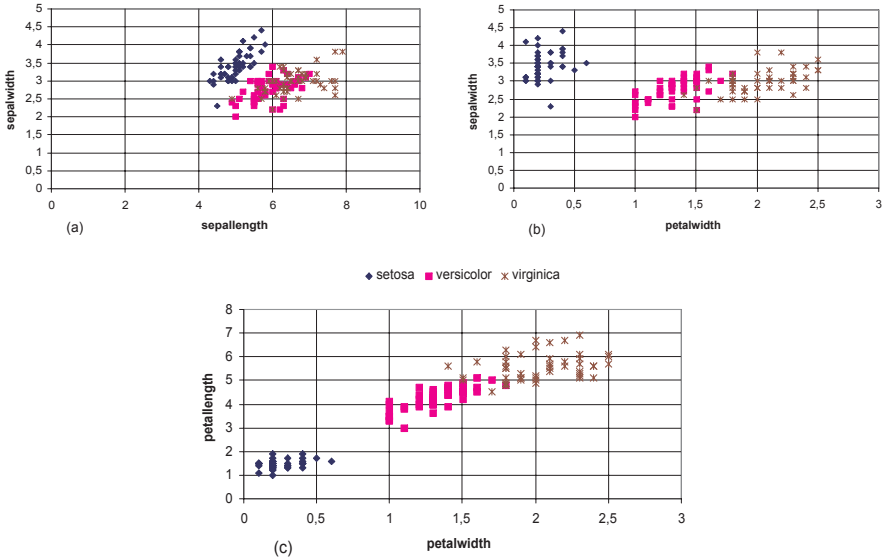

Fig. 1. Representation of Attributes (a) *Sepalwidth-Sepallength* and (b) *Sepalwidth-Petalwidth* (c) *Pepallength-Petalwidth*

Three projections of IRIS have been made in two-dimensional graphs. In Figure 1(a) it is possible to observe that if the projection of the examples is made on the abscissas or ordinate axis we can not obtain intervals where any class is a majority, only can be seen the intervals $[4.3,4.8]$ of Sepallength for the Setosa class or $[7.1,8.0]$ for Virginica. In Figure 1(b) for the Sepalwidth parameter in the ordinate axis clear intervals are not appraised either. Nevertheless, for the Petalwidth attribute is possible to appreciate some intervals where the class is unique: $[0,0.6]$ for Setosa, $[1.0,1.3]$ for Versicolor and $[1.8,2.5]$ for Virginica. Finally in Figure 1(c), it is possible to appreciate the class divisions, which are almost clear in both attributes. This is because when projecting the examples on each attribute the number of label changes is minimum. For example, it is possible to verify that for Petalwidth the first label change takes place for value 3 (setosa to Versicolor), the second in 4.5 (Versicolor to Virginica). there are other changes later in 4.8, 4.9, 5.0 and the last one is in 5.1.

SOAP is based on this principle: to count the label changes, produced when crossing the projections of each example in each dimension. If the attributes are in ascending order according to the number of label changes, we will have a list that defines the priority of selection, from greater to smaller importance. SOAP presumes to eliminate the basic redundancy between attributes, that is to say, the attributes with interdependence have been eliminated. Finally, to choose the more advisable number of features, we define a reduction factor, RF, in order to take the subset from attributes formed by the first of the aforementioned list.

Before formally exposing the algorithm, we will explain with more details the main idea. We considered the situation depicted in Figure 1(b): the projection of the examples on the abscissas axis produces a ordered sequence of intervals (some of them can be a single point) which have assigned a single label or a set of them: [0,0.6] Se, [1.0,1.3] Ve, [1.4,1.4] Ve-Vi, [1.5,1.5] Ve-Vi, [1.6,1.6] Ve-Vi, [1.7,1.7] Ve-Vi, [1.8,1.8] Ve-Vi, [1.9,2.5] Vi. If we apply the same idea with the projection on the ordinate axis, we calculate the partitions of the ordered sequences: Ve, R, R, Ve, R, R, R, R, R, R, R, R, R, R, Se, R, Se, R, Se, where R is a combination of two or three labels. We can observe that we obtain almost one subsequence of the same value with different classes for each value from the ordered projection. That is to say, projections on the ordinate axis provide much less information than on the abscissas axis.

In the intervals with multiple labels we will consider the worst case, that being the maximum number of label changes possible for a same value.

The number of label changes obtained by the algorithm in the projection of each dimension is: Petalwidth 16, Petalength 19, Sepallenth 87 and Sepalwidth 120. In this way, we can achieve a ranking with the best attributes from the point of view of the classification. This result agrees with what is common knowledge in data mining, which states that the width and length of petals are more important than those related to sepals.

3.2 Definitions

Definition 1: Let the attribute A_i be a continuous or discrete variable that takes values in $I_i = [min_i, max_i]$. Then, A is the attributes space defined as $A = I_1 \times I_2 \times \dots \times I_m$, where m is the number of attributes.

Definition 2: An *example* $e \in E$ is a tuple formed by the Cartesian product of the value sets of each attribute and the set C of labels. We define the operations *att* and *lab* to access the attribute and its label (or class): $att: E \times N \rightarrow A$ and $lab: E \rightarrow C$, where N is the set of natural numbers.

Definition 3: Let the *universe* U be a sequence of example from E . We will say that a database with n examples, each of them with m attributes and one class, forms a particular universe. Then $U = \langle u[1], \dots, u[n] \rangle$ and as the database is a sequence, the access to an example is achieved by means of its position. Likewise, the access to j -th attribute of the i -th example is made by $att(u[i], j)$, and for identifying its label $lab(u[i])$.

Definition 4: An *ordered projected sequence* is a sequence formed by the projection of the universe onto the i -th attribute. This sequence is sorted out in ascending order and it contains the value of the projected attribute. For example, in Figure 1(c) for Petalwidth attribute we have 0.1,0.2,0.3,...

Definition 5: A partition in *constant subsequences* is the set of subsequences formed from the ordered projected sequence of an attribute in such a way as to maintain the projection order. All the examples belonging to a subsequence have the same class and every two consecutive subsequences are disjointed with respect to the class. For Petalwidth in Iris, we observe [0.1,0.6][1.0,1.3]... , subsequences with different class.

Definition 6: A *subsequence of the same value* is the sequence composed of the examples with identical value from the i -th attribute within the ordered projected sequence. This situation can be originated in continuous variables, and it will be the way to deal with the discrete variables. In Figure 1(c) for Petalwidth, we have [1] a subsequence of the same value, one, with the same label, and for value [1.5] we have a subsequence with different label.

3.3 Algorithm

The algorithm is very simple and fast, see Fig. 4. It has the capacity to operate with continuous and discrete variables as well as with databases which have two classes or multiple classes. In the ascending-order-task for each attribute, the QuickSort [5] algorithm is used. This algorithm is $O(n \log n)$, on average. Once ordered by an attribute, we can count the label changes throughout the ordered projected sequence. NumberChanges in Fig. 5, considers whether we deal with different values from an attribute, or with a subsequence of the same value (this situation can be originated in continuous and discrete variables). In the first case, it compares the present label with that of the following value. Whereas in the second case, where the subsequence is of the same value, it counts as many label changes as are possible (function ChangesSameValue).

The k first attribute which NLC (number of label changes) under NLClim will be selected. NLClim is calculated applying the follow equation:

$$NLC_{lim} = NLC_{min} + (NLC_{max} - NLC_{min}) * RF \quad (1)$$

RF: reduction factor.

Main Algorithm

```

Input: E training (N examples, M attributes)
Output: E reduced (N examples, K attributes)
  for each attribute i with i in {1..M}
    QuickSort(E,i)
    NLCi = NumberChanges(E,i)
  NLC Attribute Ranking
  Select the K first

```

NumberChanges function

```

Input: E training, i
Output: Number of Label Changes (NLC)
  for each example ej in E with j in {1..N}
    if att(u[j],i) in subsequence of the same value
      NLC += ChangesSameValue()
    else
      if lab(u[j]) <> lastLabel)
        NLC++

```

After applying QuickSort, we might have repeated values with the same or different class. For this reason, the algorithm firstly sorts by value and, in

Fig. 2. Subsequence of the same value (a) two changes (b) seven changes

Fig. 3. Example

case of equality, it will look for the worst of the all possible cases (function ChangesSameValue).

We could find the situation as depicted in Figure 2(a). The examples sharing the same value for an attribute are ordered by class. The label changes obtained are two. The next execution of the algorithm may find another situation, with a different number of label changes. The solution to this problem consists of finding the worst case. The heuristic is applied to obtain the maximum number of label changes within the interval containing repeated values. In this way, the ChangesSameValue method would produce the output shown in Figure 2(b), seven changes. This can be obtained with low cost. It can be deduced counting the class' elements

In Figure 2(a) we can observe a subsequence of the same value with eight elements: three elements are class A, four class B and one C. Applying formula 2 there is no relative frequency greater than half of the elements. Then, the maximum number of label changes is $n_{elem}-1$, seven. In Figure 2(b) we verify it.

From Figure 3 it can be seen that the function ChangesSameValue will return four label changes, because a relative frequency greater than $n_{elem}/2$ exists (class A). Then, the result is $(8-6)*2=4$. In this way, we always will find the maximum number of label changes within the interval containing repeated values.

This algorithm allows working with discrete variables. We consider each projection of this attribute like a subsequence of the same value.

4 Experiments

In order to compare the effectiveness of SOAP as a feature selector for common machine learning algorithms, experiments were performed using sixteen standard data sets from the UCI repository [4]. The data sets and their characteristics are summarized in Table 3. The percentage of correct classification with C4.5, averaged over ten ten-fold cross-validation runs, were calculated for each

algorithm-data set combination before and after feature selection by SOAP (RF 0.35), CFS and ReliefF (threshold 0.05). For each train-test split, the dimensionality was reduced by each feature selector before being passed to the learning algorithms. The same fold were used for each feature selector-learning scheme combination.

To perform the experiment with CFS and ReliefF we used the Weka¹ (Waikato Environment for Knowledge Analysis) implementation.

Table 1 shows the average number of features selected and the percentage of the original features retained. SOAP is a specially selective algorithm compared with CFS and RLF. If SOAP and CFS are compared, only in one dataset (labor) is the number of characteristics significantly greater than those selected by CFS. In six data sets there are no significant differences, and in nine, the number of features is significantly smaller than CFS. Compare to RLF, only in glass2 and diabetes, SOAP obtains more parameters in the reduction process (threshold 0.05 is not sufficient). It can be seen (by looking at the fourth column) that SOAP retained 23,7% of the attributes on average.

Table 1. Number of selected features and the percentage of the original features retained

Data Set	Soap		CFS		RLF	
	Atts	Atts(%)	Atts(%)	Atts(%)	Atts(%)	Atts(%)

(denoted by ◦) or worse (denoted by •) than when performing no feature selection (column 2 and 3). Throughout we speak of results being significantly different if the difference is statistically at the 5% level according to a paired two-sided t test. Each pair of points consisting of the estimates obtained in one of the ten, ten-fold cross-validation runs, for before and after feature selection. For SOAP, feature selection degrades performance on seven datasets, improves on one and it is equal on eight. The reason for why the algorithm is not as accurate is the number of attribute selected, less than three feature. Five of these seven datasets obtain a percentage less than 10% of the original features. The results are similar to ReliefF and a little worse than those provided by CFS. Analyzing the datasets in which SOAP lost to CFS, we can observe breast-c, lymph and sonar, where the number of feature selected by SOAP is 25% of CFS (breast-c 4,1 to 1,5 with SOAP, lymph 8,9-1,8 and sonar 17,8-3). Nevertheless the accuracy reduction is small: breast-c 72,9 (CFS) to 70,24 with SOAP, lymph 75,95-72,84 and sonar 74,38-70,05.

It is interesting to compare the speed of the attribute selection techniques. We measured the time taken in milliseconds to select the final subset of attributes. SOAP is an algorithm with a very short computation time. The results shown in Table 3 confirm the expectations. SOAP takes 400 milliseconds² in reducing 16 datasets whereas CFS takes 853 seconds and RLF more than 3 minutes. In general, SOAP is faster than the other methods and it is independent of the classes

² This is a rough measure. Obtaining true cpu time from within a Java program is quite difficult.

Table 3. Data sets. Time in milliseconds

number. Also it is possible to be observed that ReliefF is affected very negatively by the number of instances in the dataset, it can be seen in “hypothyroid” and “sick”. Eventhough these two datasets were eliminated, SOAP is more than 3 times faster than CFS, and more than 75 times than ReliefF.

Figure 4 summarizes the power of our algorithm, SOAP. It diminishes, in a significant percentage, the number of attributes, obtaining simple classification models, with a computational time lower than that of the other methods and with a similar average accuracy.

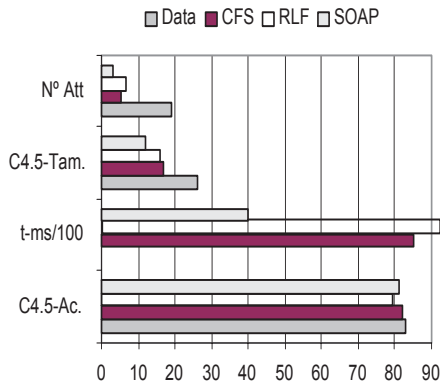

Fig. 4. Summary

5 Conclusions

In this paper we present a deterministic attribute selection algorithm. It is a very efficient and simple method used in the preprocessing phase. A considerable reduction of the number of attributes is produced in comparison to other techniques. It does not need distance nor statistical calculations, which could be very costly in time (correlation, gain of information, etc.). The computational cost is lower than other methods $O(m n \log n)$.
