

## 5. Stratigraphic Observations of Surface Snow Cover

Okitsugu WATANABE\*

Observers: Okitsugu WATANABE, Kazuhide SATOW and Masayuki INOUE

### 5.1. Introduction

Stratigraphic observations of the surface snow cover of Mizuho Plateau were carried out in 1974 - 1975.

The objects of the observations were as follows:

- 1) Estimation of snow accumulation where direct measurement is not feasible.
- 2) Investigation on interaction between the air and the snow cover in connection with process of snow surface formation, metamorphosis of snow layers, and transitional sequences of their regional characteristics.
- 3) Glacial zoning of dry snow area; detailed investigations on oxygen isotope and fission products over a snow profile together with physical properties of a firn layer.

Seven 1-m pits and nine 2-m pits were dug in 1974 - 1975 for snow stratigraphy. Sampling of 10-m snow cores was made at 15 stations including some stations where 2-m pits were excavated. These cores were carried back to Japan for precise analyses. Ram sonde profiles from the surface to a depth of 2 meters were also obtained at 53 stations. Results of studies of six 2-m pits dug and four 10-m core collected during the period of 1971 - 1973 were included in this Chapter.

### 5.2. Methods and results of observation

#### 5.2.1. Pit studies

Studies of pits including six 2-m pits dug in 1969 - 1970 summer are listed in Table 1. Station numbers, date of observation and observed items are summarized in Table 1. Two-meter pits were dug at every 100 km approximately along the traverse routes.

The dimension of the wall of a 2-m deep pit was 2.2 m in depth  $\times$  2.5 m in width. Stratigraphy of the surface snow cover was investigated by a brush-up method on the wall of each 2-m pit. At each observable layer density measurements were made with a density tube. Oxygen isotope samples were collected at a few points from each layer. Grain size was determined at a few points within one observable layer by identifying grains on a millimeter grid card under polarized light. Hardness of snow was measured with Canadian hardness gauge on the same surface wall. Also a Swiss Ram sonde was used to make a hardness profile in the proximity of a pit parallel to the wall and 30 cm from the edge of

---

\* Institute of Snow and Ice Studies, National Research Center for Disaster Prevention, Nagaoka 940.

the pit. Samples for fission products analysis (gross  $\beta$ -activity) were collected from each annual layer identified in situ. The results of 2-m pit observation in 1974 - 1975 summer are shown in Fig. 1 with legend.

The dimension of the wall of an 1-m pit was 1.2 m in depth and 0.5 m in width; the stratigraphy, density, grain size and hardness by Canadian gauge were recorded. Studies of 1-m pits which were made to complement the 2-m pit observation in the 1974 - 1975 summer, are shown in Fig. 2. Numerical data of density and oxygen isotope ratio (analyzed by Kikuo Kato, refer to Chapter IV in this volume) of 2-m pit are given in Table 2-1. The results of 2-m pit observation in the 1969 - 1970 summer are shown in Fig. 3. The numerical data of density are tabulated in Table 2-2.

#### 5.2.2. 2 m depth Ram hardness profiling

The purposes of Ram hardness profiling are as follows:

- 1) Tracing of snow stratigraphy under the similar environmental conditions: it is considered that Ram hardness profiles and existence of key layer (bed) are largely dependent on environmental conditions.
- 2) Determination of regional characteristics of depth hoar formation deduced from Ram hardness profiles.

Vertical profiling of Ram hardness with about 5 cm step to a depth of 2 m was made at every 20 km along the Route Y' and 40 km along the Routes I and J, while the results along Routes S, Z, Y and W in 1970 - 1971 have been reported by Watanabe and Ageta (1972). All the results of Ram hardness profiles from the surface to a depth of 2 m along the route of traverses in 1974 - 1975 are given in Figs. 4 A, B and C. Numerals in diagrams of Fig. 4 indicate the "Key bed", whose definition was given in Watanabe and Ageta (1972). Ram hardness numbers are tabulated in Table 3 with integrated values from the surface to 100 cm in depth and to 180 - 200 cm.

Ram hardness of surface snow suddenly decreased when the elevation reached 2,900 m, and remained considerably low in value for higher elevation than that along Routes I and J.

#### 5.2.3. 10-m core studies

Snow cores 10 m in length were obtained at 19 stations in 1969 - 1975 by the use of a SIPRE type 3-inch corer. Core catalogue is given in Table 4. These cores were wrapped with an aluminum foil and kept in corrugated cardboard boxes stuffed with snow for keeping ice saturated vapor. Cores, transported by ship from Antarctica to the cold laboratory of the Institute of Low Temperature Science, Hokkaido University, Sapporo, has been stored there at an average temperature of  $-20^{\circ}\text{C}$ . Previous to investigation, the core was divided by the following procedure; First a core was cut into two equal halves along the long axis. Then, a slab 1 cm thick for stratigraphic analysis was

sliced from one of the halves along its long axis. The rest of this half-cut core was used for geochemical and texture analyses, after the density measurement was done. The other half was preserved for other purposes. The following examinations were made on each core:

1) Stratigraphy of a core

The snow slab for stratigraphic analysis was examined on light table. Such remarkable textures as well-developed depth hoar layers (meta-layer) and lamina-forming layers (paleo-layer), which retained their original textures during a process of accumulation, and such sheet structures as ice crust and layer boundary were described. The formative process of depth hoar was described in terms of the level defined in the legend. Numbers of ice crusts in multi-layered ice crusts were also recorded.

2) Analysis of physical properties

The density was measured by volume and weight technique. Usually one sample was taken for density measurement from each homogeneous part of a layer, but two or three samples were taken from a thick part.

The grain size (diameter) was measured continuously from surface to 10 m depth with a scale graduated in 0.1 mm.

3) Collection of snow samples for chemical analyses

At least one sample for analysis of oxygen isotope content was collected from each observable layer, but when the layer was thick two or three samples were collected. Samples from those observable layers belonging to an annual layer were used as a whole for gross  $\beta$ -activity.

Stratigraphic profiles of 10 cores out of 19 cores obtained are given in Fig. 5, which consists of two parts: (1) a stratigraphic columner section with remarks at the left; (2) a combination diagram of depth hoar leveling (DHL) by a black histogram, grain size by a white histogram and profile of density at the right side. Profiles of oxygen isotope content and gross  $\beta$ -activity are given of only two stations (H 128 and S 97). Numeral data of density and oxygen isotope content were tabulated in Tables 5 and 6 respectively. Detailed stratigraphic analysis of the 10-m long cores obtained at 19 stations are still under way.

\* Elevation estimated from neighboring stations

+ did, - did not or do not yet

St. : Stratigraphic observation

P : Texture analysis by thin section photograph

$\delta^{18}\text{O}$  : Oxygen isotope ratio analysis

Gr. $\beta$ : Fission products analysis (Gross  $\beta$  activity)

Table 5. Snow density of 10-m cores.
