**Geomicrobiology of Sulfuric Acid Speleogenesis: Microbial
Diversity, Nutrient Cycling, and Controls on Cave Formation**

by

Annette Summers Engel, B.A., M.Sc.

Dissertation

Presented to the Faculty of the Graduate School of

The University of Texas at Austin

in Partial Fulfillment

of the Requirements

for the Degree of

Doctor of Philosophy

The University of Texas at Austin

May, 2004

Acknowledgements

First and foremost, it is because of my family and friends who supported me throughout this long process, and it has been with their encouragement that I was able to complete this work. I honestly think that many of them thought this day would never come.... Now, a new stage of my life begins and I feel fortunate in knowing they champion me. I am greatly indebted to Scott for his love, patience, and strength. Without his devotion and never-ending sacrifices, finishing this work would have been much more difficult. *How many days of your vacations have you surrendered in search of one last stinky spring, or for collecting slime in some godforsaken place?* To Astrid and Jason, I am grateful for our friendship and will fondly remember all the margaritas we shared together. I extend very special thanks to Megan Porter, a truly wonderful person and valued friend. This research would have suffered if not for her collaboration, companionship, and intellectual banter.

I owe much to Phil Bennett and Libby Stern, both caring and supportive individuals, for all their creativity and guidance. They honed my crazed thoughts and refined many ideas. It is still unbelievable to me how these unsuspecting souls quickly embraced the research, donned gas masks with passion, and forcibly slithered into a smelly hole in the ground. Together, after logging some 1665 hours (!!!) in the caves with friends and colleagues, we unburied quite an unforgettable treasure in Lower Kane Cave.

This work was funded in part by the National Science Foundation's Life in Extreme Environments (LExEN) program, the Geology Foundation of the

University of Texas at Austin, and the National Speleological Society. Sample acquisition would not have been possible without the cooperation of the Bureau of Land Management, Cody Office, Wyoming.

Finally, I am especially grateful to my countless friends who took precious time from their lives to help with work in Lower Kane Cave. Their interest and enthusiasm for the research will not be forgotten, and I hope that someday I can repay their kindness. The purpose and heart of a caver, of my friends and companions, are described in the poem *In Praise of Limestone* by W.H. Auden. It is with these words that I end this dedication and begin the story:

If it form the one landscape that we, the inconstant ones,
Are consistently homesick for, this is chiefly
Because it dissolves in water. Mark these rounded slopes
With their surface fragrance of thyme and, beneath,
A secret system of caves and conduits; hear the springs
That spurt out everywhere with a chuckle,
Each filling a private pool...; when I try to imagine a faultless love
Or the life to come, what I hear is the murmur
Of underground streams, what I see is a limestone landscape.

W.H. Auden, excerpt from *In Praise of Limestone*

Geomicrobiology of Sulfuric Acid Speleogenesis: Microbial Diversity, Nutrient Cycling, and Controls on Cave Formation

Publication No. _____

Annette Summers Engel, Ph.D.

The University of Texas at Austin, 2004

Supervisor: Philip C. Bennett

Much of the terrestrial subsurface is inaccessible for study, but caves represent distinctive shallow subsurface habitats where biogeochemical processes can be easily examined. Previously defined speleogenesis models are almost entirely based on abiotic chemical and hydrologic controls, as biological controls on cave formation have not been considered significant. Hydrogen sulfide-rich groundwater discharges from springs into Lower Kane Cave, Wyoming, and the sulfuric acid speleogenesis model was introduced in the early 1970s as a cave enlargement process resulting primarily from hydrogen sulfide autoxidation to sulfuric acid and replacement of carbonate by gypsum on subaerially exposed surfaces. The reduced sulfur compounds serve as rich energy sources for microorganisms that colonize the cave in both subaqueous and subaerial

environments. Several evolutionary lineages of the class “*Epsilonproteobacteria*” dominate the microbial diversity of subaqueous mats, and these microbes support the cave ecosystem through sulfur cycling and chemolithoautotrophic carbon fixation. The “*Epsilonproteobacteria*” occupy microbial mats in additional sulfidic cave and spring habitats, expanding the evolutionary and ecological diversity of these previously unknown organisms. The interior of the Lower Kane Cave microbial mats is devoid of oxygen and this provides habitat for anaerobic metabolic guilds, dominated by sulfate-reducing and fermenting bacteria. These anaerobic groups are responsible for autochthonous hydrogen sulfide and volatile organosulfur gas production. Cycling of carbon and sulfur compounds by the subaqueous microbial communities affects sulfuric acid speleogenesis. Compared to the total flux of sulfide into the cave, little hydrogen sulfide volatilizes into the cave atmosphere or oxidizes abiotically. Instead, the primary loss mechanism is from subaqueous microbial sulfur oxidation. Consequently, despite the cave waters being slightly supersaturated with respect to calcite, the “*Epsilonproteobacteria*” generate sulfuric acid as a byproduct of their metabolism, locally depress pH, and focus carbonate dissolution. The hydrogen sulfide that volatilizes into the cave air is oxidized at the cave walls where interactions between cave-wall biological and physicochemical factors influence subaerial speleogenesis and low temperature authigenic quartz precipitation. The recognition of the geomicrobiological contributions to subaqueous and subaerial carbonate dissolution fundamentally changes the model for sulfuric acid speleogenesis and the mechanisms for subsurface porosity development.

Chapter 1: Introduction

Microbial processes occurring in the absence of light have generally been considered insufficient to support ecosystem-level processes. Until recently, the dogma has been that life in the subsurface, if present and metabolically active, is dominated by heterotrophic consumption of surface-derived carbon. But the absence of light energy does not preclude life, as chemosynthesis also provides sustainable energy. Reactive rock surfaces and mineral-rich groundwater provide an assortment of potential energy sources for specialized microorganisms, defined as chemolithoautotrophs (literally a ‘self-feeding rock-eater’), that gain cellular energy from the chemical oxidation of inorganic compounds and fix inorganic carbon. Consequently, chemolithoautotrophs play important roles in global chemical and ecosystem processes, as they serve as catalysts for reactions that would not otherwise occur or would proceed slowly over geological time.

While soil and shallow bedrock (<200 m depth) are major habitats for subsurface organisms, viable microbial communities are now known to be ubiquitous in the deep subsurface, including sedimentary basins, basaltic and granitic aquifers, geothermal systems, and caves. For the most part, this is attributable to chemolithoautotrophy. These environments are often limiting in organic carbon and couple relatively constant physicochemical conditions with protection from surface hazards, such as solar radiation or cosmological events. Some researchers have suggested that modern subsurface habitats are analogous to environments where life may have originated and existed on primitive Earth, or

even possibly in extraterrestrial systems (e.g., Schopf, 1983; Stevens, 1997; Pedersen, 2001). Consequently, it has been hypothesized that total subsurface primary productivity may even surpass the activity of surface photosynthetic organisms (Stevens, 1997; Gold, 1999). With this, the functional role of active microorganisms in subsurface systems remains poorly understood, although the potential for their impact on the surrounding geologic framework has recently been suggested (e.g., Ehrlich, 1996; Bachofen et al., 1998; Ben-Ari, 2002; Newman and Banfield, 2002). Because most subsurface habitats are relatively difficult to access, little is known about the biodiversity, community structure, ecosystem functioning, or nutrient cycling of terrestrial chemolithoautotrophically-based microbial ecosystems, or how these specialized microbes have impacted geochemical and geological processes through time.

In this study I investigate the interrelationships between microbial ecosystems and the surrounding geologic and hydrologic framework in aphotic, sulfidic habitats in the shallow subsurface. Groundwater bearing dissolved hydrogen sulfide, but negligible allochthonous carbon, discharges as springs into cave passages of several known systems, including the Lower Kane Cave, Wyoming. Hydrogen sulfide is an energy-yielding substrate for microorganisms, and consequently sulfidic caves are frequently colonized by thick subaqueous microbial mats dominated by sulfur-oxidizing bacteria. Although these caves are <50 m below the Earth's surface, they offer a valuable opportunity to examine biologic-geologic interactions and microbial processes occurring in the absence of sunlight. The microbial ecology, geochemistry, and nutrient cycling investigated in

Lower Kane Cave can be used as proxies for similar processes occurring in deeper subsurface settings, such as carbonate aquifers, that can otherwise only be accessed through wells.

MICROORGANISMS IN SULFIDIC CAVES

Caves represent distinctive habitats with complete darkness, relatively constant air and water temperatures, and a limited supply of easily degradable organic matter. Since darkness precludes photosynthetic activity, the minimal organic matter found in caves is usually derived from dead photosynthetic material that has been carried into the subsurface system via air currents, speleothem dripwaters, stream drainage, or as guano from cave-dwelling organisms (Poulson and Lavoie, 2000). Early biospeleologists assumed that microorganisms in caves were secondary degraders and were food sources for higher organisms because chemosynthetic activity was not evident or was limited in most cave systems (Caumartin, 1963; Northup and Lavoie, 2001). However, more recent research in caves, including those with sulfidic water, demonstrate that bacteria generate energy as primary producers and sustain complex cave ecosystems (Sarbu et al., 1996; Porter, 1999; Sarbu et al., 2000; Vlasceanu et al., 2000; Engel et al., 2001). For instance, chemolithoautotrophy, at the base of the Movile Cave, Romania, ecosystem, supports the most diverse cave ecosystem known, with 33 new cave-adapted taxa identified from 30 terrestrial invertebrate species (24 are endemic) and 18 species of aquatic animals (9 endemic) (Culver and Sket, 2000). Essentially, the chemolithoautotrophs utilize chemical energy that would otherwise be lost to the system.

Since the 1986 discovery of the chemolithoautotrophically-based ecosystem in Movile Cave (Sarbu et al., 1996), studies of sulfur-based, subaqueous cave microbial communities (i.e., living in microbial mats) have included geochemical and microscopy surveys (Hubbard et al., 1986; Olson and Thompson, 1988; Hubbard et al., 1990; Stoessell et al., 1993; Brigmon et al., 1994; Mattison et al., 1998; Garman, 2002), phylogenetic investigations based on 16S ribosomal RNA gene (rDNA) sequence analyses (Angert et al., 1998; Engel et al., 2001; Brigmon et al., 2003), stable isotope ratio analyses (Sarbu et al., 1996; Vlasceanu et al., 1997; Sarbu et al., 2000), and cultivation studies (Brigmon et al., 1994; Vlasceanu et al., 1997; Engel et al., 2001; Brigmon et al., 2003). Moreover, chemolithoautotrophic communities from subaerial cave-wall surfaces, associated with a variety of mineral deposits, have also been described (Maltsev et al., 1997; Hose et al., 2000; Vlasceanu et al., 2000; Northup and Lavoie, 2001; Northup et al., 2003; Barton et al., 2004). Sulfidic caves often have cave-wall biofilms that develop on gypsum and elemental sulfur surfaces, with exceedingly acidic condensation droplets, ranging from pH 0 to 4.

SULFURIC ACID SPELEOGENESIS

Karst landscapes form where soluble rocks dissolve, resulting in numerous geomorphic features including caves and conduit drainage systems (e.g., White, 1988; Ford and Williams, 1989; Palmer, 1991). The classic model for karst development (speleogenesis) involves carbonic acid dissolution, usually at shallow depths rarely far below the water table. More recently, sulfuric acid speleogenesis was proposed by S.J. Egemeier from work in Lower Kane Cave (Egemeier, 1981;

Hill, 1990; Jagnow et al., 2000). Based on observations of H₂S-bearing thermal springs, extensive gypsum deposits, and gypsum-replaced limestone cave walls, Egemeier (1981) proposed the original sulfuric acid speleogenesis model to include the volatilization of H₂S from the groundwater to the cave atmosphere and H₂S oxidation to sulfuric acid on moist subaerial surfaces, where the acid reacts with and replaces carbonate with gypsum:

Gypsum, which spalls from the cave walls, easily dissolves into groundwater, and the net result is mass removal and an increase in void volume. Cave formation due to sulfuric acid is now recognized in several active sulfidic caves in the United States, Romania, Italy, and Mexico (van Everdingen et al., 1985; Hubbard et al., 1990; Galdenzi and Menichetti, 1995; Sarbu et al., 1996; Hose et al., 2000; Sarbu et al., 2000), as well as in ancient hypogene caves, e.g. Carlsbad Cavern, New Mexico (Hill, 1990; Polyak et al., 1998). In addition to the subaerial processes, cave formation due to sulfuric acid in the Guadalupe Mountains has also been attributed to sulfuric acid dissolution at or just below the water table (Hill, 1990; Palmer, 1991; Jagnow et al., 2000).

Nearly all of the studies regarding sulfuric acid speleogenesis assumed that H₂S was oxidized, and consequently sulfuric acid produced, by abiotic processes (e.g., Egemeier, 1981). The role of sulfuric acid-generating bacteria in cave formation, while previously alluded to, has never been substantiated (Symk and Drzal, 1964; Hubbard et al., 1990; Palmer, 1991; Brigmon et al., 1994; Hill, 1995; Lowe and Gunn, 1995; Sarbu et al., 1996; Vlasceanu et al., 1997; Angert et al.,

1998; Hill, 2000; Hose et al., 2000; Palmer and Palmer, 2000; Sarbu et al., 2000; Vlasceanu et al., 2000; Engel et al., 2001). This study reexamines Lower Kane Cave, focusing not only on the microbial diversity of the cave, but also on the role microorganisms play in cave formation.

PRIMARY FIELD SITE: LOWER KANE CAVE, WYOMING

The Bighorn Basin

The Kane Caves are located in the Bighorn Basin near Lovell, Wyoming, on the western margin of the Bighorn and Pryor Mountain Belts (Figure 1-1). The mountains are Precambrian-cored anticlinal structures of Laramide age (late Cretaceous to Eocene). The Bighorn Basin is a large asymmetric structural basin that contains Cambrian to Quaternary sedimentary rocks. Along the flanks of the basin, near the cities of Thermopolis, Lovell, and Cody, there are structural anticlines associated with deep thrust faults and mountain uplift. The basin is well known for its extensive Paleozoic oil fields, including the Spence Dome field (Madison Limestone, Mississippian) south of the Kane Caves on the western side of the Bighorn River, the Crystal Creek field (Madison Limestone) to the east of the Bighorn River, and the Byron, Garland, Frannie, Alkali Flats, and Goose Egg fields (Pennsylvanian through Cretaceous strata) west and northwest of the Kane Caves (Stone, 1967). Many of the Tensleep (Pennsylvanian) and Phosphoria (Permian) fields contain high hydrogen sulfide gas (Biggs and Espach, 1960).

Thermal and non-thermal springs discharge along the flanks of the basin, commonly where faults are exposed at the surface (e.g., Five Springs at the Five Spring Fault) or where a river dissects an anticline (e.g., Spence Spring at the

Bighorn River level in the Sheep Mountain anticline) (Figure 1-1) (Egemeier, 1973, 1981; Heasler and Hinckley, 1985). Anomalous thermal gradients and groundwater temperatures have been recorded from sulfidic waters in the following areas: 1) southeast of the Little Sheep Mountain anticline south of Lovell, 2) within the Sheep Mountain anticline north of Greybull, 3) the region surrounding Thermopolis and the Thermopolis anticline, and 4) near Cody in the vicinity of the Shoshone River (Heasler and Hinckley, 1985). Groundwater circulation within the Paleozoic aquifers of the basin is controlled by flow along extensional fractures in fault-cored anticlinal or monoclinal folds (Jarvis, 1986; Spencer, 1986).

Karst topography is rarely exposed within the Bighorn Basin, or in the Bighorn or Pryor Mountains. The main cave-forming unit in the region is the Madison Limestone, although small caves and pits also form within the Bighorn Dolomite (Ordovician) at higher elevations within the Bighorn Mountains (Hill et al., 1976). There are numerous pits and small caves in the Bighorn Mountains where these units are exposed, and where Mississippian-Triassic strata are exposed in Little Sheep and Sheep Mountains due to dissection of the anticlines by the Bighorn River (Figure 1-1). Most caves north of these anticlines and within the Bighorn Mountains are epigenic systems (Hill et al., 1976), while several cave systems, especially larger ones, formed or were modified by hypogenic processes involving sulfuric acid (Hill et al., 1976; Egemeier, 1981). Lower Kane Cave and Upper Kane Cave both formed from sulfuric acid speleogenesis in the upper member of the Madison Limestone at the apex of the Little Sheep Mountain anticline along the Bighorn River (Figure 1-1). Lower Kane Cave has 325 m of

mapped horizontal length, of which 180 m is stream passage (Figure 1-2). There is only one known entrance into Lower Kane Cave. Upper Kane Cave is a dry cave 30 m above Lower Kane Cave, with 290 m of total horizontal length. Upper Kane Cave has extensive gypsum deposits.

Several other caves and springs are located along the Bighorn River in the vicinity of the Kane Caves (Figures 1-1 and 1-3). PBS spring, which is slightly thermal and sulfidic, discharges from the upper member limestone/dolostone of the Phosphoria Formation at the edge of Little Sheep Mountain along the Little Sheep Mountain fault (Figure 1-3). Hellsport Cave (Egemeier, 1981), or Coon Smell Cave (Hill et al., 1976), is 20 m long and has a thermal, sulfidic spring that discharges at the back of the cave. Salamander Cave is < 3 m long and has a large non-thermal, non-sulfidic spring (Figure 1-3). Spence Cave, in the Sheep Mountain anticline, also formed from sulfuric acid speleogenesis within the Madison Limestone along the Bighorn River (Figure 1-1) (Egemeier, 1973; 1981). Spence Cave is large, has several passage levels, and is similar to Upper Kane Cave in that it has dry passages and gypsum throughout (for a cave map and a complete description, refer to Egemeier, 1973 and 1981). Thermal, sulfidic springs discharge at river level within the Sheep Mountain anticline. The Bighorn-Horsethief Cave system is located 30 km north of the Kane Caves on the Wyoming-Montana border in the Bighorn Canyon (Hill et al., 1976) (Figure 1-1). This system is similar to Spence and Upper Kane Caves. Across the Bighorn Basin near Cody are the Spirit Mountain Caverns, with gypsum mineralization throughout the cave and reportedly high concentrations of H₂S at lower elevation passage levels (Hill et al., 1976).

Although not in the Bighorn Basin, Stinkpot Cave, near Jackson Hole along the Hoback River, also has sulfidic water and microbial mats (Hill et al., 1976).

Lower Kane Cave

General Cave Description

During this study (1999-2003) there were four springs discharging into the Lower Kane Cave passage (Figure 1-2). The Fissure, Upper, and Lower Springs issue from a fissure in the cave floor and Hidden Spring emerges from a hole in mud. The fissure in the cave floor, which corresponds to a fracture in the cave ceiling, is continuous throughout the entire length of the cave. There appears to be minimal offset of this fracture (<10 cm). The fissure is disrupted in places by secondary calcite that has precipitated over the open fracture; ~10 to 30 cm-wide holes through the calcite reveal the water-filled fissure underneath. In some places in the back of the cave the fracture is filled with sediment and/or gypsum. Faults with measurable offset are perpendicular to this continuous fracture (Figure 1-2), and these faults correspond to the springs outlets. Additionally, a resistant breccia composed of chert and limestone clasts with dolomitized cement protrudes into the passage at these fault zones.

Hydrology of the cave springs has a complex history, evident from recent exploration of the cave. During the study there were two open water-filled fissures near the back of the cave (Figure 1-4); no flow was observed, although Egemeier reports that the Terminal Spring flowed in 1969 (Egemeier, 1973). In 1999, the back of the cave near the Fissure Spring and Iron Pool was dry, and only the Iron Pool (Figure 1-4B) had water and red-pigmented biological material and

mineralization in the orifice. In 2000, sulfidic water discharged from the Fissure Spring (Figure 1-5A) and the back of the cave had 1-5 cm of water in the passage and thick orange- to red-colored microbial mats. As a consequence, a stream flowed from the Fissure Spring, along the north side of the cave wall and under gypsum mounds, into the Lower Spring orifice where it mixed with sulfidic water. During the late spring 2003 sampling trip, there was no discharge from the Fissure Spring, but flow reinitiated several days later. White microbial filament bundles are found below the Fissure Spring orifice (Figure 1-5B and 1-5C).

The Upper Spring discharges $\sim 6 \text{ L}\cdot\text{s}^{-1}$ from a sediment-filled hole in a large pool, as estimated from salt-dilution traces (Figure 1-6A, 1-6B). The Upper Spring pool is ~ 2.5 m wide and up to 0.5 m deep, with white filament bundles on the pool edge and sediment bottom (Figure 1-6C). A stream channel, ranging from 5 to 10 cm in depth, flows from the orifice pool toward the cave entrance, and white filamentous mats fill the channel (Figures 1-7A, 1-7B). Because of underflow from the Fissure Spring, oxygenated water seeps into the Upper Spring pool and mixes with the incoming sulfidic water, allowing for the oxidation of iron sulfides. An area halfway between the Upper and Lower Spring orifices has a seep in which water emerges from under a gypsum pile (Figure 1-8A). A thick (~ 15 cm) red mat forms 5 cm from the gypsum pile (Figure 1-8B).

The Lower Spring has the deepest measurable orifice opening (2 m), and the orifice walls are coated with gray sediment/biological material and long white microbial filament bundles (Figure 1-9A). The water spills over the limestone lip, and a thick white mat develops downstream (Figure 1-9B). In early May 1999 the

Lower Spring microbial mat extended for > 2 m from the orifice, but following back-flooding of the Bighorn River June 1999, the mats were destroyed and consequently a mat <1 m length was present until 2003 when the mat again reached ~2 m. In 2001 through 2003, a slight trickle of sulfidic water issued from a small (~20 cm) hole in river mud at Hidden Spring (Figure 1-2), and sparse white filaments have been observed.

The Bighorn River infrequently floods Lower Kane Cave (Figure 1-10). The cave was flooded in May 1999, corresponding to a peak stage of 7.57 ft above the gaging station, approximately 1 km downstream from the cave (United States Geological Station (USGS) station #06279500 at Kane, Wyoming; 3660 ft above msl). The river stage and discharge records are maintained by the USGS (<http://waterdata.usgs.gov/nwis/sw>). Based on the available data, the minimum river stage required to flood the cave entrance is at least 7.57 ft. Consequently, there have been at least seven times since 1956 when the cave may have flooded (Figure 1-10). The consequences of flooding are believed to be moderately significant to the Lower Spring microbial mats. Because of a slight floor gradient, a river stage of 7.57 ft would backflood river water to approximately the end of the Upper Spring microbial mats, but the back of the cave and the Fissure Spring area would not be impacted.

There have not been any direct measurements to determine the age of Lower Kane Cave, but the timing of cave formation is loosely constrained by Bighorn River terraces. There is a small remnant terrace 24-m above the present river level near the entrance of Upper Kane Cave and a small terrace at the Lower Kane Cave

entrance (approximately 6 m above present river level). The 24-m terrace corresponds to a larger erosional terrace across the river, referred to as the Powell-Emblem or Sanatarium bench (Reheis, 1984). Egemeier (1981) suggests that this terrace may correspond to the Bull Lake glaciation, from 40 to 130 ka, but Reheis (1984) postulates that the 24-m terrace is much older, from 92 to 161 ka. Depending on the timing of emplacement of the upper terrace, the river level terrace may correlate to 38 ka, but also to the Pinedale glaciation at 10 ka. Additional research is needed to resolve this issue and to help constrain the age of the caves along the Bighorn River.

A Note Regarding Safety in Lower Kane Cave

Hydrogen sulfide (CAS:7783-06-4) is a colorless flammable gas (STEL = 15 ppm, IDLH = 100 ppm) that can cause headaches and nausea with prolonged low-level exposure (Beauchamp et al., 1984). Above 20 ppm, H₂S causes eye and mucous membrane irritation, and prolonged exposure can result in pulmonary edema. At all times while researchers were present, Lower Kane Cave air was monitored for H₂S, CO, and P_{O2} using an MSHA approved multigas monitor (PhD Ultra Atmospheric Monitor, Biosystems, Middleton, CT). While the concentration was typically less than STEL, all researchers worked under Level-C respiratory protection using a half-face air-purifying gas mask with organic/acid vapor cartridges (H₂S escape). These masks are effective for SO₂, organosulfur gases, and radon, but have only short term protection against high H₂S.

What initially attracted Egemeier (1973) to the Kane Caves was the prospect of economic deposits of ore minerals, and in particular uranium and

vanadium in the region (Wilson, 1960); Egemeier found the cave sediments were highly radioactive. Radioactivity (as total counts of combined α -, β -, and γ -radiation) was measured using a Geiger counter in December 2001 (Figure 1-11). The highest concentrations were near the springs and along the anaerobic stream channels, as well as at the cave floor. The area around 215 m, associated with red microbial mats (Figure 1-8B), also had high radioactivity. Radioactivity on gypsum piles was low and considered to be at background levels.

A Note Regarding Sample Collection

Caves are valuable resources, both scientifically and recreationally, and karst regions are sensitive environments. Guidelines established by the National Speleological Society and the Conservation and Cave Management Organization were followed during the research; these guidelines suggest that researchers be 'professional, selective, and minimalistic'. During field work, all researchers attempted to alter the pre-existing features, water, and biota as little as possible. At all times, conservative sample quantities were collected and removal of material from the caves was limited in order to preserve the integrity of the mineralogic, hydrologic, and ecological systems. Permission to conduct research and to sample in Lower Kane Cave, Upper Kane Cave, and Hellsport Cave was granted by the Bureau of Land Management, Cody Office.

RESEARCH QUESTIONS

The primary research questions for this work are in five areas:

1. ***Relationships between microbial diversity and habitat geochemistry:*** What are the geochemical differences between the subaqueous (cave springs and stream) and subaerial (cave-wall) habitats? Is microbial community structure controlled by habitat geochemistry and geologic framework?
2. ***Microbial diversity and endemism:*** Are the microbes found in Lower Kane Cave unique to the cave, or are they widespread in other sulfidic systems, photic or aphotic? Can the presence of these microorganisms define any of the biogeochemical processes occurring in other systems?
3. ***Nutrient acquisition and cycling:*** What are the sources and availability of nutrients to the microbial cave ecosystem? What role do allochthonous and autochthonous substrates play in the ecosystem? Do microorganisms benefit or are they adversely affected by colonization of certain geologic materials?
4. ***Microbial role in speleogenesis:*** Can abiotic H₂S autoxidation be distinguished from biotic (microbial) oxidation? What are the consequences of microbial metabolism on the geologic/hydrologic surroundings? Is carbonate dissolution and speleogenesis affected depending on how or where sulfide is oxidized?
5. ***Process biosignatures:*** Are there diagnostic geologic, chemical, or isotopic characteristics of the habitats that can be used to fingerprint microbial activity in ancient systems?

HYPOTHESES AND RESEARCH APPROACH

I used an interdisciplinary approach to examine the cave microbial communities, nutrient sources and transfers, and the potential impact of the microorganisms to cave formation and modification during sulfuric acid speleogenesis.

Chapter 2: I hypothesized that the structure of microbial communities in the subaqueous microbial mats would reflect habitat geochemistry and substrate availability, and that shifts in community composition were controlled by dissolved oxygen and hydrogen sulfide. Additionally, I postulated that chemolithoautotrophy serves as the basis of energy production in the Lower Kane Cave ecosystem. As it is often difficult to ascertain the metabolism of certain organisms based only on 16S rDNA gene sequence phylogenies (e.g., Gray and Head, 2001), elemental composition (carbon to nitrogen ratios and sulfur content) and stable carbon and sulfur isotope ratio analyses of microbial mat morphotypes were combined with the 16S rDNA phylogenies to link hypotheses of ecosystem functionality with genetic identity (e.g., Boschker and Middelburg, 2002; Chesson et al., 2002).

Chapter 3: While many different types of sulfur-oxidizing bacteria have been found in sulfidic cave microbial mats, members of the “*Epsilonproteobacteria*” dominate the subaqueous mats from Lower Kane Cave. I hypothesized that these bacteria, which are successful colonizers of marine habitats (e.g., Alain et al., 2004), were also prevalent in terrestrial sulfidic caves and springs. I employed the full-cycle rRNA approach, including the construction of 16S rDNA clone libraries and application of 16S rRNA-targeted oligonucleotide

probes for fluorescence in situ hybridization (FISH), to characterize the microbial mats from Lower Kane Cave. I also applied the newly designed probes and polymerase chain reaction (PCR) primers to identify novel epsilonproteobacterial groups in microbial mats collected from other field locations.

Chapter 4: Molecular evidence indicated that the subaqueous microbial mats in Lower Kane Cave were much more complex than previously thought, and geochemical evidence revealed that the microbial mats were physically and chemically stratified. I hypothesized that molecular methods overlooked anaerobic microbial community diversity because populations were less abundant than the aerobes (i.e., “*Epsilonproteobacteria*”). I employed culture-based approaches, including the most probable number method and enrichment cultures using specific media, to characterize the diversity of anaerobic microbial communities.

Chapter 5: Inorganic and organic sulfur-containing compounds pass through multiple components of a microbial ecosystem and volatile components are released into the atmosphere. Although production and consumption of volatile sulfur gases (including hydrogen sulfide, methanethiol, dimethyl sulfide, and carbonyl sulfide) have been studied from photic marine and freshwater environments, virtually nothing is known about the flux of these gases from subsurface settings. I hypothesized that sulfur gases were produced and consumed by various metabolic guilds within the Lower Kane Cave microbial ecosystem, and potentially impact the local or global sulfur budgets. I employed culture-based approaches with time-series incubation experiments and gas chromatography (GC) to examine abiotic and biotic sulfur gas production and consumption. Hydrogen

sulfide flux and gas dynamics were characterized by direct-inject field GC inside Lower Kane Cave.

Chapter 6: The basic mechanism for sulfuric acid speleogenesis has been debated (Jagnow et al., 2000). While it was clear that specialized microbial communities take advantage of reduced sulfur compounds as energy sources, it was not clear that biotic pathways influence karstification. I hypothesized that microbial sulfur oxidation dominated over abiotic autoxidation, and microbially-derived sulfuric acid controlled speleogenesis. I combined the interdisciplinary results from 1) H₂S gas flux data (described in Chapter 5), 2) aqueous geochemistry and mineralogy, 3) the deployment of field microcosms, and 4) fluorescence in situ hybridization of colonized carbonate surfaces to examine the subaqueous sulfide loss mechanisms and the roles of sulfur-oxidizing bacteria on carbonate dissolution.

Chapter 7: The sulfuric acid speleogenesis model of Egemeier (1981) requires volatilization and oxidation of H₂S to sulfuric acid on cave-wall surfaces, which causes aggressive carbonate rock dissolution and replacement of limestone by gypsum. I hypothesized that the chemistry of condensation on subaerial cave-wall surfaces influenced dissolution and precipitation reactions occurring on the walls, and that gypsum replacement of the walls was an episodic process. I characterized the mineralogy of the cave walls, the microbiology of cave-wall biofilms, and the chemical and physical nature of condensation droplets in Lower Kane Cave. Moreover, microcrystals of authigenic quartz that form in the cave-walls biofilms and gypsum potentially represent a biogeochemical marker of cave-wall processes.

Chapter 2: Bacterial Diversity and Ecosystem Function of Filamentous Microbial Mats from Aphotic (cave) Sulfidic Springs Dominated by Chemolithoautotrophic “*Epsilonproteobacteria*”

ABSTRACT¹

Filamentous microbial mats from three aphotic sulfidic springs in Lower Kane Cave, Wyoming, were assessed with regard to bacterial diversity, community structure influenced by geochemical changes, and ecosystem function using a 16S rDNA-based phylogenetic approach combined with elemental content and carbon and sulfur stable isotope ratio analyses. The bulk of the microbial mats had carbon isotope values (mean $\delta^{13}\text{C} = -34.7\text{‰}$, $1\sigma = 3.6$) consistent with chemolithoautotrophic carbon fixation from a dissolved inorganic carbon reservoir (cave water, mean $\delta^{13}\text{C} = -7.4\text{‰}$; $n = 8$). The most widespread mat morphotype consisted of white filament bundles, with low C:N ratios (3.5–5.4) and high sulfur content (16.1–51.2%). Bacterial diversity was low overall, and the most prevalent taxonomic group was affiliated with the “*Epsilonproteobacteria*” (68%); six genetically distinct epsilonproteobacterial groups were identified. Other bacterial sequences were affiliated with *Gammaproteobacteria* (12.2%), *Betaproteobacteria* (11.7%), *Deltaproteobacteria* (0.8%), and the Acidobacterium (5.6%) and Bacteroidetes/Chlorobi (1.7%) divisions. Epsilonproteobacterial and bacterial group abundances and overall community structure within the microbial mats

¹ A portion of this chapter was used for the publication A.S. Engel, M.L. Porter, L.A. Stern, S. Quinlan, and P.C. Bennett, 2004, Bacterial diversity and ecosystem function of filamentous microbial mats from aphotic (cave) springs dominated by chemolithoautotrophic “*Epsilonproteobacteria*”, *FEMS Microbiology Ecology*, accepted.

shifted from the spring orifices downstream, corresponding to changes in habitat dissolved sulfide and oxygen concentrations and metabolic requirements of certain bacterial groups. Most of the epsilonproteobacterial groups were identified from high sulfide and low oxygen concentrations were measured, whereas *Thiothrix* spp. and *Thiobacillus* spp. had higher abundances where conditions of low sulfide and high oxygen concentrations were observed. Genetic and metabolic diversity among the “*Epsilonproteobacteria*” maximizes overall cave ecosystem function, and these organisms play a significant role in providing chemolithoautotrophic energy to the otherwise nutrient-poor cave habitat. These results expand the evolutionary and ecological views of “*Epsilonproteobacteria*” in terrestrial habitats and demonstrate that sulfur cycling supports this subsurface ecosystem through chemolithoautotrophy.

INTRODUCTION

Microbial processes occurring in the absence of light have generally been considered insufficient to support ecosystem-level processes, and until recently, the dogma has been that life in the subsurface, if present and metabolically active, is dominated by heterotrophic consumption of surface-derived carbon (Caumartin, 1963; Pedersen, 2001; Naeem, 2002; Alfreider et al., 2003). But the absence of light does not preclude life, as reactive mineral surfaces and solute-rich groundwater provide energy sources sufficient for chemolithoautotrophic growth in the subsurface (e.g., Stevens, 1997; Kinkle and Kane, 2000). Chemolithoautotrophy is now recognized as an important ecosystem-level process in aphotic

environments, including deep terrestrial aquifers (Stevens and McKinley, 1995; Pedersen, 2001) and caves (Sarbu et al., 1996; Vlasceanu et al., 2000; Schabereiter-Gurtner et al., 2002). Because subsurface habitats are relatively difficult to access, however, little is known about the biodiversity, community structure, ecosystem functioning, or carbon cycling of terrestrial chemolithoautotrophically-based microbial ecosystems.

Caves represent distinctive habitats with complete darkness, relatively constant air and water temperatures, and a poor supply of easily degradable organic matter. Consequently, most cave ecosystems depend on allochthonous organic material for energy (Poulson and Lavoie, 2000; Simon et al., 2003). Previous investigations describing microorganisms in caves (e.g., Caumartin, 1963; Dickson and Kirk, 1976; Mikell et al., 1996), including from sediments and aquatic habitats, suggest that the microbes are similar to those found in surface environments and are only active under optimal growth conditions (Northup and Lavoie, 2001). However, groundwater bearing dissolved hydrogen sulfide and negligible allochthonous carbon discharges as springs into the passages of several caves (e.g., Egemeier, 1981; Sarbu et al., 1996; Angert et al., 1998; Hose et al., 2000); hydrogen sulfide is an energy-yielding substrate for some microorganisms, and areas of these sulfidic caves are colonized by thick subaqueous microbial mats (Brigmon et al., 1994; Angert et al., 1998), as well as extensive cave-wall biofilms (Hose et al., 2000).

Molecular phylogenetic studies based on 16S rRNA gene sequences (rDNA) have expanded our understanding of the microbial diversity in caves (e.g.,

Northup and Lavoie, 2001), including those with hydrogen sulfide-rich groundwater (Angert et al., 1998; Vlasceanu et al., 2000; Engel et al., 2001) and those without (Holmes et al., 2001; Schabereiter-Gurtner et al., 2002; Northup et al., 2003; Schabereiter-Gurtner et al., 2003; Barton et al., 2004). In sulfidic caves, the dominant bacterial groups from some subaqueous microbial mat communities belong to the “*Epsilonproteobacteria*” (Angert et al., 1998; Engel et al., 2001; Barton et al., 2002). Stable carbon isotope measurements and ¹⁴C-radiolabeled substrate experiments suggest that chemolithoautotrophy is the base of these ecosystems (Sarbu et al., 1996; Porter, 1999; Sarbu et al., 2000). There has been relatively little study, however, of the biogeochemistry and ecological roles of the dominant groups involved with energy and nutrient transfers within these ecosystems, or on the physical or chemical controls that govern community structure and dynamics.

This purpose of this chapter was to characterize microbial ecosystems and nutrient cycling in sulfidic cave habitats, using Lower Kane Cave as a proxy for deeper subsurface environments. The objectives were to describe genetic and functional diversity, and to define how habitat geochemistry controls community structure. I hypothesized that community composition and structure reflect substrate availability, and specifically that community composition shifts with changes in the concentrations of dissolved oxygen and hydrogen sulfide. As it is often difficult to ascertain the metabolism of many organisms based on 16S rDNA-based phylogenies (e.g., Gray and Head, 2001), elemental composition and stable carbon and sulfur isotope ratio analyses were combined with 16S rDNA

phylogenies to link hypotheses of ecosystem functionality with genetic identity for the as yet uncultured microorganisms (Boschker and Middelburg, 2002; Chesson et al., 2002; Naeem, 2002). The results of the isotopic and phylogenetic characterization of the Lower Kane Cave ecosystem expand the evolutionary and ecological views of “*Epsilonproteobacteria*” in terrestrial habitats and demonstrate that sulfur cycling supports this subsurface cave ecosystem through chemolithoautotrophy.

MATERIALS AND METHODS

Sample Acquisitions

Samples of each microbial mat morphotype were aseptically collected from three of the sulfidic spring sites in Lower Kane Cave, Wyoming (Figure 1-2). Multiple mat samples were used for bulk biomass, elemental analysis, carbon isotope analysis, and DNA extraction and 16s rDNA clone library construction. To preserve the integrity of the sensitive ecological systems, conservative quantities of microbiological materials were collected. Sampling sites were numbered according to their location in meters from the back of the cave, with flow always toward the cave entrance (i.e. longer distances) (Figure 1-2): Fissure Spring (124-, and 127-m), Upper Spring (190-, 195-, 198-, and 203-m), and Lower Spring (one orifice and one mat sample from 248-m). Microbial mat morphotypes were collected separately and distinguished as white filaments (denoted as ‘f’), white webs (denoted as ‘w’), yellowish-white mat (denoted as ‘y’), and whitish-gray filaments (denoted as ‘g’). White filament bundles in the water column or filaments from the surface of the mats were targeted for clone libraries; however, one library was

constructed with gray filaments ~2 cm below the top of the mat for comparison.

Geochemical Analysis

Geochemical data were acquired at the major microbiological sample locations, as well as throughout the cave, over a three year period. Unstable parameters (pH, E_H , and dissolved oxygen) were measured using electrode methods. Dissolved hydrogen sulfide (as total dissolved sulfide, $C_T S^-$), ferrous iron (Fe^{2+}), and low concentrations of dissolved oxygen were measured in the field using the Methylene Blue, Ferrozine and Rhodazine D colorimetric methods, respectively (CHEMetrics, Inc., Calverton, VA), using a MiniSpec 20 field spectrophotometer. Vertical profiles of dissolved oxygen through the mats were determined by fluorescence-quenching optical methods (Ocean Optics, Inc., Dunedin, FL). Unstable and reactive parameters (pH, oxygen, hydrogen sulfide, etc.) were also measured at several transects along and across the cave stream channels. Alkalinity (as total titratable bases, here dominated by bicarbonate) was determined in the field by titration to pH 4.5, and verified in the laboratory by endpoint seeking autotitration. Anions and acid-preserved metals were determined by ion chromatography and inductively coupled plasma mass spectrometry, respectively. Dissolved organic and inorganic carbon (DOC and DIC, respectively) were determined by Dohman DC-180 wet-oxidation carbon analyzer. Dissolved gas species (e.g., methane, aromatic hydrocarbons, hydrogen sulfide, organosulfur gases) from the spring and stream water were analyzed by headspace gas chromatography.

Scanning Electron Microscopy

Microbial mats were examined using scanning electron microscopy (SEM) by fixing biological material with a chemical critical-point drying method modified from Nation (1983). Briefly, samples were fixed with 25% gluteraldehyde, then freeze-fractured in liquid nitrogen, and freeze-dried. Samples were mounted on aluminum stubs, sputter-coated with gold, and examined using a JEOL JSM-T330A SEM in the Jackson School of Geosciences at the University of Texas at Austin.

Carbon, Nitrogen, and Sulfur Content

Aliquots of each morphotype (~2 ml) was individually homogenized, acidified with dilute HCl and rinsed with dH₂O (acidification and washing were repeated at least twice to ensure dissolution of carbonate mineral phases), followed by freeze-drying. Total organic carbon and nitrogen contents were determined by elemental analyzer interfaced with a FinniganMAT Delta Plus mass spectrometer at the University of Texas Marine Sciences Institute in Port Aransas, Texas, simultaneously with carbon isotope ratio analysis. Total sulfur content, as inorganic and organic sulfur compounds, was determined on a EuroEA3000 elemental analyzer (EuroVector, Milan, Italy).

Minimum bulk mat biomass was determined from dry weight analysis of the mats followed by comparison of the percent carbon in each aliquot, using methods described in and modified from Bratbak and Dundas (1984). Briefly, ~ 1 ml replicates were individually homogenized, acidified with dilute HCl, weighed, freeze-dried, and re-weighed to obtain the dry weight. The percentage of carbon in

each dried aliquot was determined by elemental analyzer. Cell carbon content was calculated from the standard conversion factor of $350 \text{ fg}\cdot\text{C}\cdot\text{cell}^{-1}$ (assuming an average cell size of $1 \mu\text{m}^3$; Bratbak and Dundas, 1984) to determine the number of cells per ml.

Carbon Isotope Methods

For carbon isotope ratio ($^{13}\text{C}/^{12}\text{C}$) analysis, organic carbon of 1 to 2 ml mat samples was prepared by acidifying the sample in dilute HCl to ensure removal of carbonate mineral phases. Most measurements were made by elemental analyzer interfaced with a continuous flow FinniganMAT Delta Plus mass spectrometer, but some measurements were also made by sealed tube combustion, vacuum purification, and using a dual-inlet VG Prism II mass spectrometer at the Jackson School of Geosciences. Microbial mat carbon isotope values were compared to the values obtained from cave water dissolved inorganic carbon (DIC), including a composite of $\text{CO}_{2(\text{aq})}$, HCO_3^- , and CO_3^{2-} from the cave water. DIC was extracted for ^{13}C analysis by acidifying under vacuum with 100% phosphoric acid followed by cryogenic purification of the resulting CO_2 (method modified from Hassan, 1982). At the pH and temperature of the cave water (pH ~ 7.3 at 21.5°C), the dominant DIC species was HCO_3^- ($\sim 90\%$) based on dissociation constants for H_2CO_3^* , HCO_3^- , and CO_3^{2-} species (Stumm and Morgan, 1996). Carbon isotope values for the Madison Limestone hostrock were also measured by reaction with 100% phosphoric acid (McCrea, 1950). All carbon isotope values are expressed in delta (δ) notation with respect to the international standard V-PDB, where

$$\delta^{13}\text{C} (\text{‰}) = \left[\frac{{}^{13}\text{C}/{}^{12}\text{C}_{\text{sample}} - {}^{13}\text{C}/{}^{12}\text{C}_{\text{standard}}}{{}^{13}\text{C}/{}^{12}\text{C}_{\text{standard}}} \right] \times 1000 \quad (4-1)$$

Sulfur Isotope Methods

Aqueous sulfide was collected by precipitating Ag₂S from filtered spring water with 10% AgNO₃ solution. Following sulfide removal, aqueous sulfate was collected by precipitating BaSO₄ with BaCl₂ (Carmody et al., 1998). Sulfur isotope ratios of sulfide, sulfate, and organic material were made with an elemental analyzer interfaced with a Micromass Optima mass spectrometer and ratios are expressed in delta notation with respect to the Cañon Diablo Troilite (CDT) standard.

DNA Extraction and PCR Amplification of 16S rRNA Gene Sequences

Approximately 0.2 to 0.5 ml mat morphotype material were aseptically collected and placed into tubes containing 0.5 to 1 ml sterilized DNA extraction buffer comprised of 10 mM Tris-HCl (pH 8), 100 mM EDTA, and 2% sodium dodecyl sulfate. Prior to DNA extraction and laboratory manipulation of the mat material, 9 µl Proteinase K (20 mg/ml) was added to each sample. Samples were physically disrupted by a series of freeze-thaw (3 times, -80°C to 65°C) cycles, followed by incubation at 55°C overnight. RNase was added to the digests and incubated at 37°C for up to 1 hr, following manufacturer instructions. Proteins and other cellular debris were precipitated in 7.5 M ammonium acetate by centrifugation. The supernatant was transferred to cold 100% isopropanol and then nucleic acids were precipitated overnight at -20°C. DNA was pelleted by

centrifugation and pellets were washed in 70% ethanol, air-dried, and stored in either sterile water or TLE buffer. DNA quality and quantity from each extraction were determined on a GeneQuantII spectrophotometer (Amersdam Biosciences, Piscataway, NJ).

Nearly full-length community 16S rRNA gene sequences (>1300 bp) were PCR-amplified using the eubacterial primer pair 27f (forward, 5'-AGAGTTTGATCCTGGCTCAG-3') and 1492r (reverse, 5'-GGTACCTTGTACGACTT-3') (Lane, 1991). PCR is a method that amplifies a specific DNA sequence in vitro by repeated cycles of synthesis using specific primers and DNA polymerase. Amplification was performed with a Perkin Elmer 9700 thermal cycler and AmpliTaq Gold (Applied Biosystems, Branchburg, NJ) under the following conditions: denaturation at 94°C for 1 min, primer annealing at 42°C for 1 min, chain extension at 72°C for 1.5 min, repeated for 35 cycles. A control tube containing sterile water instead of DNA was used as a negative control; *Escherichia coli* DNA was used as a positive control.

16S rRNA Gene Clone Library Construction

Amplified PCR products were purified with the GeneClean II Kit (Bio101, Inc., Vista, CA), following manufacturer recommendations. Purified PCR products were cloned using the TOPO TA Cloning kit with *E. coli* TOP10F' cells, according to manufacturer instructions (Invitrogen, Carlsbad, CA). Molecular cloning involves the isolation and incorporation of a fragment of DNA (i.e., PCR product) into a cloning vector (a plasmid), where it is transformed into and perpetuated by a

population of host cells descended from a single cell. A collection of clones from one sample, each containing a replicated PCR product, comprises a clone library.

Bacterial 16S rDNA clone libraries were constructed from eleven microbial mat morphotype samples in the Department of Integrative Biology, Brigham Young University, Provo, Utah. Plasmids containing nearly-full length inserts were extracted using a standard alkaline lysis miniprep method (Ausubel et al., 1990). Clone plasmids were digested simultaneously using *EcoRI* and *RsaI* (1U each) according to manufacturer's instructions (New England Biolabs) for restriction fragment length polymorphism (RFLP) analysis. RFLP patterns were visualized on 2% agarose gels stained with ethidium bromide and run in TBE (Tris-borate-EDTA)-buffer (refer to Appendix A for RFLP clone library results). Clones representing unique patterns from each library were selected for sequencing (Appendix A; Table A-1).

Sequencing of 16S rRNA Genes and Phylogenetic Analysis

Sequence inserts from plasmid minipreps for each clone to be analyzed were PCR-amplified using the plasmid-specific primer pair M13(-20) (5'-GTAAAACGACGGCCAGT-3') and M13(-24) (5'-AACAGCTATGACCATG-3'). PCR products were purified using Sephadex columns and sequenced using an ABI Big-Dye Ready Reaction kit (Perkin Elmer) with the primers 27f and 1492r in conjunction with the internal primers 704f (forward, 5'-GTAGCGGTGAAATGCGTAGA-3') and 907r (reverse, 5'-CCGTCAATTCCTTTRAGTTT-3'). Automated DNA sequencing was done on an ABI Prism 377X sequencer (Perkin Elmer) at Brigham Young University.

DNA sequences were submitted to the CHECK-CHIMERA program of the Ribosomal Data Base Project (RDP) II at Michigan State University (<http://rdp.cme.msu.edu/html/>) (Maidak et al., 2001) to screen for and to eliminate chimeric sequences. Clone sequences were subjected to BLAST searches within the GenBank database (<http://www.ncbi.nlm.nih.gov/>) to determine 16S rDNA sequence similarities to culturable and not yet cultured organisms (Appendix A; Table A-1).

Phylogenetic analyses were conducted by Megan L. Porter, Department of Microbiology and Molecular Biology, Brigham Young University, and detailed information can be found in Engel et al. (accepted). Briefly, nucleotide sequences were initially aligned using Clustal X (Thompson et al., 1997) and then manually adjusted based on conserved primary and secondary gene structure. Analyses were done after removal of segments that could not be unambiguously aligned corresponding to *E. coli* 16s rRNA secondary structure helices 9 and 10 (bp 181-226; all alignments), helix 17 (bp 452-481; all but the *Betaproteobacteria* alignment), helices 25 and 26 (bp 822-860; *Gammaproteobacteria* and Bacteroidetes/Chlorobi-Acidobacterium alignments), helix 30 (bp 1028-1032; *Betaproteobacteria* and *Deltaproteobacteria* alignments), and helix 33 (bp 995-1045; “*Epsilonproteobacteria*” and Bacteroidetes/Chlorobi-Acidobacterium alignments). All base pair positions correspond to *E. coli* numbering (Brimacombe et al., 1988). The minimum evolution criteria in the program PAUP* (Swofford, 2002), maximum likelihood criteria using a genetic algorithm (MLga) in MetaPIGA (Lemmon and Milimkovitch, 2002), and Bayesian inference coupled

with Markov chain Monte Carlo techniques (BMCMC) in MrBayes version 3.0b4 (Ronquist and Huelsenbeck, 2003) were used for phylogenetic analyses. As an indication of nodal support, bootstrap analyses were performed for minimum evolution (500 replicates) criteria using full heuristic searches. For BMCMC and MLga analyses, posterior probabilities were used for nodal support (Lemmon and Milimkovitch, 2002; Ronquist and Huelsenbeck, 2003).

Statistical Analysis and Sequence Population Diversity

To determine if the number of clones in each of the clone libraries was representative of microbial diversity, rarefaction curves were produced using the approximation algorithm aRarefactWin (Analytic Rarefaction, version 1.3, S. Holland, <http://www.uga.edu/~strata/software/>). The calculations for the program are based on Hurlbert (1971) and Heck et al. (1975). Rarefaction curves having 95% confidence levels were constructed by comparing the number of clones in each 16S rRNA gene library to the number of phylotypes from a particular library.

Estimates of clone library species richness and species dominance/evenness indices (combined to represent heterogeneity; e.g., Rousseau and Van Hecke, 1999; Ricotta, 2003) were calculated based on the number of phylotypes identified from RFLP and taxonomic affiliations from GenBank BLAST searches (Hughes et al., 2001; Martin, 2002; Hill et al., 2003). The nonparametric methods Abundance-based Coverage Estimator (ACE) and Chao1, and the Shannon-Wiener biodiversity function expressed as the Shannon Index (H') were computed for each library using EstimateS (version 6.0b1, R.K. Colwell, <http://viceroy.eeb.uconn.edu/estimates>). Although there are problems with the interpretation of H' (refer to Hill et al., 2003,

for a complete discussion), it is the negative sum of each phylotype proportional abundance multiplied by the log of its proportional abundance, and is a measure of the difficulty in predicting the identity of the next individual sampled. The H' value is positively correlated to richness and evenness, but because it gives more weight to rare than to common phylotypes, it is more sensitive to absolute, but not relative, changes in abundance.

The Shannon Evenness (E) and the Simpson's Dominance index (D) were also calculated based on equations presented in Hill et al. (2003). E gives the ratio of H' to the maximum possible value of H' that could be obtained theoretically with the observed number of phylotypes; E is sensitive to changes in evenness of rare phylotypes such that an increase in abundance of a rare phylotype will increase E more than the equivalent reduction in abundance of a dominant phylotype (Hill et al., 2003). D strongly weights dominant phylotypes, which provides the probability that two clones chosen at random will be from the same phylotype. D is useful expression in this RFLP study because the dominant organisms are similar in all libraries (Hill et al., 2003).

A sequence similarity matrix was constructed for the closely related clone sequences from the "*Epsilonproteobacteria*" using corrected distances based on the model selected by Modeltest 3.06 (Posada and Crandall, 1998).

Nucleotide Sequence Accession Numbers

Nucleotide sequence data reported in this study are available in the GenBank database under the accession numbers AY208806 to AY208817 for LKC2-labeled clones, and AY510166 to AY510267 for LKC3-labeled clones.

RESULTS

Spring and Stream Geochemistry

The cave springs are all calcium-bicarbonate-sulfate water type and the geochemistry of the springs did not vary significantly from sample period to sample period (Table 2-1). Although the cave forms from sulfuric acid dissolution of limestone (Egemeier, 1981), the spring and stream pH was buffered to circum-neutral by ongoing carbonate dissolution. Incoming spring water had an average concentration of total dissolved sulfide ($C_{T}S^{\ominus}$) of $\sim 38 \mu\text{mol}\cdot\text{L}^{-1}$ and non-detectable dissolved oxygen (Table 2-1). Incoming $C_{T}S^{\ominus}$ was speciated as $\sim 60\%$ HS^{\ominus} : 40% H_2S (pK 7.04) based on the pH of the cave waters. The concentration of dissolved oxygen and $C_{T}S^{\ominus}$ changed downstream in all transects, such that at the end of the microbial mats $C_{T}S^{\ominus}$ decreased to non detectable and the concentrations of dissolved oxygen exceeded $40 \mu\text{mol}\cdot\text{L}^{-1}$ (e.g., from the Upper Spring transect from 190 m to 203 m; Figure 2-1). The concentration of DOC in all the spring waters was extremely low, at $<80 \mu\text{mol}\cdot\text{L}^{-1}$ including methane.

Morphologic Description of the Microbial Mats

Four major mat morphotypes were distinguished by color and visual inspection in the cave when illuminated with white light. All three spring orifice pools contained long white filament bundles suspended in the water column. The Lower Spring (248 m) had the densest concentration of orifice bundles (Figure 2-2A), although the Upper Spring had the longest bundles at more than a meter in length. The entire microbial mat below the Lower Spring orifice pool was 2 to 5 cm

thick and less than 1 m in length; the mat was yellowish-white in appearance (Figure 2-2B). At the Upper Spring (190 m), long filament bundles in the orifice pool (Figure 2-2C, 2-2D) transitioned to shorter bundles that coalesced on the edges of the outflow channel (195 to 198 m), corresponding to a decrease in $C_T S^=$ and an increase in dissolved oxygen concentrations (Figure 2-1). Very thin, short (1 cm in length) whitish-gray filaments covered stream sediments in flowing water at the bottom of the outflow channel (195 m). Approximately 6 m downstream from the Upper Spring orifice, the gray filaments thickened and were stratigraphically below long white filaments and thin white webs that occasionally had a bumpy or knobby texture (Figure 2-2E). Oxygen microelectrode profiles at 203 m showed oxygen tension abruptly decreased ~3 mm below the mat-water interface and anaerobic conditions ($pO_2 < 10$ Pa) persisted within the 5 cm-thick mat interior, indicating that the mats are geochemically stratified. Gray filaments within the mat at 203 m (~2 cm below the white mat surface) were sampled to test for differences in the microbial community structure. For both the Upper and Lower Springs, dense white filamentous mats, with small (1-3 cm diameter) discontinuous yellow patches and feathery bundles (i.e., short, thick, and branching filaments), dominated the lower reach of the outflow channels (Figure 2-2F). Filament bundles near the orifice of the Fissure Spring (118 m) (Figure 2-2G) were also associated with web-like structures (125 m) (Figure 2-2H).

SEM examination of several mat samples revealed complex organic and inorganic structures as part of the overall mat structure. White filamentous material revealed a tight filament network (Figure 2-3A) with branching and non-branching

filaments averaging 1 μm wide (Figure 2-3B through 2-3D). Some thin filaments (~ 0.5 μm wide) were twisted and associated with long rods (Figure 2-3E and 2-3F). In comparison, gray sediment from the Upper Spring orifice (Figure 2-4) had few filaments and Fe-S framboids and crystallites were common (Figure 2-4A through 2-4D), indicating a reducing microenvironment within the sediments. Cell clusters were also observed (Figure 2-4E and 2-4F).

C:N Ratios, Sulfur Content, and Biomass Estimates

The N contents varied by mat morphotype (Table 2-2), and white filaments and white webs had the highest N content compared to gray filaments or gray sediment. Generally, the lower the C:N ratio, the higher the quality of the mat as a food source for the ecosystem (Fagerbakke et al., 1996). The mean C:N ratios for white filament morphotypes was 5.0 ($1\sigma = 0.8$), suggesting a high quality food source. The C:N ratios of gray filaments were significantly higher and more variable than white mat morphotypes, with a mean of 15.0 ($1\sigma = 10.5$). The C:N ratios were highest for gray filaments and sediment from spring orifice sites, suggesting that this biomass consisted of lower quality organic matter, while the C:N ratios for gray filaments at the end of the microbial mats approached those of the white mat morphotypes (Table 2-2).

The sulfur content of the white filaments was higher than the gray filaments (Table 2-2), presumably reflecting intracellular sulfur (as elemental S^0) rather than organosulfur compounds. Typically, in the absence of stored sulfur the highest bacterial cell sulfur content ranges up to 1% (w/w) (Fagerbakke et al., 1996).

However, the white filament sulfur content had a mean of 30.0% ($1\sigma = 11.2\%$), and the white webs had consistently the highest sulfur content. The gray filaments and sediment had significantly lower sulfur contents, with a mean of 1.9% ($1\sigma = 0.6\%$), consistent with predicted values for bacterial biomass (Fagerbakke et al., 1996). The sulfur content of white filaments was generally the same at the extreme upstream and downstream samples of the Upper Spring transect, but decreased by up to 10% in the middle stream reach (Table 2-2).

The biomass of the microbial mat samples was generally high ($\sim 10^{10}$ cells $\cdot\text{ml}^{-1}$), with less than an order of magnitude difference between white and gray filament morphotypes (Table 2-2). Biomass values may underestimate the actual biomass because cell conversion factors are for rod-shaped cells, and FISH suggests that the mats are dominated by filamentous morphotypes (Engel et al., 2003; refer to Chapter 3).

Carbon Isotope Systematics

The $\delta^{13}\text{C}$ value for the limestone bedrock was +0.95‰, and the DIC reservoir along the Upper Spring transect had an average $\delta^{13}\text{C}$ value of -7.5‰ ($n = 7$, $1\sigma = 0.1\%$), and DIC from the Fissure Spring orifice water had a slightly higher $\delta^{13}\text{C}$ value of -7.2‰. Microbial mat morphotypes had $\delta^{13}\text{C}$ values ranging from -23 to -41‰ (mean -34.1‰, $1\sigma = 4.1$) (Figure 2-5). The low $\delta^{13}\text{C}$ values reflect the large discrimination against ^{13}C exhibited by autotrophs (e.g., $\sim 25\%$ relative to total DIC for sulfur-oxidizing bacteria; Ruby et al., 1987).

Microbial mat morphotypes showed systematic variations in their carbon isotope compositions at most locations (Figure 2-5). At all three spring locations, gray filaments consistently had among the highest $\delta^{13}\text{C}$ values, whereas all coexisting white filaments had lower $\delta^{13}\text{C}$ values. More specifically, near the distal portions of the Upper Spring mats (203 m), white feathery bundles and yellow patches (Figure 2-2F) had some of the lowest $\delta^{13}\text{C}$ values, whereas the white webs and gray filaments had the highest $\delta^{13}\text{C}$ values (Figure 2-5). In contrast, however, the feathery bundles from the proximal region of the Upper Spring mats (196 m) had among the highest $\delta^{13}\text{C}$ values. Moving downstream, the $\delta^{13}\text{C}$ value of the white filaments in both Upper Spring and Fissure Spring decreased (Figure 2-5).

Sulfur Isotope Systematics

Allochthonous sulfide (C_1S^-) at the Upper Spring orifice had a $\delta^{34}\text{S}$ value of $\sim -22.5\text{‰}$, and decreased downstream by approximately 1.6‰ (Figure 2-6). Dissolved sulfate had a $\delta^{34}\text{S}$ value of $+13\text{‰}$ and was invariable. The white filamentous morphotypes, containing high concentrations of sulfur (Table 2-2), had sulfur isotope values up to 2‰ lower than the allochthonous sulfide (Figure 2-6).

Clone Library Coverage, Species Richness, and Diversity

Eleven bacterial 16S rDNA clone libraries from four different microbial mat morphotypes were constructed and over 1000 clones were screened using RFLP (Appendix A). Although the RFLP method does not provide an absolute quantity of microbial groups within a community, it does provide an estimate of the proportional abundances of microbial groups in a given sample by assuming an

RFLP pattern of an abundant 'species' will be encountered more often in the clone library (Nübel et al., 1999; Morris et al., 2002). Nearly-full length 16S rRNA genes (>1300 bp) were sequences in both directions from selected clones. Sequences from the same RFLP pattern that had $\geq 98\%$ sequence similarity were grouped as a phylotype, and this classification scheme was used to estimate community diversity (Table 2-3). This level of sequence similarity takes into account micro-variations in genetic sequences due to PCR and cloning biases and variations in 16S rRNA gene copies (Nübel et al., 1999; Speksnijder et al., 2001). Approximately 2% of the clone 16S rRNA gene sequences were chimera and removed from further analyses. Of the phylotypes identified, 44% had sequences that were $\geq 95\%$ identical to GenBank sequences, corresponding to genus-level relationships (Stackebrandt and Goebel, 1994), and 30% of the sequences were $\geq 98\%$ identical to GenBank sequences, corresponding to species-level relationships (Stackebrandt and Goebel, 1994). The remaining phylotype sequences had $\geq 90\%$ sequence similarity to GenBank sequences (Table 2-3; Appendix A; Table A-1).

Rarefaction analysis was done to determine if the libraries had saturated coverage based on the number of clones obtained per library. The rarefaction curves indicated different patterns of diversity for different morphotype clone libraries (Figure 2-7). In the non-filament clone libraries (203g, 203w, 203y, and 248y), diversity was not fully covered compared to the saturation plateau reached for most of the white filament libraries (124f, 127f, 190f, 198f) (Figure 2-7). The non-filament libraries had higher phylotype richness overall and higher nonparametric estimates (ACE and Chao1; Table 2-4). As there was an overall

increase in the rate of phylotype accumulation in these unsaturated curves, major diversity within these libraries may not be well represented, although some of these libraries (e.g., 203y) do have high dominance (D) values (Table 2-4).

Species heterogeneity among the clone libraries was generally low and many of the white filament libraries showed overwhelming dominance by one of two phylotypes. Species richness was higher for the non-filament morphotypes, with the white webs from 203 m and the yellow patches from 203 m and 248 m showing the most diverse taxonomic representation among the eleven bacterial clone libraries (Table 2-3), even though observed species richness was lower than expected based on ACE and Chao1 values (Table 2-4). In comparison, although species richness of the white filament libraries varied, ranging from one to ten observed phylotypes, ACE and Chao1 estimates for the white filament libraries indicated that the observed phylotype numbers were close to the calculated values because of near-complete clone coverage for most of those libraries (Table 2-4). The diversity (H')/dominance (D) indices changed for the white filament clone libraries downstream for both the Upper and Lower Spring transects, such that the H' values increased and D values correspondingly decreased (Table 2-4).

Phylogenetic Analysis of 16S rRNA Gene Clone Libraries

The 16S rDNA clones were affiliated with several bacterial phyla (Table 2-3; Figures 2-8 through 2-12). The majority of the sequences identified from the clone libraries belonged to the *Proteobacteria* taxonomic division, specifically the “*Epsilonproteobacteria*,” (68%) *Gammaproteobacteria* (12.2%), *Betaproteobacteria* (11.7%), and *Deltaproteobacteria* (0.8%) classes, as well as other

bacterial divisions, including the Acidobacterium (5.6%) and Bacteroides/Chlorobi (1.7%).

The “Epsilonproteobacteria” class

The highest number of clones from all the libraries (68%) was assigned to the “*Epsilonproteobacteria*” (Table 2-3; Figure 2-8). Epsilonproteobacterial sequences from 17 phylotypes clustered into six groups based on phylogenetic position (Figure 2-8) and the sequence similarity matrix (Table 2-5), which suggests that genetic microdiversity was high (Fuhrman and Campbell, 1998). At least one epsilonproteobacterial phylotype was found in all clone libraries regardless of morphotype type or location (Table 2-3). The epsilonproteobacterial groups identified from Lower Kane Cave have few closely related sequences from the public sequence databases, suggesting that the diversity of these groups, and the “*Epsilonproteobacteria*” in general, is only now being realized.

The most abundant epsilonproteobacterial groups from all three springs formed two distinct clades, LKC group I and group II. No other epsilonproteobacterial phylotype was detected in a clone library if either LKC group I or II was absent. The closest relatives to LKC groups I and II were the two environmental clones, sipK119 and sipK94, respectively (98-99% similar in nucleotide sequence), from microbial mats with a string-of-pearls morphology in sulfidic marsh springs at the Sippenauer Moor, Regensburg, Germany (Rudolph et al., 2001; Moissl et al., 2002). Clone sequences from LKC group I were also closely related (97-99% similar in nucleotide sequence) to environmental clones obtained from a petroleum-contaminated, sulfidic groundwater storage cavity in

Japan (Watanabe et al., 2000; Watanabe et al., 2002) and two clones from microbial mats from the sulfidic Cesspool Cave, Virginia (Engel et al., 2001) (Figure 2-8). The closest cultured relative for LKC groups I clones is *Sulfuricurvum kujiense*; this organism is a slightly curved rod isolated as a chemolithoautotrophic sulfur-oxidizer, capable of growth on thiosulfate, elemental sulfur, and hydrogen sulfide, and able to use molecular oxygen, nitrate, or ferric iron as electron acceptors (Kodama and Watanabe, 2003). LKC group II clones were more distantly related (90-94% similar in nucleotide sequence) to miscellaneous marine, hydrothermal vent field and epibiont clones (e.g., Longnecker and Reysenbach, 2001; Lopez-Garcia et al., 2002) and clones from a sulfidic cave microbial mat in Parker Cave, Kentucky (Angert et al., 1998) (Figure 2-8). The phylogenetic affinities (Figure 2-8) and the sequence similarity matrix (Table 2-5) demonstrate that group I and group II are distinct from each other at more than the genus-level (85-87% similar in nucleotide sequence).

LKC group III did not form a distinct phylogenetic cluster and was defined by several phylotypes from five libraries, supported by the range of sequence similarities among the sequences and moderate boot-strap node values (Table 2-5; Figure 2-8). No LKC group III clones were found at the Lower Spring. The relatives to the epsilonproteobacterial LKC groups III and IV were similar to LKC group I clones (Table 2-5).

LKC group IV, comprised of clones only from the Upper Spring, clustered closely with *S. kujiense* (Kodama and Watanabe, 2003), and groundwater and cave environmental clones (Figure 2-8). Based on the similarity matrix, LKC groups III

and IV had low sequence similarity within the groups, although each library was distinct from all the other groups (Table 2-5).

LKC group V also had a wide range of sequence similarity (Table 2-5), indicating additional diversity within this group that could not be resolved by RFLP. LKC group V was most closely related to LKC group II clones (Table 2-5).

Seventeen clones from four morphologically diverse libraries, but mostly white filament morphotypes, belonged to the novel sequence cluster LKC group VI, which was genetically distinct from all the other epsilonproteobacterial groups (Table 2-5). The closest relatives to LKC group VI clones were environmental clones from subsurface acid mine drainage and groundwater (95-96% similar in nucleotide sequence).

The Gammaproteobacteria class

Twelve percent of all the clones belonged to the *Gammaproteobacteria* (Figure 2-9). Eighty-one clones formed one phylotype, closely related to the environmental clone sipK4 from sulfidic marsh springs (99-100% similar in nucleotide sequence) (Rudolph et al., 2001), which is also closely related to *Thiothrix unzii*. The relative abundance of this phylotype generally increased downstream from the orifice to the end of the mats for all three spring transects (Table 2-3). Cultured representatives from *Thiothrix* oxidize a variety of reduced sulfur compounds and several *Thiothrix* species have been identified from other sulfidic caves, including Parker Cave (Angert et al., 1998), underwater caves and karst springs in Florida (Brigmon et al., 2003), and Cesspool Cave (Engel et al., 2001). *T. unzii*, an aerobic sulfur-oxidizing bacterium that utilizes sulfide and

thiosulfate as sole sulfur sources and stores sulfur intracellularly (Howarth et al., 1999), and environmental clones closely related to *T. unzii* are also commonly associated with activated sludge and wastewater treatment plants (e.g., Wagner et al., 1994; Howarth et al., 1999), as well as sulfidic springs where it is the dominant group (Rudolph et al., 2001; Moissl et al., 2002).

Clone library 203g was dominated by clones belonging to the Enterobacteriaceae, specifically the *Pantoea* and *Serratia* genera (Figure 2-9). The libraries 203g and 248y had six clones closely related to *Serratia marcescens* (99% similar in nucleotide sequence).

Nine sequences from the 124f and 203w libraries were distantly related to *Beggiatoa* sequences (90% similar in nucleotide sequence), with one relative being the isolate *Beggiatoa* sp. MS-81-1c from a salt marsh, described as a narrow and non-vacuolate filament (Ahmad et al., unpublished GenBank submission) (Table 2-3; Figure 2-9). The weak sequence similarity to known *Beggiatoa* sequences and low bootstrap values between the clone group and *Beggiatoa* sequences (Figure 2-9), however, indicate that Lower Kane Cave clones may belong to a different, unclassified bacterial group within the *Gammaproteobacteria*. *Beggiatoa*-like filaments have been described from a marine cave in Italy using microscopy (Airoldi et al., 1997) and from microbial mats in Parker Cave, Kentucky (Thompson and Olson, 1988), although detailed phylogenetic investigations from Parker Cave did not support the presence of *Beggiatoa* (Angert et al., 1998).

The Betaproteobacteria class

Nearly twelve percent of the clones were affiliated with the *Betaproteobacteria*, and were most closely related to *Thiobacillus* spp. (Figure 2-10). Three phylotypes were identified from two libraries. The closest relatives were the environmental clone 44a-B2-21 from acid mine drainage (Labrenz and Banfield, unpublished GenBank submission) and *Thiobacillus aquaesulis* (94-95% sequence similarity). Many *Thiobacillus* spp. oxidize reduced sulfur compounds (Kelly and Harrison, 1989), and *T. aquaesulis* is not an obligate sulfur-oxidizing chemolithoautotroph, but can grow as a facultative heterotroph on nutrient broth and yeast extract (McDonald et al., 1996). Thiobacilli have been described from caves (Vlasceanu et al., 1997; Angert et al., 1998; Hose et al., 2000; Vlasceanu et al., 2000; Engel et al., 2001), but environmental clones from those studies were not closely related to the Lower Kane Cave group.

The Deltaproteobacteria class

Less than 1% of the clones were closely related (96-97% similar in nucleotide sequence) to *Desulfocapsa thiozymogenes*, the environmental clone sipK94 from the string-of-pearls mats in Germany (Moissl et al., 2002), and the environmental clones SRB348 and SRB282 identified from the chemocline of the meromictic Lake Cadagno, Switzerland (Tonolla et al., 2000) (Table 2-3; Figure 2-11). *D. thiozymogenes* disproportionates thiosulfate, sulfite, or elemental sulfur to sulfate and sulfide (Janssen et al., 1996).

The Acidobacterium division

One phylotype representing 5.6% of all the clones obtained from this study was closely related (96-97% similar in nucleotide sequence) to uncultured environmental clones within the *Acidobacterium* division. Library 203w was dominated by this clone group, and rare clones from this phylotype were found in five additional libraries (Table 2-3). The closest relative was clone SJA-36 identified from an anaerobic bioreactor with trichlorobenzene contamination (von Wintzingerode et al., 1999) (Figure 2-12). The Lower Kane Cave phylotype also expands the *Acidobacteria*-group 7 described by Liles et al. (2003), which consists of only a few environmental clones from soil, as well as the *Acidobacteria*-subgroup-b described by Schabereiter-Gurtner et al. (2002) from La Garma Cave, Spain. Clone LKC3_156.13 had 92% sequence similarity to clone SJA-36, but also clustered as an unclassified taxonomic group within the Bacteroidetes phylum by phylogenetic analysis (Figure 2-12). Cultivated members of the *Acidobacteria* division are heterotrophs, although *Acidobacteria* have been found in many geochemically different environments, including neutral and acidic soils, marine and freshwater sediments, hot springs, deep-sea vents, and engineered systems (Barns et al., 1999; Schabereiter-Gurtner et al., 2002; López-García et al., 2003; Schabereiter-Gurtner et al., 2003).

The Bacteroidetes/Chlorobi division

Seven phlotypes, each represented by rare 'singleton' or 'doubleton' clones, belonged to the Bacteroidetes/Chlorobi (BC) taxonomic group (Table 2-3; Figure 2-12). Three phlotypes (BC groups I-III) were closely related to

environmental clones within the *Bacteroides* class, including clones from lakes and contaminated groundwater. Four phylotypes (BC groups IV-VII) were related to environmental clones within the *Sphingobacteria* class (including the genus *Cytophaga*) obtained from a wide habitat range, including deep-sea hydrothermal vent metazoans, gas hydrate sediment, soil, and contaminated groundwater.

DISCUSSION

Terrestrial subsurface environments are often inaccessible for study, limiting our understanding of ecosystem structure and dynamics, elemental cycling, and potential biogeochemical impacts to earth and atmospheric processes. The main research goals of this part of the study were to identify the bacterial groups characteristic of the cave microbial mats, to gain an understanding of how geochemistry may control microbial community diversity within the aphotic environment, and to elucidate potential ecosystem functioning and the impact of sulfur cycling and chemolithoautotrophy on the ecosystem. The results of this work suggest that similar microbial communities and concomitant microbially mediated biogeochemical cycles may be more widely dispersed in sulfidic groundwater habitats than previously recognized.

“Epsilonproteobacteria” Diversity and Ecophysiology

The majority of 16S rRNA gene sequences from the clone libraries were affiliated with the *“Epsilonproteobacteria,”* and specifically with two epsilonproteobacterial groups defined as LKC Group I and II (Figure 2-8). Additionally, there was a high level of genetic microdiversity within the

“*Epsilonproteobacteria*” identified in this study based on the range of sequence similarities for the obtained epsilonproteobacterial clones (Table 2-5).

Numerous 16S rDNA-based molecular surveys suggest that “*Epsilonproteobacteria*” successfully colonize a variety of geochemical settings, including caves (Angert et al., 1998; Engel et al., 2001; Barton et al., 2002), deep aquifers (Pedersen et al., 1997), terrestrial sulfidic springs and groundwater (Watanabe et al., 2000; Rudolph et al., 2001; Moissl et al., 2002; Watanabe et al., 2002; Elshahed et al., 2003; Kodama and Watanabe, 2003), oil fields (Voordouw et al., 1996), deep marine sediments and ocean water (Fenchel and Glud, 1998; Li et al., 1999a; Li et al., 1999b; Todorov et al., 2000; Madrid et al., 2001), hydrothermal vent sites (Moyer et al., 1995; Muyzer et al., 1995; Polz and Cavanaugh, 1995; Brinkhoff et al., 1999; Reysenbach et al., 2000; Corre et al., 2001; Longnecker and Reysenbach, 2001; Takai et al., 2003), in association with deep-sea animal life at vent sites (Haddad et al., 1995; Cary et al., 1997; Naganuma et al., 1997; Alain et al., 2002a; Lopez-Garcia et al., 2002; López-García et al., 2003), and in engineered systems including sewage sludge and contaminated waste (Engberg et al., 2000; On, 2001). Based on the geochemical diversity of these study sites and the lack of culture-based information from most phylogenetic groups within the “*Epsilonproteobacteria*”, especially those groups identified from terrestrial settings, it is challenging to predict what the ecophysiological roles of “*Epsilonproteobacteria*” in Lower Kane Cave might be (Gray and Head, 2001).

In many environments “*Epsilonproteobacteria*” are implicated in sulfur cycling, and specifically in oxidizing reduced sulfur compounds; this is supported

by several culture-based studies (Finster et al., 1997; Stolz et al., 1999; Gevertz et al., 2000; Campbell et al., 2001; Nemati et al., 2001; Alain et al., 2002b; Miroshnichenko et al., 2002; Kodama and Watanabe, 2003; Takai et al., 2003). Additionally, in nearly all of these culture-based studies, the epsilonproteobacterial strains grew chemolithoautotrophically. Therefore, reasonable metabolic hypotheses can cautiously be made for the “*Epsilonproteobacteria*” from Lower Kane Cave based on cave biogeochemistry.

It is possible that the organisms represented by LKC groups I, III, and IV clones may have metabolic similarities to *S. kujiense*, which grows under microaerophilic to anaerobic conditions. However, alternative electron acceptors such as nitrate and ferric iron are exceptionally low in the cave waters (Table 2-1). Closely related phylogenetic groups, however, do not necessarily indicate similar ecophysiological characteristics (Fuhrman and Campbell, 1998), as Takai et al. (2003) showed that the observed phylogenetic distribution of epsilonproteobacterial cultures isolated from deep-sea vents did not correlate with substrate or electron acceptor preferences, oxygen requirements, or geographic location. These deep-sea vent cultures were non filamentous and affiliated with five distinct epsilonproteobacterial taxonomic groups, yet had high metabolic diversity which included sulfur and thiosulfate oxidation using nitrate or molecular oxygen (at 1% or 10%) or H₂-dependent sulfur-reduction (Takai et al., 2003).

Clearly, the high concentrations of dissolved sulfide discharging from the springs provide a rich energy source for sulfur-oxidizing bacteria. Although it is unlikely that abiotic autoxidation (i.e., chemical oxidation) and volatilization cause

sulfide loss exclusively, there was an observed decrease in dissolved sulfide concentrations downstream (Figure 2-1). Abiotic sulfide autoxidation is extremely slow in disaerobic water at pH ~7.4 (the autoxidation half-life was calculated at >800 hours; $\text{H}_2\text{S}:\text{HS}^-$ pK 7.04) and sulfide volatilization from the water to the atmosphere accounts for <8% of the sulfide loss in the stream based on gas flux experiments (see Chapters 5 and 6). With no other mechanism for $\text{C}_\text{T}\text{S}^-$ loss, there would be, for example, significantly higher sulfide concentrations at the end of the Upper Spring microbial mat, as well as at the cave entrance 150 m further downstream. However, a very rapid decrease in $\text{C}_\text{T}\text{S}^-$ is observed (Figure 2-1). Microbial catalysis under microaerophilic conditions causes rapid sulfide consumption; therefore, most of the epsilonproteobacterial groups identified must consume dissolved sulfide as sulfur-oxidizers (see Chapters 5 and 6).

Another line of evidence to suggest that “*Epsilonproteobacteria*” in the microbial mats oxidize sulfur compounds is from the measured $\delta^{34}\text{S}$ values (Figure 2-6). The decrease in $\delta^{34}\text{S}$ values for $\text{C}_\text{T}\text{S}^-$ from the cave spring to the end of the mats, by up to 2‰, indicates that allochthonous $\delta^{34}\text{S}$ values are being offset by biogenic sulfide generated by sulfate-reducing bacteria (e.g., *Desulfocapsa thiozymogenes*) within the mats (Canfield, 2001b). H_2S produced by sulfate-reducing bacteria would have more negative $\delta^{34}\text{S}$ values isotopes than the incoming sulfide, as the ^{34}S discrimination expressed by sulfate reduction is variable and can be as high as 45‰ (Canfield, 2001a; 2001b). In comparison, the processes of sulfide volatilization (Van Everdingen et al., 1985; Fry et al., 1986) and abiotic autoxidation (Fry et al., 1988) would result in a ^{34}S enrichment in the residual

dissolved sulfide. Because there is a high sulfur concentration in the microbial biomass, presumably as intracellular sulfur, the $\delta^{34}\text{S}$ values for microbial biomass are interpreted as a direct measure of the sulfide source utilized by the sulfur-oxidizers. Current thought is that sulfur-oxidizing bacteria exhibit negligible ($\pm 1\%$) sulfur isotope fractionation during both the transformation of sulfide to elemental sulfur and elemental sulfur to sulfate (Toran and Harris, 1989). Specifically, if the bulk of the microbial biomass that oxidized reduced sulfur compounds utilized only allochthonous sulfide, then the $\delta^{34}\text{S}$ values for the mats would be nearly the same as the spring water sulfide (Kaplan and Rittenberg, 1964). The general ^{34}S depletion in the microbial biomass relative to the source (i.e., dissolved sulfide) suggests that sulfur-oxidizing bacteria utilize a mixture of both allochthonous and autochthonous sulfide (Toran and Harris, 1989; Canfield, 2001a).

Geochemical Controls on Community Structure and Ecosystem Function

Studies from aquatic environments suggest that shifts in community structure could result from changes in nutrient availability, salinity, light penetration, turbidity, oxygen content, sulfide, or pH (e.g., Skirnisdottir et al., 2000; Nübel et al., 2001). At present, however, there have not been any investigations that describe the controls on changing community structure from a freshwater aphotic habitat. Specifically, light penetration, turbidity, and salinity are not critical physicochemical conditions to influence cave microbial communities, and changes in the pH of the cave waters are not important because of the buffering of pH to circum-neutral conditions by dissolving carbonate rock. Instead, I propose

that 1) variations in dissolved hydrogen sulfide concentrations, 2) increasing dissolved oxygen concentrations downstream, 3) colonization of the springs and outflow channels by “*Epsilonproteobacteria*”, and 4) changes in organic carbon production and storage as a result of chemolithoautotrophy by epsilonproteobacterial groups are the most critical parameters affecting microbial community structure within the microbial mats.

The relative abundances of epsilonproteobacterial and other taxonomic groups shifted moving downstream with changing dissolved sulfide and oxygen concentrations (Table 2-3). In general, the abundance of both epsilonproteobacterial LKC groups I and II decreased from the orifice pools downstream, and the highest abundance of epsilonproteobacterial LKC group I was from samples where the concentration of dissolved oxygen was very low at both the Fissure and Upper Springs. Clone libraries from the three spring orifices, which originated from areas continuously replenished by sulfidic spring water, were dominated by one epsilonproteobacterial group, whereas downstream libraries had higher bacterial diversity (Table 2-3). For example, at the Lower Spring, all clones screened by RFLP belonged to the epsilonproteobacterial LKC group II, whereas 1 m downstream in the microbial mat nine other bacterial groups were identified. At the three springs, there was also an increase in the abundance of *Thiothrix*- and/or *Thiobacillus*-like clones downstream, which is in accordance with the characterized metabolism and sulfide and oxygen preferences for these groups (e.g., Howarth et al., 1999). Specifically, *Thiothrix* spp. tolerate or require higher dissolved oxygen concentrations compared to what is known about the oxygen requirements for some

cultured “*Epsilonproteobacteria*”. At the Upper Spring, LKC group III was most abundant in downstream libraries (203f) where the dissolved oxygen concentration was higher, suggesting that while this group may be involved with sulfur cycling, this group may prefer higher habitat oxygen content. The dominance of *Acidobacterium* in the 203w clone library, from the surface of the mat where dissolved oxygen is highest, suggests that this group prefers higher oxygen and lower sulfide concentrations.

Sulfur storage in the microbial mats from the three springs, as indicated by the sulfur content of the mats, also changed downstream (Table 2-2), which corresponds to the types of microbial groups present in the mats. The highest sulfur content was from white filament bundles collected from the orifices and from the mat termini; lower sulfur contents were measured from the filament libraries from the middle of the stream transects. There is no indication from cultures that “*Epsilonproteobacteria*” store sulfur intracellularly like *Thiothrix* spp. (Howarth et al., 1999), possibly as a mechanism to attenuate changes in substrate availability in the environment (Chesson et al., 2002). The marine epsilonproteobacterial strain “*Candidatus Arcobacter sulfidicus*” forms extracellular sulfur filaments (Taylor et al., 1999; Wirsen et al., 2002) and cultures of nitrate-reducing sulfur-oxidizing “*Epsilonproteobacteria*” form sulfur as the metabolic end-product when nitrate is limiting or absent (Gevertz et al., 2000; Nemati et al., 2001). Some neutrophilic *Thiobacillus* spp. are also known to precipitate sulfur outside the cell (Kelly and Harrison, 1989). Therefore, the high sulfur content in white filaments from the spring orifice samples, dominated by “*Epsilonproteobacteria*” could be due to

extracellular sulfur or sulfur accumulation due to nitrate-reduction. Higher sulfur content in downstream samples could also be due to incomplete sulfide oxidation to elemental sulfur by *Thiothrix* spp. The exceptionally low sulfur content in the 203y sample (8.6%) compared to other morphotypes may be because the thiobacilli oxidize sulfur within the mat morphotype due to the diminished dissolved sulfide concentration in the stream water. Therefore, the distribution of sulfur content in the microbial mats may explain how several bacterial groups with similar metabolic requirements (e.g., presence of reduced sulfur compounds) coexist, as there appears to be distinct differences in spatial and temporal resource use by the microbial populations in the mat morphotypes moving downstream (Chesson et al., 2002).

Based on experiments from deep-sea vent sites where “*Epsilonproteobacteria*” are the first to colonize virgin surfaces, López-García et al. (2003) suggest that epsilonproteobacterial groups initially and rapidly diversify metabolically within a habitat (natural or artificial), and thereby create microniches (such as anoxic regions) where other bacteria will subsequently colonize. High diversity among the specialized “*Epsilonproteobacteria*” would essentially maximize ecosystem functionality of other microbial groups and make the entire system more productive because of high growth rates, significantly higher biomass, and quick adaptations to specific geochemical conditions of the habitat. Additionally, Chesson et al. (2002) describe the tendency for the most productive species to also be the most dominant in a habitat, and thereby push others species to comparatively lower densities. These ecological caveats may explain why the

microbial mats in Lower Kane Cave have high diversity within the “*Epsilonproteobacteria*”, but lower bacterial diversity overall.

The bacterial community composition of the 203g clone library is one of the most telling examples of the controls geochemistry has on community structure, and perhaps as an ecological consequence of “*Epsilonproteobacteria*” creating anoxic regions within the mat. The interior of the mat was dominated by clones with 99% nucleotide similarity to *Pantoea agglomerans* and environmental clones. *Pantoea* spp. are ubiquitous in natural and engineered environments, and are saprophytic, facultative anaerobes with diverse metabolic capabilities, including dissimilatory metal reduction. Recently, Northup et al. (2003) report a single *Pantoea* 16S rDNA clone from corrosion residues in Lechuguilla Cave, New Mexico, a cave that formed over several million years from sulfuric acid dissolution. This clone, however, is not closely related to those from Lower Kane Cave. There were also clones with 99% sequence similarity to *Serratia marcescens*, which is common to soil, water, and plants. *S. marcescens* is saprophytic and an opportunistic pathogen known to cause a variety of infections and diseases (Su et al., 2003). Although rare clones closely related to *D. thiozymogenes* were also identified from some samples (Table 2-3), preliminary culture investigation of gray filaments and other mat samples suggest that sulfate-reducing bacteria are present (see Chapter 4).

The presence of fermenting and sulfate-reducing bacteria in the deepest, most anaerobic portion of the mat is consistent with reducing conditions measured from oxygen microelectrodes, the presence of reduced mineral phases (Figure 2-4),

and the low C:N ratios for the gray sediment and filaments (Table 2-2). The ratios suggest enhanced processing of biological material due to heterotrophy, and possibly fermentation. While molecular methods allow for the characterization of organisms that are difficult, if not impossible to cultivate (e.g., Head and Gray, 1998), unfortunately molecular methods can create significant biases and underestimations of particular microbial groups, especially if abundances are $<10^7$ cells per volume (von Wintzingerode et al., 1997; Speksnijder et al., 2001). Therefore, because this part of the study focused on the white filament morphotypes, it is likely that the diversity of anaerobes is underrepresented with respect to total genetic diversity, and combined culture- and molecular-based approaches are necessary.

Chemolithoautotrophy in the Subsurface

Most caves are traditionally energy- and nutrient-limited, commonly fed by surface streams in which photosynthetically-derived organic matter and sediments, as well as microorganisms, are washed into the subsurface and deposited (Poulson and Lavoie, 2000; Simon et al., 2003). Previous studies have shown that most microorganisms in caves are not chemolithoautotrophs, but instead are translocated soil heterotrophs, chemoorganotrophs, or fecal coliform bacteria from contaminated surface water (Poulson and Lavoie, 2000). Mikell et al. (1996) estimate that $\geq 75\%$ of microbial communities in caves are heterotrophs. While it would be difficult to assess the metabolic pathways for all the microbial groups identified from the clone libraries using culture-based methods, or even to speculate about the metabolism for some groups with no cultured relatives, I used stable carbon isotope systematics

to interpret the source of carbon to the microbial mats, as well as to determine how carbon is cycled among different metabolic guilds. I propose that primary productivity was linked to the sulfur cycle through chemolithoautotrophy, as the geochemistry of the cave waters is consistent with reduced sulfur compounds being important components of the energy budget of the microbial ecosystem and because the most abundant microbial groups are associated with sulfur metabolism.

While the Bighorn River may have had a role in inoculating the cave with microorganisms during past flood stages (refer to Figure 1-10), I suggest that the microbial communities in Lower Kane Cave are endemic and virtually unaffected by surface hydrologic conditions, on the basis of these findings: 1) the discharging cave springs contribute little to no allochthonous DOC or particulate organic carbon to the microbial community (Table 2-1); 2) bacterial groups common to most soil environments, as evidence of translocated soil microbes, were not identified based on 16S rDNA phylogenies; and 3) the filamentous microbial biomass in Lower Kane Cave reaches at least 10^{10} cells·ml⁻¹ (Table 2-2), significantly higher than 10^2 to 10^4 cells·ml⁻¹ commonly found in aquatic cave systems (Brown et al., 1994). Furthermore, the overall carbon isotope compositions of the microbial biomass reflect significant isotopic discrimination against ¹³C relative to the inorganic carbon source (Figure 2-5), with 77% of the microbial mat samples having $\delta^{13}\text{C}$ values $\leq 30\text{‰}$, well below that of terrestrial biomass (Coplen et al., 2002), demonstrating that inorganic carbon is predominately fixed through chemolithoautotrophy. Porter (1999; unpublished data) verified chemolithoautotrophic productivity from the white filamentous microbial mats at

the Lower Spring by H^{14}CO_3 -assimilation, which suggested that there was more than six times higher autotrophic productivity than heterotrophic productivity, as tested by ^{14}C -leucine-incorporation. The results of the 16S rRNA gene phylogenies also suggest that only a very minor component of the community is potentially heterotrophic.

Chemolithoautotrophy in a cave ecosystem is important because it serves as the base for the cave food web, increasing both food quality and quantity (Kinkle and Kane, 2000; Poulson and Lavoie, 2000). Movile Cave, Romania, was the first documented chemolithoautotrophically-based cave and groundwater ecosystem (Sarbu et al., 1996), and subsequently chemolithoautotrophy has been found in several different sulfidic caves systems around the world, including marine caves from Cape Palinuro, Italy (Airoldi et al., 1997), the Frasassi Caves, Italy (Vlasceanu et al., 1997; Sarbu et al., 2000), Cueva de Villa Luz, Mexico (Hose et al., 2000), Cesspool Cave (Engel et al., 2001), and the flooded Nullarbor caves, Australia (Holmes et al., 2001). The bulk of the white filament microbial biomass in Lower Kane Cave has low C:N ratios averaging 5.0, compared to a C:N ratio of 5.7 for microbial mats from Movile Cave (Kinkle and Kane, 2000). The C:N ratios for Lower Kane Cave mats match previously reported ratios for bacterial cells (C:N = 3 to 5; Paul and Clark, 1996), but also to periphyton in surface streams (C:N = 4 to 8; Gregory, 1983) and bacteria from a marine hydrothermal vent site (C:N = 3.8 to 9.4; Gugliandolo and Maugeri, 1998). These C:N ratios are consistent with an insignificant influx and processing of allochthonous carbon, and instead suggest that carbon is provided in situ through autotrophy. The especially low C:N ratios

for the white filaments from Lower Kane Cave suggest a high quality food that could be used by heterotrophic microorganisms and higher trophic levels (McMahon, 1975). Incidentally, there is a large population of snails (*Physa spelunca*) that graze on the microbial mats in Lower Kane Cave. In contrast, the high C:N ratios in the gray filaments indicate carbon storage and accumulation of processed biomass, but a reduction in nitrogen availability.

The mechanisms for inorganic carbon fixation were not evident based on carbon isotope analyses, as there are several different pathways for inorganic carbon fixation, and not all fixation pathways and their isotopic effects are known. Microorganisms that fix CO₂ by the Calvin reductive pentose phosphate pathway (Calvin-Benson-Bassham cycle), the predominant and most important CO₂-fixation pathway for photosynthetic and chemosynthetic bacteria, have isotopic values that fall into two categories based on the form of CO₂-fixing enzyme, ribulose- 1,5-bisphosphate carboxylase/oxygenase (RubisCO) (Robinson and Cavanaugh, 1995). The fixation pathway using the reductive citric acid (TCA) cycle imparts a smaller (~-10‰) carbon isotope fractionation (Preuß et al., 1989; Taylor et al., 1999; Wirsen et al., 2002). Nearly all of the mat samples from Lower Kane Cave had δ¹³C values that fit into the RubisCO form I group, ranging between -27 to -35‰ (the ‘-30‰ group’) (Robinson and Cavanaugh, 1995). Physicochemical conditions, such as velocity, water depth, temperature, pH, and CO₂ concentrations, can affect the effective isotope discrimination of autotrophs, which would result in tremendously different discrimination values (Preuß et al., 1989; Simenstad et al.,

1993; France, 1995; France and Cattaneo, 1998). However, the Upper Spring transect stream water maintains constant chemistry and turbulent flow.

Nutrient Spiraling

There were systematic differences in the carbon isotope composition among the mat morphotypes at any location, however, which suggests that there may be distinct carbon isotope effects imparted by specific populations due to autotrophic production versus heterotrophic consumption. Changing abundances of bacterial populations downstream could account for this observation if the downstream populations express larger ^{13}C discrimination. An alternative explanation for the downstream carbon (and sulfur) isotope trends may be that mat stratification, caused by redox conditions, creates an environment for nutrient spiraling, a process first described from surface stream ecosystems in which nutrients are cycled between multiple components of the ecosystem while being transported further downstream in each subsequent cycle (Newbold et al., 1981; Newbold et al., 1982; Newbold, 1982; Allan, 1995). Nutrient spiraling has neither been described from subsurface ecosystems, nor from chemosynthetic systems.

Variations in the $\delta^{13}\text{C}$ composition among the different microbial mat morphotypes (white filaments versus gray filaments) in downstream transects suggest carbon cycling between chemolithoautotrophs and heterotrophs. The physical model of the nutrient spiral is based on the energy transfer between redox (metabolic) environments, and without the metabolic complexity and juxtaposition of aerobic and anaerobic populations, nutrient spiraling would not occur. The autotrophically-fixed carbon, which may be respired as CO_2 with a low $\delta^{13}\text{C}$ value,

is transported downstream and preferentially reassimilated by autotrophs in the mat boundary layer; the proportion and intensity of recycling of the fixed carbon derived from respiration should increase downstream (Newbold, 1982). Downstream, filamentous sulfur-oxidizing bacteria form a thick mat that restricts the downward flux of oxygen into the mat interior, and the occupation of the exterior of the microbial mats by sulfur-oxidizers results in consumption of most of the available oxygen. This creates an anaerobic mat interior where compounds are transported by diffusion only, maintaining a habitat for obligate anaerobic populations. The anaerobic consortium, consisting of predominately sulfate-reducing and fermenting bacteria (refer to Chapter 4), generates biogenic sulfide that diffuses outward for consumption by the sulfur-oxidizers. Classically, the components of a nutrient spiral are transported by stream advection, and DIC, sulfate, and allochthonous sulfide move through the system in this manner. However, the effect of the anaerobic system bounded by the oxidizing system is a partial retention of both organic carbon and biogenic sulfide relative to stream advection, which promotes spiraling of sulfur between redox environments.

CONCLUSIONS

Molecular techniques and carbon and sulfur isotope ratio analyses were combined to examine the dynamics of microbial community structure and nutrient cycling in an aphotic sulfidic cave system. Microbial mat bacterial diversity was low overall, with most communities being dominated by several evolutionary lineages within the “*Epsilonproteobacteria*”. Certain bacterial groups were found only in one microbial mat morphotype, and most bacterial groups were rarely found

or were completely absent in other morphotypes. The concentrations of dissolved oxygen and dissolved sulfide controlled the distribution of sulfur-oxidizers with differing requirements for oxygen, such that those preferring higher oxygen conditions were found at the end of the microbial mats where dissolved oxygen was highest. The “*Epsilonproteobacteria*” play a significant role in providing chemolithoautotrophic energy to the otherwise nutrient-poor cave habitat. Additionally, these filamentous sulfur-oxidizing bacteria initially colonize the cave springs, forming a dense mat that provides habitat for other bacterial groups with heterotrophic or chemoorganotrophic metabolism (Horner-Devine et al., 2003), and thereby increase mat species richness. The physical model of carbon and sulfur spiraling is based on the energy transfer between redox environments within the mats, and without aerobic and anaerobic metabolic complexity, nutrient spiraling would not occur. Spiraling carbon and sulfur between aerobe and anaerobe, autotroph and heterotroph, significantly extends the mat community.

Table 2-1: Geochemical parameters from representative Lower Kane Cave spring and stream water samples from August 2001, reported in $\text{mmol}\cdot\text{L}^{-1}$, unless otherwise noted.

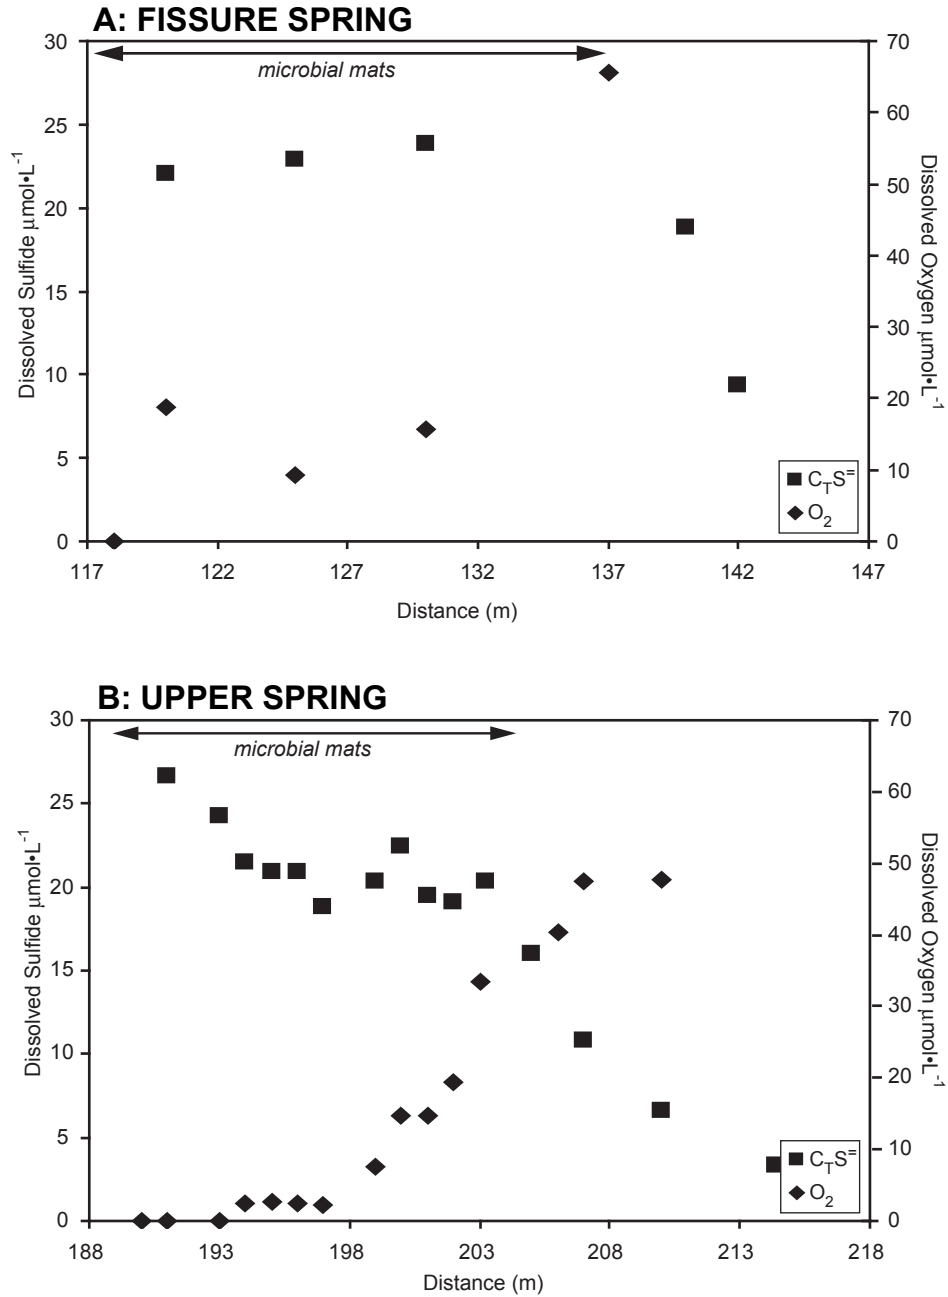

Figure 2-1: Total dissolved sulfide ($C_T S^-$) (■) and dissolved oxygen (O_2) (◆) versus distance profiles from spring orifice through stream transects for the (A) Fissure Spring and (B) Upper Spring. Distance was measured from the back of the cave to the entrance.

Figure 2-2: Sampling sites, springs, and microbial mats in Lower Kane Cave, Wyoming. Black arrows in all photographs point in the direction of flow. (A) Lower Spring orifice (248 m) occupied by emergent sulfidic groundwater (flowing over the lip at the lower left) and white filament bundles. A thick white filamentous mat forms at the edge of the orifice. Orifice walls are made of limestone, while gypsum occurs around the edge of the orifice pool (upper right). (B) End of thick microbial mat below Lower Spring (248 m). The mat is composed of white filaments and dense gel-like yellow masses. Black spots on rocks at the edge of the mat (upper left) are snails (*Physa spelunca*, 2 mm long). Gas bubbles of carbon dioxide, methane, and hydrogen sulfide gases form in this portion of the mat. (C) Upper Spring Pool (190 m) area, looking upstream, with gray sediment on the orifice pool bottom and white filaments suspended in the water column. Water depth at the deepest part of the pool is ~ 2 m, although average water depth is 30 cm. (D) Upper Spring filament bundles suspended in the water column (190 m). (E) Knobby white webs on the surface of the mat within the Upper Spring channel (203 m). Thin white filaments are suspended in the water column above the webs. (F) Yellowish-white patches within white filament area at 203 m from the Upper Spring channel. Chert fragments are the stream bed substrate (lower center and lower left). Gas bubbles have also been observed at this locale. (G) Fissure Spring orifice (118 m). The orifice pool area consists of limestone cobbles and gray sediment, mostly clay. (H) Thin white filament bundles and white webs in the Fissure Spring outflow channel (125 m). Gas bubbles are also present.

Figure 2-9: 16S rRNA gene-based phylogenetic tree showing the phylogenetic position of *Gammaproteobacteria* bacterial clones from Lower Kane Cave. Clones are labeled in bold with corresponding sample and clone numbers. Reference sequences (including GenBank accession numbers) were chosen from the RDP to represent the diversity of each division. Each tree was rooted with different members of the *Proteobacteria* and other bacterial divisions. Tree topology was inferred from the results of minimum evolution (ME) analysis, and the phylogenetic affiliations of the clones were confirmed by comparison with different reconstruction methods. This tree is a representative topology from 14 trees. Numbers along tree branches refer to support values for each node corresponding to ME bootstrap proportions, MLga and BMC MC posterior probabilities.

Figure 2-10: 16S rRNA gene-based phylogenetic trees showing the phylogenetic position of *Betaproteobacteria* bacterial clones from Lower Kane Cave. Clones are labeled in bold with corresponding sample and clone numbers. Reference sequences (including GenBank accession numbers) were chosen from the RDP to represent the diversity of each division. Each tree was rooted with different members of the *Proteobacteria* and other bacterial divisions. Tree topology was inferred from the results of minimum evolution (ME) analysis, and the phylogenetic affiliations of the clones were confirmed by comparison with different reconstruction methods. This tree is a representative topology of 2 trees of the same score inferred from ME analyses, with the differences among the ME trees from the same search due only to changes in the relative position of sequences within clades of the LKC clones. Numbers along tree branches refer to support values for each node corresponding to ME bootstrap proportions, MLga and BMCMC posterior probabilities.

Figure 2-11: 16S rRNA gene-based phylogenetic trees showing the phylogenetic position of *Deltaproteobacteria* bacterial clones from Lower Kane Cave. Clones are labeled in bold with corresponding sample and clone numbers. Reference sequences (including GenBank accession numbers) were chosen from the RDP to represent the diversity of each division. Each tree was rooted with different members of the *Proteobacteria* and other bacterial divisions. Tree topology was inferred from the results of minimum evolution (ME) analysis, and the phylogenetic affiliations of the clones were confirmed by comparison with different reconstruction methods. The ME analysis of the *Deltaproteobacteria* alignments resulted in a single tree. Numbers along tree branches refer to support values for each node corresponding to ME bootstrap proportions, MLga and BMCMC posterior probabilities.

Figure 2-12: 16S rRNA gene-based phylogenetic trees showing the phylogenetic position of Bacteroidetes/Chlorobi and Acidobacterium bacterial clones from Lower Kane Cave. Clones are labeled in bold with corresponding sample and clone numbers. Reference sequences (including GenBank accession numbers) were chosen from the RDP to represent the diversity of each division. Each tree was rooted with different members of the *Proteobacteria* and other bacterial divisions. Tree topology was inferred from the results of minimum evolution (ME) analysis, and the ME analysis of the Bacteroidetes/Chlorobi-Acidobacterium alignments resulted in a single tree. Numbers along tree branches refer to support values for each node corresponding to ME bootstrap proportions, MLga and BMCMC posterior probabilities.

Chapter 3: Prevalence of Novel “*Epsilonproteobacteria*” from Filamentous Microbial Mats in Sulfidic Caves and Springs

ABSTRACT¹

A molecular phylogenetic approach and fluorescence in situ hybridization (FISH) were used to survey white filamentous microbial mat populations in Lower Kane Cave, Wyoming. FISH probes were designed from thirty-two 16S ribosomal DNA (rDNA) gene sequences obtained from Lower Kane Cave clones belonging to two distinct clusters within the “*Epsilonproteobacteria*,” designated LKC group I and LKC group II. FISH proved to be an efficient tool for identifying and quantifying the previously uncharacterized, filamentous “*Epsilonproteobacteria*” from the cave microbial mats. Bacterial group quantification from six different Lower Kane Cave mat samples indicated that filamentous LKC group II populations dominated most of the bacterial communities ($\leq 70\%$ of the total bacteria). The microbial mats from Lower Kane Cave represent the first non-marine natural system demonstrably driven by the activity of “*Epsilonproteobacteria*”. Moreover, to demonstrate that these novel “*Epsilonproteobacteria*” are broadly distributed throughout sulfidic terrestrial habitats, occupying a range of physicochemical conditions, microbial mats from three additional sulfidic caves and nine surface-discharging mesothermal and thermal sulfidic springs were examined using lineage-specific

¹ A portion of this chapter originated from the publication A.S. Engel, N. Lee, M.L. Porter, L.A. Stern, P.C. Bennett, M. Wagner, 2003, Filamentous “*Epsilonproteobacteria*” dominate microbial mats from sulfidic springs: Applied and Environmental Microbiology, vol. 69(9), p. 5503-5511.

epsilonproteobacterial PCR primers based on the LKC sequences. Microbial mats from four geographically-distinct sulfidic caves in the USA and Italy, and nine surface-discharging springs were examined. Of the sites surveyed, positive amplification of 16S rDNA was obtained for both LKC groups I and II from two caves and five springs, ranging in water temperature from 8°C to 55°C. Several sites only had one group present. This work expands the evolutionary history and biogeographic diversity of the “*Epsilonproteobacteria*” and demonstrates the importance of this class to widespread biogeochemical cycling in terrestrial sulfidic habitats.

INTRODUCTION

The “*Epsilonproteobacteria*” class is, by and large, the most poorly characterized division within the *Proteobacteria* (Garrity and Holt, 2001; On, 2001). At present, the “*Epsilonproteobacteria*” consists of two genetically distinct orders, the “*Campylobacterales*”, and the *Nautiliales* (Miroshnichenko et al., 2004). The family *Campylobacteraceae* comprises the genera *Campylobacter*, *Arcobacter*, *Sulfurospirillum*, and *Thiovulum*, the family “*Helicobacteraceae*” is formed by the genera *Helicobacter* and *Wolinella*, and the family *Nautiliaceae* consists of the genera *Nautilia* and *Caminiibacter* (Vandamme and De Ley, 1991; Miroshnichenko et al., 2004). While several genera within this group have been well characterized, such as *Helicobacter* and *Campylobacter* because of pathogenicity (On, 2001), most lineages have only been described from environmental 16S rRNA-based phylogenetic studies. Moreover, of all the genera described, *Thiovulum* and *Sulfurospirillum* are not associated with metazoans.

Many as yet uncultured phylogenetic groups have been characterized from environmental sequences retrieved from marine settings, including seawater and muds (Todorov et al., 2000; Madrid et al., 2001), deep-sea hydrothermal vent sites (Reysenbach et al., 2000; Corre et al., 2001; Longnecker et al., 2001; Takai et al., 2003), and associated with vent metazoans (Moyer et al., 1995; Reysenbach et al., 2000; Corre et al., 2001; Longnecker and Reysenbach, 2001; López-García et al., 2003; Takai et al., 2003; Alain et al., 2004). Recent culture-based investigations expanded the metabolic diversity of evolutionary groups from marine habitats (Takai et al., 2003; Alain et al., 2004), and several studies have resulted in new genera and species descriptions (Alain et al., 2002; Miroshnichenko et al., 2002; Alain et al., 2004; Miroshnichenko et al., 2004). In many investigations, “*Epsilonproteobacteria*” are characterized as mesophiles and occupy environments with low oxygen tensions, but many strains that have been isolated can also grow in the absence of oxygen (e.g., Luijten et al., 2003), and have been implicated in sulfur cycling, and especially oxidation (e.g., Finster et al., 1997; Gevertz et al., 2000; Nemati et al., 2001; On, 2001; Takai et al., 2003).

Comparatively, epsilonproteobacterial groups identified from terrestrial environments are only now being recognized (e.g., Engel et al., 2003), as little is known about the diversity, ecophysiology, and biogeochemical importance of terrestrial sulfur-based habitats. Environmental sequences of “*Epsilonproteobacteria*” have been retrieved from microbial mats at surface-discharging sulfidic springs (Rudolph et al., 2001; Barton et al., 2002; Moissl et al., 2002; Elshahed et al., 2003; Rzonca and Schulze-Makuch, 2003), groundwater associated with

hydrocarbons (Gevertz et al., 2000; Watanabe et al., 2000; Watanabe et al., 2002; Kodama and Watanabe, 2003), and caves with sulfidic springs and streams (Angert et al., 1998; Engel et al., 2001); Engel et al. 2003; Engel et al., in review). Kodama et al (2003) and Gevertz et al. (2000) isolated strains of rod-shaped cells from petroleum-contaminated groundwater and oil field production waters, respectively. Relatively little is known about “*Epsilonproteobacteria*” from non-marine settings because the terrestrial subsurface, including groundwater, is often inaccessible for study. However, the subsurface is reachable through caves and springs. Although springs vary geochemically and hydrogeologically, some of the most common types are associated with sulfidic water, and sulfidic caves and springs could be exceptional habitats for “*Epsilonproteobacteria*”.

The main purpose of this chapter was to examine terrestrial sulfidic habitats for “*Epsilonproteobacteria*”, based on initial 16S rRNA gene characterization of the filamentous microbial mats from Lower Kane Cave, Wyoming (Chapter 2) and previous work from other sulfidic caves (Angert et al., 1998; Engel et al., 2001; Barton et al., 2002). To identify and reliably quantify “*Epsilonproteobacteria*”, I designed, evaluated, and applied two new 16S rRNA-targeted oligonucleotide probes specific for the detection of novel “*Epsilonproteobacteria*” using fluorescence in situ hybridization (FISH). With the complementary oligonucleotide sequences to target DNA, I also designed PCR primers to amplify lineage-specific epsilonproteobacterial DNA from microbial mats in other sulfidic caves and surface-discharging springs. The results of this work expand the geographic diversity of “*Epsilonproteobacteria*” to many different sulfidic springs and caves

that have been previously overlooked. The “*Epsilonproteobacteria*” play an important role in the widespread biogeochemical cycling of carbon and sulfur nutrients, and in subterranean geological processes.

MATERIALS AND METHODS

Sample Acquisition from Lower Kane Cave, Wyoming

Two major and two minor anaerobic, sulfidic springs discharge into Lower Kane Cave along a fracture zone (Figure 1-2; see Chapter 1). Samples for DNA extraction were obtained from microbial mats, and 16S rDNA clone libraries were constructed from a subset of six samples from the cave: Fissure Spring orifice white filament bundles (sample 21), Upper Spring orifice white filament bundles (samples 57 and 58), Upper Spring orifice white filament bundles (sample 114), Upper Spring thin white filaments (sample 190), Lower Spring orifice white filament bundles (sample 199), and Lower Spring yellowish-white mat (sample 198). Mat samples used for FISH were collected from the Fissure Spring orifice, Lower Spring orifice, the white filamentous mat from the Lower Spring, Upper Spring orifice, and three white filamentous mat samples from the Upper Spring stream channel (white mat 1, 2, and 3).

Sample Acquisition from Other Sulfidic Caves and Springs

White filamentous microbial mats from four sulfidic cave springs (12 to 22°C), four mesothermal (10 to 33°C) sulfidic surface-discharging springs, and eight thermal sulfidic surface-discharging springs (45 to 65°C) were sampled from the United States and Italy (Table 3-1). The broad geography and geochemical conditions were of interest in order to survey for “*Epsilonproteobacteria*” related to

those from Lower Kane Cave using epsilonproteobacterial-specific PCR primer sets. Refer to Appendix B for descriptions of the field sites. Spring pH and sulfide content were not significantly different (Table 3-1). There were several surface springs with phototrophic microbial biomass associated with the white filamentous mat morphotypes (Appendix B, Figures B-1 through B-10). All of the caves that were sampled formed in limestone or travertine, and almost all of the surface springs discharged from carbonates, either limestone or travertine (Table 3-1). The Lazio springs in Italy issued from volcanics (e.g., rhyolite), although the spring waters were also actively depositing travertine, and Palmetto Spring, Texas, discharged from sandstone, but the spring orifice was in an artificial concrete basin.

DNA Extraction

Approximately 0.2 to 0.5 ml of microbial mat from caves and springs were aseptically collected in the cave and transferred into 0.5 to 1 ml DNA extraction buffer containing 10 mM Tris-HCl (pH 8), 100 mM EDTA, and 2% sodium dodecyl sulfate (SDS). Total community DNA was extracted using an extraction protocol similar to the commercially available Purgene DNA extraction kits (Gentra Systems, Minneapolis, Minnesota), with the following modifications: 9 μ l Proteinase K (20 mg/ml) was added to each DNA extraction buffer prior to digestion; a freeze-thaw (3 times at -80°C to 65°C) series was used; samples were incubated at 55°C overnight to digest cellular material; RNase was added to the digests and incubated at 37°C for up to 1 hr; and nucleic acids were precipitated in isopropanol overnight at -20°C .

PCR Amplification

For Lower Kane Cave samples, nearly full-length 16S rDNA gene sequences were PCR-amplified using the primer pairs 27f (forward, 5'-AGAGTTTGATCCTGGCTCAG-3') and 1492r (reverse, 5'-GGTTACCTGTTACGACTT-3') for the domain *Bacteria*, according to the protocol described by Lane et al. (1991). Amplification was performed with a Perkin Elmer 9700 thermal cycler by Megan L. Porter at Brigham Young University, Department of Integrative Biology (Provo, Utah). The following conditions were used: denaturation at 95°C for 1 min, primer annealing at 42°C for 1 min, chain extension at 72°C for 1.5 min. Fifty PCR cycles were used. A control tube containing sterile water instead of DNA was used as a negative control.

For other cave and spring samples, 16S rDNA gene sequences were PCR-amplified using lineage-specific epsilonproteobacterial PCR primers designed during FISH probe design from the PROBE-DESIGN tools of the ARB software package (<http://www.arb-home.de>) (Ludwig and Strunk, 1996). For epsilonproteobacterial LKC group I, the primer pairs 'eps59f' (forward, 5'-AGTCGAACGATGAGAGGA-3') and 1492r for the domain *Bacteria* were used. For epsilonproteobacterial LKC group II, the primer pairs 'eps174f' (forward, 5'-CCCCATACTCCTTCTCAT-3') and 1492r. Amplification was performed in the Jackson School of Geosciences at the University of Texas at Austin with a MJ Research thermal cycler under the following conditions: denaturation at 95°C for 1 min, primer annealing at 45°C for eps59f and 47°C for eps174f for 1 min, chain extension at 72°C for 1.5 min. A control tube containing sterile water instead of

DNA was used as a negative control. Thirty cycles were done. PCR bands were visualized by electrophoresis on a 1% agarose gel.

Cloning, Sequencing, and Phylogenetic Analysis of 16S rRNA Genes

Amplified PCR products for Lower Kane Cave samples were purified with the GeneClean II Kit (Bio101, Inc., Vista, California), as recommended by the manufacturer. Purified PCR products were cloned using the TOPO TA Cloning Kit (Invitrogen, San Diego, California), following manufacturer's instructions.

The 16S rDNA clones obtained from Lower Kane Cave were lysed in 50 μ l buffer (10mM Tris-HCl; 0.1 mM EDTA, pH 8.0) for 10 min at 96°C. Clones were randomly selected for sequencing, and sequence inserts were then PCR-amplified from lysed cells using plasmid-specific primer pairs M13(-20) (5'-GTAAAACGACGGCCAGT-3') and M13(-24) (5'-AACAGCTATGACCATG-3') and the following PCR conditions: denaturation at 94°C for 1 min, primer annealing at 55°C for 1 min, chain extension at 72°C for 3 min, for 35 cycles. PCR products were purified using Sephadex columns and sequenced using an ABI Big-Dye Ready Reaction kit (Perkin Elmer) using the primers 27f and 1492r in conjunction with internal primers 907r (reverse, 5'-CCGTCAATTCCTTTRAGTTT-3') and 704f (forward, 5'-GTAGCGGTGAAATGCGTAGA-3'). Automated DNA sequencing was done on an ABI Prism 377XL sequencer (Perkin Elmer) at Brigham Young University.

The DNA sequences were submitted to the CHECK-CHIMERA program of the Ribosomal Data Base Project (RDP) II at Michigan State University (<http://rdp.cme.msu.edu/html/>) (Maidak et al., 2001). Clone sequences were

subjected to BLAST searches within the GenBank database (<http://www.ncbi.nlm.nih.gov/>) to determine 16S rRNA gene sequence similarities to culturable and not yet cultured organisms.

The retrieved nucleotide sequences were first aligned using Clustal X (Thompson et al., 1997) and then manually adjusted based on conserved gene primary and secondary configuration. Phylogenetic analyses were done by Megan L. Porter at Brigham Young University, using maximum likelihood, minimum evolution, and maximum parsimony criteria in PAUP* (Swofford, 2000) and Bayesian inference in MrBayes (Huelsenbeck and Crandall, 1997). For minimum evolution, Bayesian inference, and maximum likelihood searches, a model of evolution was chosen based on likelihood ratio tests (Huelsenbeck and Crandall, 1997), as implemented in Modeltest 3.06 (Posada and Crandall, 1998). As an indication of nodal support, bootstrap analyses were performed for maximum likelihood (100 replicates), minimum evolution (500 replicates), and maximum parsimony (1000 replicates). For Bayesian inference analyses, posterior probabilities were used for nodal support. All trees were rooted using *Desulfocapsa thiozymogenes* (X95181) and *Hydrogenophaga pseudoflava* (AF078770) as outgroups.

16S rRNA Oligonucleotide Probes

Oligonucleotide probes specific for two epsilonproteobacterial clone groups from Lower Kane Cave (LKC group I and group II) were designed using the PROBE-DESIGN tools from ARB and probe designations according to Alm et al. (Alm et al., 1996). Probe LKC59 (S-*-eProt-0059-a-A-18) is specific for LKC

group I clones, and probe LKC1006 (S-*-eProt-1006-a-A-18) targets LKC group II clones. Probe specificity was verified using the RDP PROBE-MATCH function (Maidak et al., 2001) and the PROBE-MATCH tool of the ARB software package, and a 16S rRNA data set including all publicly available sequences from “*Epsilonproteobacteria*” (at the time of probe design, 238 epsilonproteobacterial GenBank sequences were available for comparison). Sequences and optimal hybridization conditions for probes LKC59, LKC1006, and other probes used, are listed in Table 3-2, including probe EPS710, designed to target environmental clones within the “*Epsilonproteobacteria*” (Watanabe et al., 2000) and *Sulfuricurvum kujiense* (Kodama and Watanabe, 2003). More information about the applied probes can be found at probeBase (<http://www.microbial-ecology.net/probeBase>) (Loy et al., 2003).

Fluorescence In Situ Hybridization (FISH), Microscopy, and Quantification

For FISH, microbial mat samples were collected and shipped on dry ice to Dr. Michael Wagner and Dr. Natuschka Lee in the Department of Microbial Ecology, Technische Universität in Munich, Germany. Samples were preserved in two ways (with respect to the general requirements for successful FISH of gram-negative and gram-positive bacteria) within 48 hr of collection: (i) with 4% (wt/vol) paraformaldehyde for 3 hr before final wash with saline phosphate buffer as described by Manz et al. (1992), and (ii) with ice-cold ethanol according to Roller et al. (1994).

I performed all hybridizations and examined samples using a LSM510 confocal laser scanning microscopy (CLSM) (Zeiss, Oberkochen, Germany) in

Germany. Prepared cells were attached to Teflon-coated nonfluorescence slides and air-dried overnight before dehydrating by sequential washes in 50, 80, and 100% (vol/vol) ethanol for 3 min each. The probes were synthesized and directly labeled with the monofunctional, hydrophilic, sulfoindocyanine dyes indocarbocyanine (Cy3) and indodicarbocyanine (Cy5), or with FluosPrime (5,6-carboxyfluorescein-*N*-hydroxysuccinimide ester), purchased from Hybaid-Interactiva (Ulm, Germany). Hybridization and washes were performed as described by Manz et al. (1992). Briefly, the hybridization solution contained 5 M NaCl, 1 M Tris/HCl (pH 8), 10% [wt/vol] SDS, and formamide (as given in Table 3-2 for each probe). Cy3 and Cy5-labelled probes were applied at $30 \text{ ng}\cdot\mu\text{l}^{-1}$ each, while FluosPrime probes were applied at $50 \text{ ng}\cdot\mu\text{l}^{-1}$. Washing buffer consisted of 5 M NaCl, 1 M Tris/HCl (pH 8), 10% SDS, and 0.5 M EDTA (pH 8) and was preheated to 48°C. The wash buffer salt concentration was adjusted to the hybridization buffer formamide concentration according to Manz et al. (1992).

Optimal hybridization stringency for probes EPS710, LKC59, and LKC1006 was determined by increasing the formamide concentration of the hybridization buffer in increments of 5 or 10% while maintaining a constant hybridization temperature of 46°C. Because of a lack of suitable reference cells, the optimal hybridization stringency for the probes was defined by the highest stringency allowing unambiguous visual detection of probe target cells in fixed samples of the white filamentous microbial mats from two different sampling locations ('Upper Spg white mat 1' and 'Upper Spg white mat 3').

To determine the percentage of all cells detected with the bacterial probe set, EUB338I-III mix-hybridized mat samples were additionally stained with 10 μ l of a 10,000-fold dilute SYBR Green I (FMS Bioproducts, Rockland, Maine) working solution in the dark for 10 min at room temperature. Slides were then washed briefly with double-distilled H₂O and air-dried. Before examination, samples were covered with the antifading agent Citifluor AF1 (Chemical Laboratory, Caterbury, England). A CLSM equipped with a UV laser (351 and 364 nm), an Ar ion laser (450 to 514 nm), and two HeNe lasers (543 and 633 nm) was used to visualize FISH results. All images were recorded with a Plan-Apochromat 63x (1.4; oil immersion) objective. Image processing was performed with the LSM510 software (version 1.6). Quantification of probe-detected cells was achieved using Carl Zeiss Vision KS400 software in conjunction with the RAM (Relative Area Measurement) macro (Schmid et al., 2000).

Nucleotide Sequence Accession Numbers

The 16S rRNA gene sequences determined in this study, labeled with the prefix "LKC1", were submitted to GenBank, with accession numbers from AY191466 to AY191497.

RESULTS

Phylogenetic Analysis of 16S rRNA Clone Sequences from Lower Kane Cave

From six mat samples, 44 clones were randomly selected for sequencing in order to conduct a broad survey of the microorganisms present in Lower Kane Cave mat communities. Nearly full-length 16S rRNA gene fragments from the

clones were amplified and sequenced. None of the sequences were identified as chimera from RDP analysis. All clone sequences belonged to the *Proteobacteria* division; 85% of the clones were affiliated with the “*Epsilonproteobacteria*”, 11% of the clones belonged to the *Betaproteobacteria*, and 4% of the clones clustered within the *Gammaproteobacteria*, and specifically *Thiothrix* spp.

The Lower Kane Cave epsilonproteobacterial clones clustered into two different clades, referred to as LKC group I and LKC group II, with high bootstrap values supporting their phylogenetic position (Figure 3-1), similar to results described in Chapter 2. The closest relatives to both LKC group I and group II were two environmental clones, sipK119 and sipK94, obtained from microbial aggregates with a string-of-pearls-like morphology in sulfidic springs at the Sippenauer Moor, Regensburg, Germany (Rudolph et al., 2001; Moissl et al., 2002). Group I clones, identified from the Fissure and Upper Spring orifice samples, clustered closely (98-99% similar in nucleotide sequence) with clone sipK119 and Cesspool Cave clone group CC-4 (Engel et al., 2001). The closest cultured representative of LKC group I sequences was *Sulfuricurvum kujiense* (Kodama and Watanabe, 2003). LKC group II clones, obtained from Upper and Lower Spring orifice and white mat samples, were closely related to the sipK94 clone (99% similar in nucleotide sequence), and more distantly to various marine and hydrothermal vent clones (91-94% similarity), as well as to Parker Cave clones (92-94% identical) (Angert et al., 1998).

Fluorescence In Situ Hybridization of Lower Kane Cave Microbial Mats

FISH probes were used to identify and to quantify specific microorganisms in the filamentous microbial mats from Lower Kane Cave (Appendix B). Thirty-two clone sequences, thirteen from LKC group I and nineteen from LKC group II (Figure 3-1), were used to design rRNA-specific oligonucleotide probes. Probes LKC59 and LKC1006 targeted clone sequences from group I and group II, respectively, based on the PROBE-MATCH function in the ARB software (Table 3-3). Although LKC group I is closely related to other environmental clones from groundwater and caves (Figure 3-1), probe LKC59 has at least one mismatch with these and all other rRNA gene sequences in the database. Probe LKC1006 also did not target any other sequences in the database, including clone sipK94 which has 99% 16S rRNA gene sequence similarity to LKC group II sequence (Figure 3-1). Another probe for LKC group II was LKC174, targeting base position 174; however, the LKC174 probe did not work for FISH (no hybridization signal was observed), possibly because the 16S rRNA target region was inaccessible; probe LKC174 was disregarded for further FISH analyses. The target sequence was used instead as a PCR primer for LKC group II. Three of the LKC group II clones possess a single mismatch within the target site of probe LKC1006 and might not be detectable by this probe (Table 3-3). These mismatches indicate either actual genetic microheterogeneity or originate from PCR and/or sequencing artifacts.

Optimal hybridization stringency was determined for the newly designed probes, as well as for the previously published probe EPS710 (Watanabe et al., 2000); (Kodama and Watanabe, 2003). Because no cultured strains possessing the

target sites for probes LKC59 and LKC1006 are available, optimal hybridization stringency was inferred by visual comparison of filament fluorescence from cave samples (Figure 3-2; Appendix B). For all three probes, mat filaments showed bright fluorescence if hybridization buffers with up to 30% formamide were used (Figure 3-2); under more stringent conditions (higher formamide concentrations), signal intensity decreased.

In the six samples analyzed, between 68% and 88% of the cells stainable with a general nucleic acid dye (SYBR green I) could be detected with a bacterial probe set (Table 3-2; Appendix B). Of the ten different group- and genus-specific probes applied, positive hybridization signals were observed with the probes BET42a, GAM42a, G123T, and ARCH915. Long filamentous cells hybridized strongly with probes GAM42a and G123T, indicating the presence of *Gammaproteobacteria*, and in particular *Thiothrix* spp., which also hybridized to EUB338I-III mix (Figure 3-3A and 3-3B). Probe BET42a labeled small rods specifically, but weakly, in all samples (Figure 3-3C), indicating the presence of rare *Betaproteobacteria*. The FISH results for *Betaproteobacteria* and *Gammaproteobacteria* are similar to the results obtained from the 16S rRNA clone libraries (Chapter 2), in that these bacterial groups occur in the mats but are not dominant. In addition to the filamentous *Gammaproteobacteria*, the other filaments (Figure 3-3D) hybridized with EUB338I-III mix, are likely “*Epsilonproteobacteria*”. Interestingly, filaments that hybridized with GAM42a and G123T also hybridized with ARCH915. The PROBE-MATCH function in ARB suggested that the probe ARCH915 targeted some *Thiothrix* sequences,

particularly *T. unzii*, and therefore may not be a suitable probe when *Thiothrix* is present. No further analyses with the ARCH915 probe were done (Appendix B).

The three probes targeting subgroups within the “*Epsilonproteobacteria*” were used in different combinations to survey probe overlap. All probes exclusively hybridized to filamentous microbes, and conferred very bright signals to their target cells, indicating high rRNA contents (Amann et al., 1995). Filaments detected by probe LKC59 had an average diameter of 1 μm and appeared kinked or twisted, while straighter, longer, and slightly thicker filaments were detected by LKC1006 (Figure 3-4). Twisted filaments were observed with scanning electron microscopy (Figure 2-3E). Simultaneous hybridization with the epsilonproteobacterial probes LKC59 and EPS710 showed that they stained the same filamentous cells (Figure 3-4, row I), and as expected, neither probe EPS710 nor probe LKC59 overlapped with probe LKC1006 (Figure 3-4, rows II and III). In the study by Watanabe et al. (2000), probe EPS710 hybridized only to short rods during FISH. The different morphologies that hybridize to the EPS710 probe may indicate the potential for more group diversity than previously identified, and that the probe may confer genus-level or higher taxonomic specificity.

Epsilonproteobacterial filaments belonging to LKC group II dominated five of the six microbial mats examined and made up to 70% of the biovolume of those cells detectable by FISH with a bacterial probe set (Table 3-4). Only in Lower Spring white mats, which were dominated by *Thiothrix* spp., epsilonproteobacterial filaments occurred at relatively low numbers (4% of the bacterial biovolume). In contrast, epsilonproteobacterial filaments of LKC group I were below the detection

limit in three of the six samples investigated, and made up less than 10% of the biovolume in the other three samples (Table 3-4).

Distribution of “*Epsilonproteobacteria*” in Other Caves and Springs

The primer sequences for eprot59f (group I) and eprot174f (group II) were analyzed in GenBank for lineage-specificity (Table 3-5). Primer eprot59f showed a perfect match for the clone sipK119, the closest relative to LKC group I sequences. Other sequences, including members of the *Actinobacteria*, had one or more mismatches at the end of the primer. Primer eprot174f showed a perfect match for the epsilonproteobacterial clone T6-ph07-987 from deep-sea experimental chamber associated with *Alvinella* (Alain et al., 2004), but not for clone sipK119 (99% sequence similarity).

Previous 16S rRNA-based studies of several sulfidic springs have revealed the presence of “*Epsilonproteobacteria*” (Engel et al., 2001; Barton et al., 2002; Elshahed et al., 2003; Rzonca and Schulze-Makuch, 2003), and microbial mat samples from several of these sites (e.g., Table 3-1; Lower Kane Cave, Cesspool Cave, Glenwood Springs, and Soda Dam Spring) were used to test the utility of the new primers. Certainly, to verify that the phylogenetic groups of interest were amplified completely, the resulting PCR products should be cloned and sequenced. Additionally, a positive result does not always indicate that the organisms of interest are present if primers are not optimally applied (e.g., by using annealing temperatures that are not stringent). However, positive amplification using lineage-specific primers is a first step to circumvent the need to sequence many products randomly; if PCR is not successful following multiple approaches, no further

analyses are likely needed. Moreover, quantification is not possible by using this PCR-based method, so to determine if the groups are numerically important, additional studies using FISH are needed. FISH will also reveal the morphology of the microbial groups, which is important to demonstrate that the epsilonproteobacterial groups that hybridize with the LKC probes are filamentous in other habitats.

Positive PCR amplification with the lineage-specific primers was achieved for many white filamentous microbial mat samples; the general bacterial primer set was also used to verify results. Both epsilonproteobacterial primer sets had positive PCR amplification to Lower Kane Cave samples, as well as from Hellspont Cave and PBS Spring, sites downstream from Lower Kane Cave along the Bighorn River (Table 3-6; Figure 1-3). Based on phylogenetic relationships, the epsilonproteobacterial clone groups identified from Cesspool Cave were closely related to LKC group I (Engel et al., 2001), and PCR amplification with the eps59f/1492r primer set showed positive amplification, but not with the LKC group II primers (Table 3-6). “*Epsilonproteobacteria*” were also described from 16S rDNA investigations from the Drinking Spring at Glenwood Springs, Colorado (Barton et al., 2002), and Soda Dam spring, New Mexico (Rzonca and Schulze-Makuch, 2003); successful PCR amplification was obtained using both primer sets for Glenwood Springs, and only the eps59f/1492r set for Soda Dam spring (Table 3-6). PCR amplification with the eps59f/1492r primers was successful for mat samples from all the sulfidic caves and several springs (Table 3-6). The group II

primers successfully amplified all samples except those from Cesspool Cave and several springs (Table 3-6).

DISCUSSION

Defining the composition of microbial communities can aid in our understanding of biogeochemical cycling that occurs in remote and difficult-to-characterize habitats. Particularly for the terrestrial subsurface, little is known about microbial community structures because of the limited number of investigations done on such systems. The application here of the full-cycle rRNA approach to characterize microbial mats and “*Epsilonproteobacteria*” from cave and spring habitats, with Lower Kane Cave as the feature site, enabled assessment of the biogeochemical significance of these previously unknown “*Epsilonproteobacteria*” groups in a variety of environments.

The majority of 16S rRNA gene clones from Lower Kane Cave microbial mats from this investigation were assigned to two evolutionary lineages within the “*Epsilonproteobacteria*”, designated LKC group I and II, neither of which have closely related cultured representatives. Several 16S rDNA sequences retrieved from groundwater at an underground petroleum storage cavity (Watanabe et al., 2000; Watanabe et al., 2002) and *S. kujiense* (Kodama and Watanabe, 2003), an anaerobic sulfur oxidizer recently isolated from this habitat, cluster with LKC group I (Figure 3-1). Two clone groups (CC-4 and CC-9) from Cesspool Cave (Engel et al., 2001) are also closely related to LKC group I (Figure 3-1). In contrast, LKC group II forms a monophyletic grouping with the 16S rRNA gene sequence of an uncultured filamentous epibiont associated with the vent annelid

Alvinella pompejana (Campbell et al., 2001), and clone groups from phylogenetic studies of Parker Cave, another sulfidic cave system (Angert et al., 1998), are found in sister clades (Figure 3-1).

Quantitative FISH with two newly developed 16S rRNA-targeted oligonucleotide probes specific for LKC group I and II revealed that both groups in Lower Kane Cave are filamentous bacteria. Filamentous “*Epsilonproteobacteria*” have not previously been identified, as most “*Epsilonproteobacteria*” are demonstrably rod-shaped, helical, curved, or ovoid in cell morphology (Miroshnichenko et al., 2004). Bright FISH signals observed for both groups also suggest that the microbes were physiologically active when the mats were collected (Amann et al., 1995). LKC group I filaments were detected in low abundances in three samples, and were not detected in other samples. In contrast, LKC group II filaments dominated five of six samples by biovolume, and represented 50% to 70% of the community bacterial biovolume (Table 3-4).

The FISH results do complement the 16S rDNA clone libraries, as described in Chapter 2, but disparate results also point to the importance of using more than one molecular method to characterize microbial communities. Specifically, the quantification results with FISH for LKC groups I and II (Table 3-4) are slightly different than the phylotype results from restriction fragment length polymorphism (RFLP) that suggest both LKC groups I and II have nearly the same population sizes in some of the microbial mat samples (Chapter 2; Table 2-3), although in any one filamentous mat sample either one of the groups could

dominate. For example, LKC group I clones were prevalent by RFLP in samples from the Fissure Spring, but not LKC group II as indicated by FISH (Table 3-4).

Results from FISH did not target high microdiversity within the “*Epsilonproteobacteria*” that was identified from RFLP (Chapter 2; Table 2-3 and Table 2-5; Figure 2-8). The FISH probes designed in this part of the study were intended for LKC groups I and II only, but probe LKC59 (LKC group I) could also target three of 17 clone sequences from LKC group III (Figure 2-8). Probe LKC1006 targeted only LKC group II clone sequences. Conversely, probe EPS710, designed by Watanabe et al. (2000) for a group of “*Epsilonproteobacteria*” from groundwater, targeted LKC group I, III, and IV clone sequences, indicating that the EPS710 probe could broadly hybridize to a large group of “*Epsilonproteobacteria*” in which most of the environmental clones are from groundwater and caves, much more broadly than the LKC probes or primers. Sequences for the LKC groups V and VI are not targeted by any 16S rRNA probe currently known, indicating additional diversity within the “*Epsilonproteobacteria*”. Since these groups were not numerically important by RFLP, probes or primers were not constructed, although future work to describe complete epsilonproteobacterial diversity will require targeting these groups.

While high in situ abundance of free-living and eukaryote-associated “*Epsilonproteobacteria*” have been described from many marine environments, including hydrothermal vent and field communities and marine sediments, there has been no evidence that members of the “*Epsilonproteobacteria*” are also numerically important in terrestrial systems. The only exceptions currently known

are from two engineered systems and caves in which “*Epsilonproteobacteria*” exist in significant numbers. In the petroleum-contaminated groundwater associated with a storage cavity in Japan, between 12% and 24% of the total prokaryote cells could be identified via FISH as epsilonproteobacterial curved rods (Watanabe et al., 2000; Watanabe et al., 2002). Relatively low abundances of *Arcobacter* (4%) were identified with FISH from activated sludge in a wastewater treatment plant (Snaider et al., 1997). Epsilonproteobacterial abundance estimates from 16S rRNA clone libraries in Parker and Cesspool Caves, at 73% and 47% “*Epsilonproteobacteria*”, respectively, are similar to the FISH biovolume estimates for LKC groups I and II (Angert et al., 1998; Engel et al., 2001). Although the mats from the sulfidic springs in Sippenauer Moor harbor “*Epsilonproteobacteria*” closely related to LKC group I and II, FISH analysis revealed that these mats are dominated not by “*Epsilonproteobacteria*”, but by *Thiothrix* spp. and novel *Archaea* (Rudolph et al., 2001; Moissl et al., 2002). Consequently, the mats from Lower Kane Cave represent the first non-marine natural system demonstrably driven by the activity of “*Epsilonproteobacteria*”.

“*Epsilonproteobacteria*” obviously are successful at colonizing a range of marine habitats, and one of the goals of this study was to determine if “*Epsilonproteobacteria*” potentially are as widespread in terrestrial sulfidic environments as they are in marine settings. Results suggest that terrestrial “*Epsilonproteobacteria*” can occupy a variety of physicochemical conditions, and specifically a range of thermal conditions (Table 3-1; Appendix B). Most of the sampling locations were associated with discharge from limestone or travertine

(Table 3-1), suggesting that the “*Epsilonproteobacteria*” may prefer to colonize habitats where acidity generated from their metabolism (e.g., sulfur oxidation) is potentially buffered by dissolving limestone.

The prevalence of “*Epsilonproteobacteria*” in terrestrial environments may be even more widespread than results of this study indicate, and the utility of the epsilonproteobacterial-specific probe and primer sets is significant. There are fewer terrestrial epsilonproteobacterial 16S rDNA gene sequences available in the public databases compared to marine-originating sequences, indicating a lack of information regarding the presence of “*Epsilonproteobacteria*” in terrestrial settings. The clone sequences previously retrieved from Cesspool Cave (Engel et al., 2001) and Sippenaeuer Moor (Rudolph et al., 2001) provided the first indications that at least LKC group I was more widely distributed in terrestrial sulfidic spring and cave habitats than previous research suggested. It is possible that other sites are occupied by members of the “*Epsilonproteobacteria*” that are not targeted by the eps59f or eps174f PCR primers. For instance, epsilonproteobacterial clone groups that are phylogenetically distinct from LKC clone groups have been reported from the sulfidic Parker Cave, Kentucky (Angert et al., 1998), and Zodletone Spring, Oklahoma (Elshahed et al., 2003) (Figure 2-8), indicating additional diversity not targeted by the lineage-specific primers applied in this study.

Because of the specificity of the epsilonproteobacterial primers designed in this study, however, it is highly probable that the epsilonproteobacterial groups in the systems I examined are closely related in nucleotide sequence to the Lower

Kane Cave groups, and may not be genetically distinct enough to suggest different microbial species. A low degree of genetic divergence within these groups would indicate that modern geographic isolation may not be a driving factor in the speciation of the LKC epsilonproteobacterial groups, in contrast to what has been demonstrated for some cyanobacteria from hot springs around the world (Papke et al., 2003). Obtaining the full-length 16S rRNA gene sequences, as well as other gene sequences, are required in the future to examine the significance of geographic isolation and genetic evolution for "*Epsilonproteobacteria*". At the onset, however, this study expands the geographic diversity of "*Epsilonproteobacteria*" to a variety of terrestrial photic and aphotic sulfidic habitats, suggesting that these groups may be more important ecologically and geologically than previously considered.

Chapter 4: Diversity of Anaerobic Microorganisms in Cave Microbial Mats: Using a Culture-based Approach to Understand Carbon and Sulfur Cycling

ABSTRACT

Hydrogen sulfide-rich groundwater discharges from springs into Lower Kane Cave and Hellsport Cave, Wyoming, where filamentous sulfur-oxidizing bacteria form thick microbial mats, and through chemolithoautotrophy, these bacteria serve as the energetic base of the cave ecosystems. Spring waters entering the caves, as well as the interior of the microbial mats, are devoid of oxygen, and a culture-based approach was used to characterize and to enumerate anaerobic metabolic guilds, including sulfate- and sulfur-reducing bacteria, fermenting bacteria, iron-reducing bacteria, sulfur-oxidizing nitrate-reducing bacteria, and methanogens. Anaerobic microbes were more abundant in mat samples, with up to 10^6 cells·ml⁻¹, compared to water or sediment samples. Sulfate-reducers and fermenters represented the dominant culturable groups from the mats, while sulfur-reducers, iron-reducers, and methanogens were in low abundance ($<10^3$ cells·ml⁻¹). Eight fermentation pathways were identified from Lower Kane Cave enrichments, suggesting that fermenters play a significant role in degrading the chemolithoautotrophically produced organic carbon. This work expands the diversity of some anaerobic metabolic guilds to microbial mats in sulfidic caves, and demonstrates that anaerobic processes are as vital to the cave ecosystem as chemolithoautotrophy.

INTRODUCTION

Ecosystems are arranged structurally and functionally such that there is a producer component and a consumer component, and the primary goal in ecology is to understand the spatial arrangements of these organisms (Eiler et al., 2003; Horner-Devine et al., 2003). While autotrophs generate organic carbon, predominately carbohydrates (e.g., Hayes, 2001), consumers decompose the carbon, releasing and recycling new compounds back into the ecosystem (Wardle, 2002). While characterizing ecosystem primary productivity is essential, understanding the diversity of microbial consumers and the variety of carbon breakdown pathways are also crucial aspects for differentiating total ecosystem functioning.

A significant finding from previous molecular-based investigations of the microbial mats in Lower Kane Cave, as presented in Chapter 2, is that sulfur-oxidizing bacterial communities do not occur in isolation, but have the potential to form a complex mat structure with diverse metabolic guilds (Engel et al., 2003; Engel et al., accepted). While sulfate-reducing bacteria (SRB) have long been implicated in the degradation of organic contaminants in many different habitats (e.g., Widdel and Bak, 1992; Stoessell et al., 1993; Voordouw et al., 1996; Ulrich et al., 1998; Minz et al., 1999a; Minz et al., 1999b; Rios-Hernandez et al., 2003), colonization of sulfidic caves by SRB, or even sulfur-reducing bacteria (S⁰RB), has not been previously recognized. Other microorganisms responsible for fermentation or methanogenesis have been characterized from total community 16S rRNA gene

sequences retrieved from subaqueous cave mats (Angert et al., 1998; Engel et al., 2001), but most groups have not been intensely studied in detail.

Molecular methods allow characterization of a microbial community that may be difficult, if not impossible, to cultivate (Head et al., 1998). Unfortunately, molecular techniques can create significant biases and underestimations of particular microbial groups, especially if certain organisms have extremely high dominance, or conversely abundances $\leq 10^7$ cells per volume (von Wintzingerode et al., 1997; Speksnijder et al., 2001). Although Leff et al. (1995) suggest that only 1% of environmental bacteria can be cultured, and that standard culturing methods do often introduce a selective bias toward microorganisms able to grow quickly and to utilize substrates provided in the medium (“r-strategists”) more efficiently than other organisms in the community (McDougald et al., 1998), culturing does allow quantification of metabolically active organisms (Palleroni, 1997).

Based on previous geochemical and molecular investigations (Chapter 2), I anticipated that redox stratification of the mats would result in a range of metabolically active anaerobic microorganisms in the microbial mats, and that most would be concentrated in their anaerobic interior. Molecular methods may have overlooked less abundant populations of anaerobic microorganisms in the microbial mats, and this chapter describes a culture-based approach to characterize anaerobic microbes in both Lower Kane Cave and Hellsport Cave, Wyoming (Figure 1-1). I used the most probable number (MPN) method for enumeration and enrichment to examine a variety of anaerobes from mat samples, including many different groups

of fermenting bacteria, sulfur-oxidizing nitrate-reducing bacteria, iron-reducing bacteria, three different types of sulfate-reducing bacteria, sulfur-reducing bacteria, and three methanogenic groups. This work demonstrates that anaerobic microbial processes that cycle carbon and sulfur are as vital to the cave ecosystem as chemolithoautotrophy.

MATERIALS AND METHODS

Sampling Strategy and Protocol

Several iterations of the enrichment culturing and biomass estimate techniques were done from 2000 to 2003. Microbial mat samples from Lower Kane Cave and Hellsport Cave were collected aseptically, placed into 15-ml sterile Falcon tubes, and shaken vigorously to disrupt the mat structure prior to inoculation into enrichment media. Shaking proceeded for 1 to 5 min, depending on the type of mat being sampled (i.e., longer times for white filaments, shorter durations for gray sediment). No dispersion amendments were added to the mat samples (e.g., Tween20) because some microbes can utilize these substrates (Holdman and Moore, 1972).

Aliquots of disrupted mat material, ranging from 0.1 ml to 0.5 ml depending on the dilution series, were inoculated by syringe into pre-reduced and sterile (PRAS prepared; Holdman and Moore, 1972) medium in the first bottle in a dilution series, per media type. Serial dilutions were performed in triplicate per sampling site, per enrichment medium; for a 10-fold dilution series, there would be a 30 total bottles in three separate dilution series. For Lower Kane Cave samples,

all of the first bottle inoculations were done in the cave. At Hellsport Cave, because of sampling restrictions and hazardous sulfide levels, samples were brought out of the cave and manipulated. Samples were removed from the cave within 1-3 hr of inoculation, and bottles were sonicated for 2 min to promote disaggregation and homogenization prior to material transfer. All serial dilutions were initiated within 3-7 hr of collection. Several bottles of sterile media (no inoculations) were used as controls. All bottles were incubated in the dark at room temperature (~21-23 °C).

Anaerobic Biomass Estimates from Enrichment Cultures

Microbes were enumerated for each metabolic group using the MPN method (Hurely and Roscoe, 1983). A 10-fold serial dilution series was used for cultivable fermenters, and SRB, and a 5-fold serial dilution series was used for S⁰RB, methanogens, and iron-reducers. Upon returning to the laboratory, inoculated bottles were transferred to a Coy anaerobic chamber with N₂:H₂ mixed gas to maintain anaerobic conditions. The computer program MPN Calculator (Build 2.0; M. Curiale, <http://members.ync.net/mcuriale/mpn/index.html>) was used to calculate MPN biomass estimates from bottles having positive growth, using 95% confidence intervals (Appendix C).

Fermenting Bacteria

Fermentative bacteria were initially enumerated using 25% Schaedler's Broth (Difco Laboratories, Detroit, MI) dispensed into 25 ml serum bottles. The medium was prepared per manufacturer instructions. Growth, as visible turbidity,

was scored positive after two days. Strain isolates were obtained non-selectively on solid 25% Schaedler's Broth and screened for a variety of fermenting abilities and possible H₂S production using triple-sugar iron (TSI) broth (Difco). TSI agar is traditionally used to screen for the physiological activities of some Enterobacteriaceae groups (Hajna, 1945). Cells were grown on TSI agar slants in an anaerobic chamber, and growth was screened within 18-24 hr. A combination of cell growth, acid production, gas generation, and medium blackening caused by H₂S production in the butt of the tube and/or in the slant describes a specific pathway (although it should be noted that a particular combination of attributes may not be specific to just one group of organisms; (Hajna, 1945). Following TSI screening, strains were maintained on a modified low-nutrient (MLN) broth of (w/v) 1% sucrose, 0.5% peptone, 0.3 % yeast extract, 0.2% glucose, and 0.2% NaCl.

Sulfate-reducing Bacteria

Sulfate-reducing bacteria (SRB) are divided into two broad physiological subgroups: Group I SRB use lactate, pyruvate, ethanol, or other fatty acids as carbon sources, and Group II SRB oxidize acetate (Widdel and Bak, 1992). Certain species from both SRB groups are capable of growing chemolithoautotrophically with hydrogen as the electron donor, sulfate as the electron acceptor, and CO₂ as the sole carbon source (Widdel and Bak, 1992). Carbon-utilizing SRB were cultured from media designed for this work from modified Baar's and Postgate's C media (MacFarlane and Gibson, 1991). Three components were mixed: 400 ml of

Component I with 2 g $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 2 g NaSO_4 , 0.5 g NH_4Cl , 0.06 g $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$; 200 ml of Component II with 0.5 g K_2HPO_4 ; and 400 ml Component III having the carbon source(s) and 0.1% yeast extract (Fisher Scientific). Components I and II were pre-autoclaved (121°C , 20 min), before mixing with boiled Component III. Non-acetate oxidizers (Group I SRB) were provided with a mixture of 20 mM 60% Na-lactate and 20 mM Na-formate. Group II SRB were provided with 20 mM acetate. SRB Groups I and II capable of autotrophic growth were cultured using only Components I and II. Per liter, 10 ml Wolfe's trace element solution was added to each media mixture. Media were PRAS-prepared, with the exception that to reduce the potential for blackening of the media from abiotic iron reduction by cysteine or evolved microbial H_2S during growth, 0.01% L-cysteine (Fisher) was added as a PRAS reducing agent. Media were dispensed anaerobically into 10 ml serum bottles, crimp-sealed with butyl rubber caps and aluminum seals, and autoclaved to 121°C (20 min). Following inoculation, Groups I and II SRB bottles were pressurized with N_2 and CO_2 , whereas the autotrophic bottles were pressurized with a 70:30 mixture of H_2 : CO_2 to 140 kPa.

Instead of scoring positive growth from visual medium blackening due to the formation of iron-sulfides, from cell and iron-sulfide turbidity, or by using lead-acetate paper (e.g., Bekins et al., 1999), bottles were scored for positive growth by measuring evolved headspace H_2S with gas chromatography (GC) (refer to Chapter 5 for GC details). This is a much more sensitive and accurate method for

determining sulfate-reducing activity. SRB growth was found to be very rapid and growth was scored by GC after 7 days.

Sulfur-reducing Bacteria

A sulfur-reducing bacteria (S^0 RB) medium was designed for this study, and consisted of the following components: Component I, 0.5g NH_4Cl in 400 ml, and Component II, 0.5 g K_2HPO_4 in 200 ml; Component III, 20 mM Na-formate, 2 mM Na-acetate, and 1 g Difco yeast extract in 400 ml. Components I and II were autoclaved separately (121°C, 10 min) and mixed with pre-boiled Component III and PRAS preparation. No cysteine was added to the medium. Elemental sulfur flowers were washed with distilled H_2O , and crushed with a sterile mortar and pestle under water to hydrate surfaces. Approximately 5 ml sulfur slurry were dispensed anaerobically into 25 ml serum bottles prior to the addition of 10 ml media. Bottles were individually purged with a 90:10 mixture of $N_2:H_2$, crimp-sealed with butyl rubber caps and aluminum seals, and autoclaved at 112 °C (S^0 melts at 121°C) for 20 min. Evolved gases were measured using GC after 2 weeks. Uninoculated bottles were also incubated to ensure no contamination occurred due to the lower autoclaving temperature.

Iron-reducing Bacteria

Iron-reducing medium was previously described by Lovely and Phillips (1986) and Bekins et al. (1999). The medium was dispensed in 25 ml serum bottles and autoclaved for 15 min. After inoculation, bottles were pressurized with a 70:30

mixture of H₂:CO₂ to 140 kPa. Positive growth was scored after 6 weeks by the bipyridine method (Bekins et al., 1999).

Methanogens

A variety of methanogens were enriched for using PRAS-prepared dilute mineral salts media previously described in Bekins et al. (1999). Briefly, mineral salts media were amended with 20 mM Na-acetate for methanogens that utilized acetate, and in separate medium 20 mM 60% Na-formate was amended for formate-utilizing methanogens. Hydrogen-oxidizing methanogens were enumerated on only mineral salts medium pressurized with a 70:30 mixture of H₂:CO₂ to 140 kPa. The use of acetate, formate, or hydrogen distinguishes among different groups of methanogens based on nutrition (Garcia et al., 2000); methanogens that produce methane from methyl-compounds (methylotrophs) were not enumerated. After inoculation, bottles were incubated a minimum of 6 weeks, and scored positive from GC analysis of evolved headspace methane.

Denitrifying Bacteria

Nemati et al. (2001) suggest that if sulfur-oxidizers use nitrate as an alternative electron acceptor at low O₂ tensions, and if sufficient nitrate is not available, then elemental sulfur will accumulate in culture as an indication of positive growth,

Using this scheme to test for the presence of nitrate-reducing sulfur-oxidizing bacteria from the microbial mats, the following solutions were combined: Solution

A, 2.0 g KH_2PO_4 , 2.0 g KNO_3 , 1.0 g NH_4Cl , 0.8 g $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ in 940 ml dH_2O ; Solution B, $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$ in 40 ml dH_2O ; Solution C, 1.0 g NaHCO_3 in 20 ml dH_2O ; Solution D, 2.0 g $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ in 1.0 ml 0.1N H_2SO_4 . Solutions A, B, and D were autoclaved separately at 121 °C (15 min). Solution C was 0.22 μm -filter-sterilized. The four solutions were combined anaerobically, 2.0 ml sterile Wolfe's trace element solution was added, and medium was dispensed into 250 ml Erlenmeyer flasks in an anaerobic chamber. Flasks were sealed with rubber stoppers to limit oxygen diffusion following inoculation, and flasks were shaken for 2 weeks at ~200 rpm. Medium color was noted (yellow representing sulfur, S^0 , accumulation) and cell growth was visualized using phase-contrast microscopy.

RESULTS

Diversity and Biomass of Anaerobic Enrichment Cultures

Several attempts were made to estimate biomass from the Lower Kane Cave and Hellsport Cave microbial mats (Table 4-1; Appendix C). In most of the mat samples analyzed, sulfate-reducers and/or fermenters represented the highest MPN estimates, with up to 10^6 cells·ml⁻¹. However, compared to the overall biomass estimates from the microbial mats of approximately $\sim 10^{10}$ cells·ml⁻¹ (Table 2-2), the MPN estimates of anaerobic microorganisms were up to four orders of magnitude less. There was little correlation in cell count or metabolic guild to the type of mat morphotype cultured (e.g., between white versus gray morphotypes). For instance, iron-reducers grew from gray sediment in the Upper Spring, but were also present in the white webs and stream water (Figure 4-1; Appendix C).

Moreover, there were nearly equal abundances of S^0 RB in white and gray filament types, although less S^0 RB in the stream and orifice water. Excluding the higher abundances for methanogenic and iron-reducing groups in the Hellsport Cave sample (Figure 4-2), there were no statistical differences in the abundances of fermenters or SRB between Hellsport and Kane cave samples.

Sampling was focused at the Lower Kane Cave Upper Spring microbial mats (Figure 4-1). SRB abundance increased from the orifice downstream through the microbial mats, but SRB were less abundant in the cave stream at 215 m. Both SRB Groups I and II were present in nearly all the samples, including mat and water, with less than 1- to 1000 fold differences in cell abundance overall (Figure 4-1; Appendix C). In some samples, fermenting bacterial biomass was almost equivalent to or surpassed SRB (Figure 4-1). Chemolithoautotrophic SRB were not detected in all samples, and generally had up to four orders of magnitude less cells than SRB Groups I or II. S^0 RB were detected in most samples, with relatively low biomass overall with up to 10^2 cells·ml⁻¹. There were a few iron-reducers enumerated (up to 10^3 cells·ml⁻¹) in microbial mat samples, but none were detected in spring or stream water. Methanogens were rarely enumerated, with <14 cells per 100 ml⁻¹ from the Upper Spring gray sediment and stream channel white filament samples, consistent with low detectable CH₄ in the water. (Figure 4-1); hydrogenotrophic methanogens most abundant in Hellsport Cave (Figure 4-2). Four of eight enrichment cultures for nitrate-reducing sulfur-oxidizing bacteria,

although not enumerated, had positive growth, and cells from the enrichments were single-celled rods (~ 1-2 μm long) (Table 4-1).

Fermentation Diversity

Of the 28 fermenting bacterial strains isolated from 13 mat samples, most of the strains were classified as 'A/A, G', representing acid production in the tube butt and slant (A/A) and gas production (G) (Table 4-2). There were three variations in gas production; gas was produced throughout the agar, only in the butt, or only in the slant (Table 4-2). Eight strains produced H_2S , as well as other gases and acidity. Overall, there were eight distinct types of growth identified. Three strains did not change medium pH or generate gas, although they did grow.

DISCUSSION

Diversity and Ecology of Anaerobic Microorganisms

Anaerobic microorganisms are common in marine and freshwater habitats, from anoxic sediments and bottom waters to rice paddies (e.g., Bak and Pfenning, 1991; Widdel and Bak, 1992; Wind et al., 1999; Scholten et al., 2002), and even in oxic regions of microbial mats (Minz et al., 1999a; Minz et al., 1999b). Of the anaerobic microbial guilds, especially SRB and S^0RB , many have not been studied in detail from groundwater and springs from karst terrains. Although one group of SRB and several types of fermenters were identified from 16S rDNA sequences retrieved from the microbial mats (Chapter 2), culture-based methods indicate that anaerobic microbial diversity is greater than previously determined, as is subsequent ecosystem functional diversity.

There are several reasons why the results of this culture-based study must be considered ‘estimates’ of microbial diversity. First, culturing techniques can distort the original population abundances and community structure, as there is no one medium that can suit all the organisms (e.g., McDougald et al., 1998). Secondly, enrichment techniques can narrow community structure by providing selective media that eliminate large groups of physiologically distinct bacteria. A rich nutrient source may allow a rare, lesser abundant metabolic group to compete ecologically, and thereby artificially offset community structure. Moreover, assessments of ecosystem function can be distorted if organisms utilize multiple electron acceptors in enrichments that are not available in the natural habitat.

The apparent dominance of SRB among the anaerobic metabolic groups enumerated here from Lower Kane and Hellspont Cave microbial mats was not surprising, as dissolved sulfate concentrations in the cave waters are high. Interestingly, the abundance of SRB in white and gray mat morphotypes was not significantly different, although there were more SRB in both groups in the more distal mat samples compared to mats proximal to the orifice. These results suggest that either microhabitats with low oxygen tension exist in more aerobic portions of the mat (white morphotypes), or that the SRB tolerate more oxygenated conditions (e.g., Minz et al., 1999a).

The estimated abundances of Group I and II SRB were similar; in most samples these groups had equal biomass values (Figure 4-1; Appendix C). Although SRB can use a variety of electron donors, the most common low-

molecular weight organic compounds are lactate and formate (Group I SRB) and acetate (Group I SRB) (Widdel and Bak, 1992). There is some evidence that Group I SRB associate closely with Group II SRB, as some formatotrophs do not completely oxidize lactate to CO₂, but instead oxidize it to acetate that is then completely oxidized to CO₂ by a Group II SRB (Ehrlich, 1996). This may explain why the abundance of these groups overlaps in some samples, suggesting that carbon is actively cycled between the groups.

Fermenting bacteria generate low molecular weight compounds, including amino acids, carbohydrates, and organic acids and alcohols, as intermediaries from the breakdown of complex organic matter (Ehrlich, 1995). TSI agar was used to test for mixed-acid fermentation from sugar breakdown, which yields either lactic, acetic, and succinic acids, formic acid (or CO₂ and H₂), ethanol, or 2,3-butanediol (Stainer et al. 1986). Other fermentation pathways common to anaerobic microorganisms, such as propionate, butyrate, or succinate fermentation, or fumarate reduction, could not be examined using TSI agar. Therefore, although it is apparent that a range of fermentation processes are evident based on culturing, actually assigning a specific pathway to an organism or genera is only a speculative process. A combination of culture- and molecular-based approaches will be essential to characterize the fermenting bacteria in the future.

Eight fermentation pathways were detected from culture, indicating there is a range in metabolic preferences and capabilities for the microbes from the cave microbial mats (Table 4-2). The most common fermentation pathway identified

involved acid production from mixed-sugar metabolism to organic acids, indicated by a reduction in medium pH below 4.5. CO₂ production was also common, and bacteria associated with sugar metabolism and gas production include *Escherichia*, *Proteus*, and most species of *Salmonella*, *Aeromonas* (Stainer et al., 1986). CO₂ production is an indication of formate cleavage by the enzyme formic hydrogenase, and formic acid (the end fermentation product) is replaced by CO₂ and H₂. Four of the 28 strains generated acidity but not CO₂ gas, a pathway characteristic of organisms that do not have formic hydrogenase, such as some species of *Shigella*. Of the 28 strains, eight produced H₂S, which is characteristic of species from *Citrobacter*, *Salmonella*, and *Proteus*. Sulfide production results from breakdown of the sulfur-containing amino acid cysteine, or thiosulfate disproportionation. However, Kolmos and Schmidt (1987) caution that some H₂S-producing Enterobacteriaceae were not detected using TSI agar.

For three strains, medium pH was not lowered and no gas was produced, which could indicate one of four possibilities: 1) no fermentation; 2) fermentation occurred but did not reduce pH because large amounts of 2,3-butanediol or ethanol were produced, which would also not generate CO₂; 3) only lactose fermentation was occurring, but strains lacking certain enzymes for efficient breakdown may not grow fast enough to illicit a medium pH reaction; or 4) since colony growth was obvious for these strains, it is also possible that peptone catabolism was occurring, in which there neither would be acid nor gas production. Butanediol and ethanol production are common to *Serratia*, and species from several other genera

including *Erwinia*, produce butanediol (Stainer et al. 1986); *Serratia* spp. was identified in a 16S rDNA clone library from a gray filament sample (Chapter 2; Table 2-3), suggesting that *Serratia* may have been at least one of the strains isolated. Lactose fermentation is characteristic of *Escherichia* and *Enterobacter*, but absent in *Shingella*, *Salmonella*, and *Proteus* (Stainer et al. 1986).

While not abundant, iron-reducers were enumerated from several mat samples. The concentration of Fe^{3+} is low in the cave (Table 2-1), and could be one reason why iron-reducers are not abundant. The presence of Fe-S framboids in the gray mat interior (Figure 2-4), however, may indicate microbial Fe^{3+} reduction. Iron-reducers can also use humic substances (Lovley and Phillips, 1986), and acetate is likely the major electron donor. Some iron-reducers ferment glucose, or can use monoaromatic compounds and fatty acids (Lovely, 2001). Competition with SRB, which represents a much larger biomass, for carbon substrates may be another reason why iron-reducers are not prevalent.

Enrichment cultures for nitrate-reducing sulfide-oxidizing bacteria were successful for half of the mat samples examined. However, although some sulfur-oxidizing organisms could reduce nitrate in the laboratory, this does not mean that sulfur oxidation through nitrate reduction also occurs in the cave microbial mats. Using the enrichment scheme from Nemati et al. (2001) for *Thiobacillus denitrificans* and *Thiomicrospira* spp., incomplete oxidation of sulfide to sulfate occurs if nitrate is not sufficient; the result is an accumulation of elemental sulfur. Brunet and Garcia-Gil (1996) suggest that if sulfide concentrations are $<50 \mu\text{mol}\cdot$

L^{-1} , as they are in Lower Kane Cave, nitrate is reduced to N_2 . Conversely, at higher sulfide concentrations incomplete nitrate reduction to nitrite, NO, and N_2O occurs, which can inhibit sulfate reduction and methanogenesis (Scholten et al., 2002). As the concentration of sulfide is below the reported threshold, nitrate is likely reduced completely to N_2 , if reduction is occurring at any significant rate. More often than not, however, nitrate is a limiting nutrient in freshwater habitats, as it is in Lower Kane Cave (Table 2-1), making sulfide-dependent nitrate reduction either non-existent or indicating that nitrate is kept at an exceedingly low concentration because it is so tightly cycled between production and consumption.

Methanogens are ubiquitous in most anaerobic environments with decomposing organic material (Garcia et al., 2000). Conversely, methanotrophy, a metabolic pathway not investigated in this study, is an important metabolic pathway in Movile Cave, Romania (Hutchinson et al., 2003), where the concentration of methane in the cave water is greater than that measured at Lower Kane Cave (Sarbu et al., 1996). It is well known that competition between methanogens and SRB is significant, and if the concentration of dissolved sulfate is high, this has been shown to inhibit methanogenesis (e.g., Garcia et al., 2000). Therefore, the low concentration of methane in Lower Kane Cave, lack of methanogens, and high sulfate concentration supporting high SRB biomass, suggest that methanogenesis is not a prominent physiology in the microbial mats.

Implications for Carbon and Sulfur Cycling

There have been many ecological studies (albeit from surface environments such as forests and soils) that indicate habitat diversity is an important determination for organism diversity, and therefore the organisms that affect niche diversity also affect the biological diversity of other organisms in that habitat (Naeem, 2002; Wardle, 2002). The microbial mats are grossly structured with white filamentous mat morphotypes of sulfur-oxidizing “*Epsilonproteobacteria*”- and *Thiothrix*-dominated communities in contact with flowing stream water, covering a microbial consortium within a gray mat interior. Niche development by the sulfur-oxidizers provides habitat for anaerobic microorganisms within the mat interior, while conversely the benthic orifice and stream sediments are depleted in anaerobic microbes by the absence of a mat structure.

Clearly, organic carbon quality and quantity are important factors in influencing the types of physiological processes that will occur in an ecosystem (Eiler et al., 2003; Horner-Devine et al., 2003). Horner-Devine et al. (2003), based on work in shallow phototrophic ponds, also suggest that primary productivity influences the composition and richness of bacterial communities. Although chemolithoautotrophically-based cave ecosystems have been previously described with respect to metazoans (Sarbu et al., 1996; Airoldi et al., 1997; Hose et al., 2000; Sarbu et al., 2000; Vlasceanu et al., 2000; Engel et al., 2001; Garman, 2002), the diversity and dependence of anaerobic microbial guilds from chemosynthetic primary productivity have not been considered. Based on 16S rDNA sequences

retrieved from the microbial mats (refer to Chapter 2), bacterial diversity increased downstream, including both the “*Epsilonproteobacteria*” and the other bacterial groups. In caves, one of the consequences of chemolithoautotrophy is that the quality and quantity of organic carbon is greater than most aphotic ecosystems typically have (Sarbu et al., 1996; Kinkle and Kane, 2000; Poulson and Lavoie, 2000; Simon et al., 2003). The bulk of the white filamentous microbial biomass in Lower Kane Cave has low C:N ratios (refer to Chapter 2; Table 2-2), indicative of an extremely high quality food source (McMahon, 1975), but also consistent with an insignificant influx and processing of allochthonous carbon.

In Lower Kane Cave, the trend of microbial biomass stable carbon isotope values demonstrates nutrient spiraling (Chapter 2), which suggests that carbon is cycled through an active microbial detrital loop and possibly that a significant portion of autotrophic biomass is cycled heterotrophically (Allan, 1995; Porter, 1999). A percentage of heterotrophic carbon recycling can be based on the raw ratio of heterotrophic productivity to autotrophic productivity, and this ratio is doubled to assume 50% growth efficiency (Kirchman et al., 1993; Engel et al., 2001). Porter (1999) determined the rate of chemolithoautotrophic primary productivity in Lower Kane Cave, by H^{14}CO_3 assimilation, to be 96.5 ± 6.0 mg C·grams dry weight (gdw^{-1})· hr^{-1} for the white channel mats. By comparison, the heterotrophic productivity by ^{14}C -leucine incorporation was only 14.8 ± 5.7 mg C· gdw^{-1} · hr^{-1} (Porter, 1999). Therefore, ~ 30% of the autotrophic productivity in Lower Kane Cave is processed through heterotrophy. Comparatively,

bacterioplankton utilization of phytoplankton production in a variety of open ocean systems ranges from 10-40% (Kirchman et al., 1993, and references therein).

While allochthonous sulfide most likely originates from dissimilatory sulfate reduction deeper in the Bighorn Basin, as determined on the basis of sulfur isotope values (see Chapter 2; Carmody et al., 1998), SRB within the cave also generate autochthonous sulfide (refer to Chapter 5). Sulfur isotope values support that there is a component of autochthonous sulfide with lower $\delta^{34}\text{S}$ values, compared to allochthonous sulfide, that is incorporated by sulfur-oxidizing bacterial biomass (Figure 2-6; Chapter 2 for discussion). While fermenting bacteria in mixed anaerobic communities are key to carbon cycling, the contribution of fermenting bacteria to sulfur cycling has not been well established. Results from this study indicate that some of the fermenting bacteria have the ability to generate H_2S from reduced inorganic and organic sulfur compounds, thereby also affecting sulfur cycling inside the cave. This led to the hypothesis that fermenting bacteria, in addition to SRB and S^0RB , can contribute to autochthonous H_2S gas production, as well as other reduced sulfur gases, in the microbial mats (Chapter 5).

In conclusion, although resolving the detailed structural and functional aspects of the anaerobic microbial community are not possible based only on the culture-based assessments used in this study, results do indicate 1) higher abundances of culturable anaerobes in the mats than sediment or water; 2) little difference in the abundance of SRB groups in white or gray mat morphotypes, suggesting that the conditions for SRB anaerobic growth are favorable throughout

the subaqueous cave environment; 3) many different fermentation pathways, indicating a variety of ways the chemolithoautotrophically produced organic carbon can be processed in the microbial mats; 4) methanogenesis is not a significant carbon cycling pathway in the anaerobic microbial mats; and 5) a large component of autotrophically produced carbon is cycled through a detrital microbial loop. This study expands the diversity and importance of anaerobic microorganisms in cave microbial mats and demonstrates the importance of these organisms to the cave ecosystem, despite low biomass.

Chapter 5: Production and Consumption of Hydrogen Sulfide and Volatile Organosulfur Compounds in a Sulfidic Cave System

ABSTRACT¹

Hydrogen sulfide gas ($\text{H}_2\text{S}_{(g)}$) and volatile organosulfur compounds (VOSC) were examined in filamentous microbial mats formed in anaerobic, sulfidic water in Lower Kane Cave, Wyoming. Total dissolved sulfide (C_TS^-) decreases from upstream to downstream through the microbial mats, while $\text{H}_2\text{S}_{(g)}$ at the air-water interface directly over the microbial mats averages 30 ppmv, corresponding to an average $\text{H}_2\text{S}_{(g)}$ flux of $44 \mu\text{mol}\cdot\text{m}^{-2}\cdot\text{min}^{-1}$. The measured $\text{H}_2\text{S}_{(g)}$ volatilization accounts for less than 8% of the C_TS^- flux into the cave, and abiotic sulfide autoxidation accounts for $<0.014\%$ C_TS^- loss, suggesting that the primary C_TS^- loss mechanism is caused by oxidation of C_TS^- by subaqueous sulfur-oxidizing bacteria. Incubations of cave water and microbial mat samples demonstrate that $\text{H}_2\text{S}_{(g)}$ and VOSC are of biogenic origin, and are cycled by aerobic and anaerobic mat communities. Anaerobic laboratory enrichment cultures of fermenting, sulfate-, and sulfur-reducing bacteria from the cave microbial mats were screened for sulfur gas production. Enrichments of sulfur-reducing bacteria generated only $\text{H}_2\text{S}_{(g)}$, but sulfate-reducing and fermenting bacteria produced VOSC, in order of abundance: $\text{H}_2\text{S}_{(g)}$, methanethiol, dimethyl sulfide, and carbonyl sulfide. Twenty-nine percent of fermenting bacteria strains generated $\text{H}_2\text{S}_{(g)}$ with

¹ A portion of this chapter originated from the paper A.S. Engel, L.A. Stern, and P.C. Bennett, 2004, Microbial contributions to cave formation: new insights into sulfuric acid speleogenesis, *Geology*, v. 32 (5) p. 369-372.

growth medium, and two of the isolated strains produced $\text{H}_2\text{S}_{(\text{g})}$ when thiosulfate and cysteine were present in the growth medium, but not with sulfate; methanethiol was produced when methionine was present. In anaerobic enrichment cultures and natural mat incubations, generation of methanethiol and dimethyl sulfide was always preceded by the generation of $\text{H}_2\text{S}_{(\text{g})}$. Inhibition of microbial sulfate reduction by addition of molybdate in the incubations resulted in diminished to no VOSC production. There was no correlation between VOSC concentration and methane gas production, indicating that methanogenesis is not an important sulfur gas consumption mechanism in this system. Natural mat samples, dominated by active sulfur-oxidizing bacteria, degraded methanethiol and dimethyl sulfide aerobically when supplemented with VOSC. Active cycling of VOSC by anaerobes and aerobes from a freshwater, subterranean environment has not been previously demonstrated. As photochemical degradation of these gases is not possible, sulfur-based microbial mat communities in the subsurface represent a new terrestrial source for sulfur gases and the impact of subterranean microorganisms to the global sulfur cycle should be considered.

INTRODUCTION

Bacterial processes are largely responsible for recycling inorganic and organic sulfur-containing compounds within the sulfur cycle, and volatile components are released into the atmosphere (Taylor, 1991; Kelly et al., 1994). Hydrogen sulfide gas ($\text{H}_2\text{S}_{(\text{g})}$) and volatile organosulfur compounds (VOSC), including carbonyl sulfide (COS), methanethiol (MT), dimethyl sulfide (DMS), and

dimethyl disulfide (DMDS), contribute to the global sulfur cycle, and consequently these sulfur gases have been intensively studied with respect to their contribution to acid precipitation and global warming (Legrand et al., 1991; Bates et al., 1992; Bodenbender et al., 1999; Watts, 2000). Understanding natural abiotic and biogenic emission is vital to evaluate the magnitude of anthropogenic perturbations to the global sulfur cycle. Marine and volcanic gas emissions make up a significant fraction of the global sulfur flux; while terrestrial biogenic emissions may be insignificant at the global scale, they are likely more important to local cycles (e.g., Andreae and Andreae, 1988; Bates et al., 1992; Watts, 2000). Attempts to estimate natural terrestrial emissions from surface environments have had variable results, showing disparate emission patterns spatially and temporally.

Most studies of natural $\text{H}_2\text{S}_{(g)}$ and VOSC production and consumption rates have investigated marine environments (Zinder et al., 1977; Visscher et al., 1991; Bodenbender et al., 1999; Fritz and Bachofen, 2000; Kristensen et al., 2000; Visscher et al., 2003), freshwater limnic systems (Stoner et al., 1994; Fritz and Bachofen, 2000), hot springs (Stoner et al., 1994), soil (Conrad, 1996; Yang et al., 1998), and flooded sediments and wetlands (Lomans et al., 1997; Lomans et al., 1999a; Lomans et al., 1999b; DeLaune et al., 2002). However, virtually nothing is known about the production of reduced sulfur gases from terrestrial, aphotic environments (caves) or sulfidic groundwater systems, although $\text{H}_2\text{S}_{(g)}$ has been detected in several caves (Galdenzi and Menichetti, 1995; Sarbu et al., 1996; Angert et al., 1998; Hose et al., 2000). $\text{H}_2\text{S}_{(g)}$ and VOSC have been identified rarely in caves, including from Lower Kane Cave, Wyoming (Egemeier, 1981), and

Cueva de Villa Luz, Mexico (Boston et al., 2001). VOSC in the subsurface do not photodegrade, and consequently cycling of reduced sulfur gases in the aphotic unsaturated zone may be a significant source of sulfur to the global budget. This is particularly important geologic environments from which gases can diffuse into the atmosphere, such as fractured bedrock or karst. Sulfur-based microbial communities can utilize the ubiquitous reduced sulfur compounds in anaerobic, sulfidic groundwater, and sulfur cycling may be more widely dispersed in the terrestrial subsurface than currently recognized.

This study describes the production and consumption of $\text{H}_2\text{S}_{(\text{g})}$ and VOSC in Lower Kane Cave by sulfur-based microbial communities. While there have been investigations of VOSC utilization by some microbial groups, including *Thiobacillus* spp. (Kanagawa and Kelly, 1986) and *Hyphomicrobium* (DeBont et al., 1981), these organisms have mostly been studied in engineered systems (e.g., sewage sludge) or in photic microbial mats (e.g., Visscher et al., 1991). “*Epsilonproteobacteria*”, the dominant sulfur-oxidizing bacteria in the Lower Kane Cave microbial mats (refer to Chapter 2 and 3; Engel et al., 2003), have not been previously linked to VOSC consumption or utilization. Based on gas chromatography (GC) methods designed specifically for the cave environment, I report $\text{H}_2\text{S}_{(\text{g})}$ and MT gas flux rates from the subterranean sulfidic springs and microbial mats, as well as detailed regarding microbially mediate sulfur gas transformations from native microbial mat samples and laboratory enrichment cultures.

MATERIALS AND METHODS

Cave Gas Sampling and Flux Measurements

A description of Lower Kane Cave, Wyoming, and its geological and hydrological setting are presented in Chapter 1 (Figure 1-1 and 1-2). Cave atmosphere components (CO_2 , CH_4) and sulfur gases (H_2S , COS, SO_2 , CS_2 , MT, DMS) were determined in the cave by direct-inject GC on a SRI 310 (SRI Instruments, Torrance, CA) using either a Restek XL sulfur column and TCD/FID detectors, or a 60m 0.53mm MXT-1 column with FID/FPD detectors, respectively. In the cave, the MXT-1 column resulted in better gas separation with an isothermal run.

The GC was placed in an area of the cave previously determined to have extremely low to negligible sulfur gases, away from the cave stream (Figure 5-1A). A gas-powered Honda generator was placed at the cave entrance and 150 m of heavy-duty-outdoor extension cord was extended through the cave to the GC. $\text{H}_2\text{S}_{(\text{g})}$ flux at the water-mat boundary layer was measured using a 16-cm² flux chamber suspended over the water and partially submerged to approximately 2 to 10 mm into the cave water (Figure 5-1B). Cave air was pumped through a reactive copper intake tube connected to the chamber to remove ambient VOSC (Figure 5-1C), and the chamber gas was withdrawn and pumped through Teflon tubing to a 1 ml Teflon sample loop for injection into the GC (Figure 5-1D). The entire gas flow path from the flux chamber to the GC was Teflon due to the reactivity of sulfur gases. The chamber gas outflow was monitored continuously for CO_2 (Comfort

Chek 100/200 CO₂ analyzer, Bacharach, Inc., Pittsburgh, PA) and flow rate using a mass flow meter. Replicate flux measurements were determined with variable pumping rates to achieve a representative flux rate. Individual gas samples were also collected throughout the cave in cleaned and non-reactive plastic syringes, and samples were analyzed immediately by GC. Dissolved gases in the stream were measured from sample bottles by headspace GC and by the bubble-strip method (Chapelle et al., 1997).

Enumeration of Anaerobic Enrichment Cultures

Microbes from the cave water and microbial mats were enriched using the most probable number (MPN) method in pre-reduced anaerobic media specific to certain physiologic groups, including fermenting bacteria, chemolithoautotrophic, acetate-, and lactate-/formate-utilizing sulfate-reducing bacteria (SRB), sulfur-reducing bacteria (S⁰RB), methanogens, and iron-reducers. Gas evolution (H₂S, COS, MT, DMS, CH₄, CO₂) was measured by GC in the enrichment headspace (Chapter 4).

Isolation of Fermenting Bacteria and Metabolism of Sulfur Compounds

Some strains of fermenting bacteria (isolates obtained as described in Chapter 4) were tested for utilization of different sulfur substrates, including thiosulfate, sulfate, cysteine, and methionine. 100 µl of cell suspension was harvested from strain isolates, washed with filter-sterilized tap water, and inoculated into fresh serum bottles containing 10 ml MLN media (Chapter 4) supplemented with one of the following: 2.5 mM NaS₂O₃; 4 mM MgSO₄·7H₂O + 9 mM NaSO₄; 0.01% L-cysteine (Fisher); or 0.01% L-methionine (FisherBiotech).

MLN broth with no addition of sulfur compounds was a live-control. In each sulfur substrate series, a killed cell suspension was used as a sterile control (121°C, 20 min). All bottles were pressurized with N₂ to ensure anaerobic conditions. One bottle was used to measure microbial growth as optical density (OD) using a Perkin Elmer Lambda 6 UV/VIS spectrophotometer at a wavelength of 588 nm (traditionally, 600 nm is used to measure cell absorbance, but there was interference at 600 nm by the medium). pH was measured by electrode and headspace gas was quantified by GC. Growth rate for each strain was calculated using the modified Monod expression

$$OD_{(t)} = OD_0 e^{\mu t} \quad (5-1),$$

where OD_(t) is the optical density at time *t*, OD₀ is the optical density at the start, and μ is the specific growth rate. Doubling times (*t_d*) were calculated using

$$\mu = \ln 2 / t_d \quad (5-2)$$

Gas Cycling by Native Microbial Mat Communities

H₂S and VOSC production from homogenized mat samples

In separate cave-incubated and laboratory-incubated gas production experiments, approximately 100 ml of aseptically collected and homogenized microbial mat from the end of the Upper Spring and Lower Spring, and 150 ml of 0.22- μ m-filtered (cold-sterilized) spring water, were dispensed into sterile 500 mL black Teflon chambers equipped with gas-sampling and electrode ports. Microcosms were amended with 10 ml of a gypsum-saturated, cold-sterilized solution to provide dissolved sulfate. For the cave incubations, a control chamber

containing 250 ml filter-sterilized spring water and 10 ml gypsum-saturated solution was used. The laboratory incubations had two controls: one sterile control with 250 ml filtered spring water and 10 ml gypsum-saturated solution, and another killed control of autoclaved (121 °C, 30 min) microbial mat. Microcosms were incubated in the cave or at room temperature, and pH in the live chambers was monitored continuously using an Accumet portable pH/mV meter with a double-junction pH electrode (Fisher Scientific). For the laboratory incubations, sterilized pieces of Iceland Spar calcite (Wards Scientific), totaling 1 g for closed-chamber microcosms and 0.1 g for serum bottles, were added prior to mat inoculation to maintain circum-neutral pH and to provide an inorganic carbon source to autotrophic populations. Emitted sulfur gases and headspace CO₂ from cave-incubated chambers were measured in the cave by GC and using the portable Comfort Chek CO₂ monitor, respectively, and O₂ was measured by GC using a CTR-1 column. For the laboratory chambers, sulfur gases, methane and hydrocarbons, and CO₂ were separated by GC with FPD, FID, and TCD, respectively.

Inhibition of H₂S and VOSC production from homogenized mat samples

Aerobic and anaerobic gas production and consumption were measured in sterile 60-ml glass serum bottles inoculated with 10 ml homogenized microbial mat material, 20 ml cold-sterilized spring water, and 2 ml gypsum-saturated, filtered solution. Some bottles were supplemented with 4mM Na-molybdate to inhibit microbial sulfate reduction, while others were supplemented with 25 mM 2-bromoethanesulfonic acid (BES) to inhibit methanogenesis (Oremland and Capone,

1988; Lomans et al., 1997; Scholten et al., 2000), or with ~30 μl HgCl -saturated solution for a killed control. Abiotic controls were prepared from bottles of 30 ml cold-sterilized spring water and 2 ml gypsum-saturated solution, and of sterilized mat (121 $^{\circ}\text{C}$; 20 min). Bottles were sealed with butyl rubber stoppers and aluminum seals, and were incubated in the dark at room temperature (~21-23 $^{\circ}\text{C}$).

VOSC consumption by homogenized mat samples

Cold-sterilized spring water was purged with a mixed-sulfur gas standard (71.0 ppmv COS, 75 ppmv MT, 68.5 ppmv DMS) for 2 hr to examine VOSC degradation. Purged water was cold-sterilized into glass serum bottles and 10 ml homogenized aliquots of microbial mat were added. Some bottles were amended with 25 mM BES or HgCl_2 for a killed control. One bottle with mat was sterilized by autoclaving (121 $^{\circ}\text{C}$; 20 min). Immediately following sealing and gentle shaking, headspace samples were taken to determine starting gas concentrations. Samples were incubated in the dark at room temperature.

RESULTS

Hydrogen Sulfide Dynamics in the Cave

Field description

Cave spring waters had pH values ranging from 7.1 to 7.3 and a nearly constant temperature of 21.5 $^{\circ}\text{C}$ (Table 2-1). Total dissolved sulfide (C_TS^-) at all orifice discharge pools averaged 30 $\mu\text{mol}\cdot\text{L}^{-1}$, but decreased rapidly from the discharge point downstream through the microbial mats (refer to Chapter 2; Figure 2-1). The total flux of C_TS^- at the Upper Spring was calculated from the incoming concentration and the stream discharge determined by salt dilution tracing.

Discharge $C_{\text{T}}\text{S}^{\ominus}$ flux, determined from the 191-m concentration of dissolved sulfide, was $\sim 8700 \mu\text{mol}\cdot\text{min}^{-1}$ (Table 5-1). $C_{\text{T}}\text{S}^{\ominus}$ was not detected downstream from the mat terminus at the Lower and Upper Spring (2 and 20 m flow path distance from the orifice, respectively), although $C_{\text{T}}\text{S}^{\ominus}$ ($\sim 20 \mu\text{mol}\cdot\text{L}^{-1}$) was measured 25 m from the Fissure Spring where the mats ended (Figure 2-1A).

At the Upper Spring orifice, water had no detectable dissolved O_2 (Table 5-1) and $\text{H}_2\text{S}_{(\text{g})}$ was not detectable directly over this anaerobic spring water (Figure 5-2; Appendix D). Along the outflow channel, $C_{\text{T}}\text{S}^{\ominus}$ was approximately constant as dissolved O_2 increased. From the orifice and along the stream channel, the water transitioned from anaerobic to disaerobic ($\text{O}_2 = 0.1$ to $5.0 \mu\text{mol}\cdot\text{L}^{-1}$), with $21 \mu\text{mol}\cdot\text{L}^{-1}$ $C_{\text{T}}\text{S}^{\ominus}$. The mats abruptly terminated at 205 m, and here dissolved O_2 exceeded $45 \mu\text{mol}\cdot\text{L}^{-1}$ while $C_{\text{T}}\text{S}^{\ominus}$ decreased to $<6 \mu\text{mol}\cdot\text{L}^{-1}$ (Figure 2-1B).

The approximately constant, and subsequently steep and concave-down $C_{\text{T}}\text{S}^{\ominus}$ vs. distance profile (Figure 5-3A) is not the expected shallow, concave-up first-order loss profile characteristic of abiotic first-order loss mechanisms (Millero et al., 1987; Brezonik, 1994). A first-order loss curve was estimated from the initial $C_{\text{T}}\text{S}^{\ominus}$ at the spring and the distance at half- $C_{\text{T}}\text{S}^{\ominus}$ [$t_{1/2} = \ln 2/k$; Brezonik, 1994] and an estimated stream velocity of $0.5 \text{ m}\cdot\text{s}^{-1}$ along the proximal 6 m channel from the orifice. The observed $t_{1/2}$ was ~ 0.5 min ($k = 1.5$) (Figure 5-3A). Stream velocity decreased to $0.2 \text{ m}\cdot\text{s}^{-1}$ at the mat terminus as the stream channel widened, and another first-order loss curve was estimated from the $C_{\text{T}}\text{S}^{\ominus}$ at 203 m, near the end of the mat, with an observed $t_{1/2} \sim 0.2$ min ($k = 3.0$) (Figure 5-3A).

Field flux experiments and theoretical volatilization

Although $\text{H}_2\text{S}_{(\text{g})}$ flux varied along the outflow channel at different sampling times, the highest $\text{H}_2\text{S}_{(\text{g})}$ flux was consistently quantified from directly over the microbial mats from the 193 to 194-m locations where dissolved $\text{C}_\text{T}\text{S}^\ominus$ was relatively lower than $\text{C}_\text{T}\text{S}^\ominus$ at the spring orifice (Table 5-1; Figure 5-2). MT was measured above the detection limit (<1 ppmv) from a flux chamber at 191 m, but upon repeating the experiment, MT was not detected again. The average concentration of $\text{H}_2\text{S}_{(\text{g})}$ at the air-water interface for the entire stream length was 22 ppmv; this steady state concentration resulted in an average $\text{H}_2\text{S}_{(\text{g})}$ flux of $44 \mu\text{mol m}^{-2} \text{min}^{-1}$ (Table 5-1).

The measured $\text{H}_2\text{S}_{(\text{g})}$ flux was compared to a theoretical volatilization rate calculated from the 2-film model of Liss and Slater (1974) (Table 5-1), using the average water depth of 10 cm and an average channel width of 1 m. It was assumed that the shallow stream channel results in a completely mixed aqueous system and a purely fluid film-controlled volatilization rate. Volatilization half-life was determined from the first-order liquid phase mass transfer coefficient,

$$K_L = \frac{\left(\frac{H'}{RT}\right)k_g k_l}{\left(\frac{H'}{RT}\right)k_g + k_l} \quad (5-3)$$

where k_g is the gas phase exchange coefficient, k_l is the liquid phase exchange coefficient, H' is the dimensionless Henry's constant, T is temperature in Kelvin, and R is the gas constant; k_g and k_l are estimated from the ratio of the mass of water vapor and CO_2 , respectively, to the mass of H_2S (Liss and Slater, 1974). Dissolved H_2S was speciated from $\text{C}_\text{T}\text{S}^\ominus$ for pH ($\text{H}_2\text{S}:\text{HS}^-$ pK = 7.04; Stumm and Morgan,

1996). The theoretical volatilization rate yielded an estimated flux of $23 \mu\text{mol m}^{-2} \text{min}^{-1}$, with a first-order volatilization half-life ($t_{1/2}$) of 13 min (Table 5-1). This compares very closely to the actual volatilization $t_{1/2}$ of ~ 6 min based on the mean measured $\text{H}_2\text{S}_{(\text{g})}$ flux. Over the entire length of the Upper Spring stream channel, however, the total $\text{H}_2\text{S}_{(\text{g})}$ volatilization accounted for less than 8% of the total influx $\text{C}_\text{T}\text{S}^-$ (Figure 5-3B), suggesting that the bulk of subaqueous $\text{C}_\text{T}\text{S}^-$ is lost by other mechanisms, not by volatilization.

Abiotic autoxidation rates

The rates of abiotic autoxidation were estimated to evaluate their contribution to $\text{C}_\text{T}\text{S}^-$ loss. The rate of sulfide autoxidation in water is a complex function of temperature, salinity, reactant concentration, dissolved metal concentration, pH, and the presence of ferric hydroxides (Millero, 2001; Millero et al., 1987). At low sulfide concentrations and low temperatures, the sulfide loss rate is first-order with respect to sulfide concentration and first-order with respect to oxygen, and second-order overall for the disappearance of sulfide (Millero et al., 1987):

$$\frac{d[\text{H}_2\text{S}]_\text{T}}{dt} = k_2[\text{C}_\text{T}\text{S}^-][\text{O}_2] \quad (5-4)$$

where $[\text{O}_2]$ is the concentration of dissolved oxygen, $[\text{C}_\text{T}\text{S}^-]$ is the total concentration of all sulfide species, and k_2 is the second-order rate constant. At pH values near the pK of H_2S , k_2 consists of two components, k_0 and k_1 , corresponding to the oxidation of H_2S and HS^- , respectively. Therefore, the second-order rate of sulfide oxidation, in water at 25°C at $\text{pH} < 6$, is dominated by k_0 of $\sim 11 \text{ L}\cdot\text{mol}^{-1}\cdot\text{hr}^{-1}$,

with an activation energy of 43.5 kJ·mol⁻¹. For pH >8 the rate is dominated by HS⁻ oxidation, with a second-order rate constant of ~48 L·mol⁻¹·hr⁻¹ at 25°C, with an activation energy of 53.5 kJ·mol⁻¹ in freshwater (Millero et al., 1987). Using a pH of 7.3 at 22°C, a second-order rate constant of 40 L·mol⁻¹·hr⁻¹ was estimated.

Using these rate constants, the calculated C_TS⁼ autoxidation under the conditions in the disaerobic cave waters (20 μmol·L⁻¹ C_TS⁼ and a constant O₂ of 20 μmol·L⁻¹; conditions at 201 m) is extremely slow. The autoxidation rate of dissolved sulfide was estimated from the kinetic data determined at 25.0 °C for low ionic strength aqueous systems using a constant [O₂] to yield a pseudo-first order rate constant and half-life (Zhang and Millero, 1983; Millero et al., 1987). For the analysis, the point along the stream where [O₂] = C_TS⁼ was chosen, because for kinetic evaluation, choosing the point where starting concentration [A]₀ = [B]₀ for a second-order overall reaction, greatly simplifies the evaluation. For a closed system under these conditions, the half-life is (Brezonik, 1994):

$$t_{1/2} = \frac{1}{k_2[C_T S^=]_0} \quad (5-5)$$

and was estimated to be 1250 hr at the 201 meter-location along the stream channel. Alternatively, the concentration of dissolved oxygen can be fixed so that the second-order reaction can be evaluated as a pseudo first-order reaction, where the rate is independent of the variable component (H₂S) and dependent only on the fixed concentration of dissolved oxygen:

$$t_{1/2} = \frac{\ln 2}{k_2[O_2]_0} \quad (5-6)$$

and was estimated at 866 hr at 201 m. Upstream, where the concentration of oxygen was lower, the rate was much slower, while the rate increased slightly downstream with increasing oxygen, and the half-life decreased by a factor of ~3 at 215 m (Table 5-1). Therefore, $C_T S^-$ autoxidation rate represented ~0.014% of the potential abiotic loss in this oxygen-limited system with low concentrations of dissolved metals (Figure 5-3B).

Microbial Mat Sulfur Gas Production and Consumption Experiments

Enrichment cultures of anaerobic microorganisms

Microbial mat sampling was focused at the Upper Spring mats. Sulfur gas, and specifically $H_2S_{(g)}$, production was used to detect SRB and S^0 RB growth in MPN enrichment cultures, and sulfur gases were also measured from the headspaces of fermenting bacteria enrichment bottles (Table 5-2). SRB cell abundance based on MPN increased downstream, from the orifice water and orifice sediment samples moving through the microbial mats. Both lactate/formate (Group I)- and acetate (Group II)-utilizing SRB were present in nearly all the microbial mat samples, with 1- to 1000-fold differences in cell abundance overall (refer to Chapter 4; Figure 4-1). In some samples, fermenting bacterial biomass was almost equivalent to or surpassed SRB abundances (Figure 4-1). S^0 RB were detected in most samples, with relatively low biomass overall (10^2 cells·ml⁻¹). Methanogens were rarely detected by MPN, with <14 cells·100 ml⁻¹ (Figure 4-1). While $H_2S_{(g)}$ was generated in SRB, S^0 RB, and some fermenting enrichment bottles, MT was detected in cultures of SRB Groups I and II and some fermenter enrichments (Table 5-2). COS was only generated from Group I SRB and fermenter enrichments from

the Upper Spring orifice samples (Table 5-2). DMS was produced in the headspace of rare fermenter and SRB Group II enrichment cultures (Table 5-2),

Sulfur gas production from fermenting bacteria

Twenty-nine percent of the fermenting bacterial strains produced $\text{H}_2\text{S}_{(\text{g})}$ when provided with thiosulfate or sulfur-containing amino acids. Two of these strains (LKC-232 and LKC-322) were used to measure rates of $\text{H}_2\text{S}_{(\text{g})}$ production given various inorganic and organic sulfur sources, and to test for possible VOSC formation from natural precursors (Figure 5-4). Both strains produced $\text{H}_2\text{S}_{(\text{g})}$ from thiosulfate (Figure 5-4A and 5-4B); MT was only detected in bottles supplemented with methionine (Figure 5-4C). Strain LKC-232 reached exponential growth earlier when supplemented with thiosulfate than LKC-322, and had a faster doubling time at $0.19\cdot\text{hr}^{-1}$ compared to $0.43\cdot\text{hr}^{-1}$ for LKC-322 (Figure 5-4D and 5-4E). The addition of thiosulfate strongly stimulated $\text{H}_2\text{S}_{(\text{g})}$ formation, compared to the small $\text{H}_2\text{S}_{(\text{g})}$ concentrations measured in bottles supplemented with SO_4^{2-} , cysteine, and methionine at levels approximately that of the control, suggesting those $\text{H}_2\text{S}_{(\text{g})}$ concentration profiles represent background sulfur assimilation rates.

Native mat incubations

$\text{H}_2\text{S}_{(\text{g})}$ was present in the headspace initially, but decreased to non-detectable after 57 hr (Figure 5-5A; M-series). After a lag phase (~15 hr), the concentration of $\text{H}_2\text{S}_{(\text{g})}$ in live mat samples increased rapidly, while MT was not generated in the live samples until after 200 hr (Figure 5-5B). COS and DMS were not detected in any bottles (Figure 5-5C). Decreases in oxygen concentration in the live mat incubations corresponded to increases in $\text{H}_2\text{S}_{(\text{g})}$, but not in the sterile water

or killed controls (Figure 5-5D). The observed increase in headspace oxygen in the live sample incubations, with a corresponding rapid decrease in $\text{H}_2\text{S}_{(\text{g})}$, may be related to oxygen leaking into the chambers during the course of the experiment and subsequent sulfide oxidation.

Homogenized mat incubations and inhibition experiments

Two different types of microbial mats were collected for three separate incubation experiments (Figure 5-6 through 5-8). In the A- and B-series, the concentration of headspace $\text{H}_2\text{S}_{(\text{g})}$, MT, COS, and DMS were measured (Figures 5-6 and 5-7). $\text{H}_2\text{S}_{(\text{g})}$ concentrations in the A- and B-series increased rapidly within the first day (6-15 hr) (Figures 5-6A and 5-7A), but in the C-series, $\text{H}_2\text{S}_{(\text{g})}$ production occurred from 16-79 hr (Figure 5-8A). Headspace MT in the live mat incubations increased after 50 hr (e.g., Figure 5-6B), faster than observed from the M-series. MT was not detected from the C-series. While $\text{H}_2\text{S}_{(\text{g})}$ concentration varied over time, the concentration of MT steadily increased in the live incubations (Figures 5-6B and 5-7B). COS was not measured from filtered spring water, suggesting that COS was produced biogenically in the mat environment (Figures 5-6C and 5-7C).

Inhibition of sulfate reduction and methanogenesis allowed for an examination of the possible roles of these anaerobic groups to sulfur gas cycling. Limited $\text{H}_2\text{S}_{(\text{g})}$ evolved in molybdate-amended samples in any incubation series, resulting from either 1) unsuccessful inhibition of sulfate reduction, or 2) sulfur assimilation and $\text{H}_2\text{S}_{(\text{g})}$ production by fermenting bacteria at low O_2 levels (e.g., Figure 5-6A). For the B-series, significant $\text{H}_2\text{S}_{(\text{g})}$ was only produced in the BES-amended bottle, but not in the molybdate-amended bottle (Figure 5-7A). MT

headspace evolution was the same for BES-amended samples, but not the molybdate-amended samples, suggesting that MT production may be from SRB activity. In the A- and B-series, however, MT was detected in the molybdate-amended bottles, although at lower concentrations than the unamended incubations or BES-amended incubations. This indicates that other metabolic groups, such as the fermenting bacteria (e.g., Figure 5-4D and 5-4E), may also be responsible for MT production under low O₂ conditions. In the B-series (Figure 5-7C), COS increased in the unamended live mat incubations under low oxygen conditions, above the concentration in the filtered water (Figure 5-9C, 5-9F), but not in the BES-amended sample, indicating that COS production may be linked to methanogenic activity. Conversely in the A-series, COS increased in the BES-amended sample, suggesting association with sulfate reduction (Figure 5-6C). DMS was detected earlier in the BES-amended incubation than in an unamended sample in the A-series, but at the same rate in the B-series (Figures 5-6D and 5-7D).

Rapid increases in H₂S_(g) concentrations corresponded to an increase in headspace CO₂ in the A- and B-series (Figures 5-6E and 5-7E), but to a more subdued increase in the C-series (Figure 5-8E). CO₂ did not increase in the headspaces of the sterile water and killed controls in any of the incubation series, indicating the CO₂ production was a result of microbial activity. The rapid increase in headspace CO₂ in the A- and B-series, coinciding with decreases in O₂, may be related to aerobic CO₂ utilization by aerobic chemolithoautotrophs (e.g., sulfur-oxidizers), and that CO₂ consumption slows when O₂ becomes low. This is

supported by the rates of $\text{H}_2\text{S}_{(\text{g})}$ increase corresponding to decreases in headspace O_2 to <15% (Figure 5-6F, 5-7F, 5-8F).

VOSC consumption by homogenized mats

No $\text{H}_2\text{S}_{(\text{g})}$ was detected from the spring water following sparging with VOSC (Figure 5-9); however, $\text{H}_2\text{S}_{(\text{g})}$ was measured in the autoclaved microbial mat control, possibly because of VOSC degradation. The concentrations of both MT and DMS in the filtered water were nearly equal to the concentrations of the standard gases used for sparging. COS was extremely low following sparging, suggesting that the gas concentration in the water had not equilibrated and should have been sparged longer. Initially, headspace concentrations of MT and DMS were lower in the live microbial mat incubations compared to those from the headspace of the sterile water sample, suggesting aerobic microbial consumption of both gases, as the samples still had oxygen present (Figure 5-9F). MT increased above the concentration in the sterile sample after 16 hr (Figure 5-9B), corresponding to a rapid increase in headspace CO_2 (Figure 5-9E) and decreases in O_2 (Figure 5-9F).

DISCUSSION

The processes affecting the consumption and production of sulfur gases in aphotic spring systems and associated microbial mats were studied by gas flux measurements and by incubations of native and homogenized microbial mats. Changes in $\text{C}_{\text{T}}\text{S}^-$ along the Upper Spring stream channel result from the combined effects of abiotic volatilization, autoxidation, and microbial processes, including biological production and consumption (microbial consumption includes both

catalyzed sulfide oxidation, as well as sulfur utilization for biosynthesis). VOSC production from incubations of the cave microbial mats, but low amounts measured from the habitat, suggest that the microbes in Lower Kane Cave, as well as other aphotic subsurface environments, play a role in VOSC flux to the atmosphere.

At the Upper Spring the observed $C_T S^-$ loss at the orifice is much faster than can be accounted for from the combined effects of abiotic autoxidation and volatilization loss mechanisms (Figure 5-3B). Based on the estimated autoxidation, and actual and theoretical volatilization rates alone, $C_T S^-$ at the cave entrance should be only slightly lower than the measured Upper Spring $C_T S^-$. In this anaerobic to disaerobic cave system, autoxidation $t_{1/2}$ is considerably slower ($t_{1/2} = 866$ to 1250 hr) than measurements from air-saturated natural waters with low salinity (Avrahami and Golding, 1969; Chen and Morris, 1972) and several deep waters from anoxic marine basins, such as Framvaren Fjord ($t_{1/2} = 19$ - 20 min) and the Chesapeake Bay ($t_{1/2} \sim 8.3$ min), where the autoxidation rates are enhanced as a result of reaction with dissolved constituents (e.g., metals) in the water and mixing with surface waters (Millero, 2001). Therefore, the observed rapid decrease in $C_T S^-$ near the mat terminus requires subaqueous microbial sulfide consumption.

Microbial consumption of $C_T S^-$ occurs under disaerobic to aerobic conditions in the cave stream (Figure 5-3A). Using the full-cycle 16S rRNA approach to describe the microbial communities in the Lower Kane Cave mats (refer to Chapters 2 and 3), mat biovolume is dominated by “*Epsilonproteobacteria*” (~70% of the bacterial biovolume), with minor assemblages of known sulfur-oxidizing bacterial groups belonging to the genera

Thiothrix and *Thiobacillus* (McDonald et al., 1996; Cha et al., 1999). Although cultures of the “*Epsilonproteobacteria*” from Lower Kane Cave have not been successfully established to date, closely-related taxonomic groups consume dissolved sulfide in culture (Fenchel and Glud, 1998; Gevertz et al., 2000; Campbell et al., 2001; Nemati et al., 2001; Kodama and Watanabe, 2003), and even at oxygen tensions as low as 1% (Takai et al., 2003). Qualitative assessment of microbial sulfide oxidation was done from the mat incubation experiments. In the M-, A-, and B-series incubations, there were low to non-detectable concentrations of headspace $H_2S_{(g)}$ when O_2 levels were >15%. Headspace $H_2S_{(g)}$ increased when O_2 decreased, suggesting that microbial sulfide consumption occurs over a narrow range of O_2 levels for aerobic to microaerophilic sulfide consumption. Microbial consumption could also be occurring at lower O_2 tensions, but consumption rates may not be as rapid nor as competitive compared to microbial $H_2S_{(g)}$ production by SRB, S^0 RB, and fermenting bacteria at low O_2 .

The observed $C_T S^-$ versus distance profile showing nearly constant $C_T S^-$ through the microbial mats (Figure 5-3A) and enhanced $H_2S_{(g)}$ flux directly over the microbial mats in the stream channel (Table 5-1) indicate that the mats in the cave stream are sites for in situ $H_2S_{(g)}$ production by SRB and S^0 RB, and possibly, to a lesser extent, from sulfur assimilation or growth on dissolved thiosulfate by fermenting bacteria (Figure 5-4). MPN biomass estimates demonstrate that anaerobic metabolic guilds are ubiquitous in the microbial mats, and that SRB are the most abundant anaerobic metabolic guilds (refer to Chapter 4; Figure 4-1). The sulfur isotope values of the dissolved sulfide in Lower Kane Cave, averaging -

22.5‰, support autochthonous microbial sulfate reduction. The $\delta^{34}\text{S}$ values for dissolved sulfide in the spring waters indicate that dissimilatory sulfate reduction is the source of sulfide to the cave (refer to Chapter 2; Figure 2-6) (Canfield, 2001a). However, the decrease in $\delta^{34}\text{S}$ values at the end of the Upper Spring microbial mats suggests that sulfide, with a lighter $\delta^{34}\text{S}$ value, is being generated within the stream; in situ sulfate reduction would generate a decrease in the sulfide $\delta^{34}\text{S}$ composition.

MT, DMS, and COS generated in incubations were biogenic in origin because VOSC were not emitted from filtered spring water or killed microbial mat samples. The prevalence of MT production from cultures (Table 5-2), bulk mat incubations (Figure 5-5), and from the small flux from the cave stream suggest that MT is the most abundant VOSC in the cave. These results are in agreement with studies from other anoxic freshwater and marine settings where MT is also the dominant VOSC (Kiene, 1988; Kiene et al., 1990; Lomans et al., 1997; Bodenbender et al., 1999; Lomans et al., 1999a; Fritz and Bachofen, 2000).

Lomans et al. (1997) suggest that MT and DMS form from the methylation of $\text{H}_2\text{S}_{(\text{g})}$ due to the degradation of sulfur-containing amino acids and methoxylated compounds by SRB during degradation of organic material in anoxic sediments. Some microbes can demethylate methionine to MT (Taylor, 1991; Dias and Weimer, 1998); (Seiflein and Lawrence, 2001). Taylor (1991) describes that various enzymes are responsible for VOSC production from successive methylation of precursor sulfur gases. If these processes were occurring, a decrease in $\text{H}_2\text{S}_{(\text{g})}$ would be expected. However, decreasing $\text{H}_2\text{S}_{(\text{g})}$ could also be from microbial sulfide consumption. Only when aerobic or microaerophilic consumption was

lessened could the effects of methylation be resolved. For the M-series and B-series (Figures 5-5 and 5-7), decreases in $H_2S_{(g)}$ under anaerobic conditions could be correlated to MT increases. Therefore, MT production by the microbes from Lower Kane Cave may be due to both amino acid breakdown and sulfide methylation.

Disparate results for COS from the incubations of homogenized mat samples may be due to differences in the microbial populations within the sample, such that the Upper Spring sample (A-series) may have a greater abundance of methanogens compared to the Lower Spring sample (B-series). Previous research supports that COS is primarily derived from bacterial activity in marine environments, but COS can also form chemically in soil stimulated by thiocyanate (Conrad, 1996), from photochemical oxidation of CS_2 in the atmosphere (Bodenbender et al., 1999; Watts, 2000), or by autoclaving or γ -irradiating soils (Lehmann and Conrad, 1996). COS evolved in the headspace of two live mat incubations and BES-amended samples (Figures 5-6C and 5-7C), suggesting that COS may be produced by SRB or fermenters (Table 5-2). However, because the COS concentrations were relatively low for all of the incubations, additional work is required to verify microbial COS cycling.

VOSC consumption by microorganisms may be a mechanism by which VOSC concentrations are kept low in the cave. MT, and DMS to a lesser extent, were degraded under aerobic conditions (Figure 5-9B), which may have been due to microbial consumption. Previous work with sulfur-oxidizing bacteria, including *Thiobacillus thioparus* strain 5 and *Thiobacillus novellas* strain SRM, indicates that these organisms grow using DMS, MT, DMDS (Visscher et al., 1991). Some

sulfur-oxidizing bacteria (e.g., Smith and Kelly, 1988; Jordan et al., 1995; Conrad, 1996) and other metabolically diverse bacteria (e.g., Smith et al., 1991; Ensign, 1995; Seefeldt et al., 1995) can also grow using COS.

Headspace DMS remained relatively low during the incubations, except for the BES-amended bottles (e.g., Figure 5-6D) which may suggest that methanogens are important for DMS cycling. Several researchers suggest that methanogens are vital to VOSC cycling (Kiene et al., 1986; Rajagopal and Daniels, 1986; Lomans et al., 1999a; Lomans et al., 1999b). Specifically, Lomans et al. (1999a) demonstrate that high concentrations of VOSC result in methane production through methanogenesis in marine and brackish settings. Anaerobic heterotrophs, such as proteolytic (fermenting) clostridia, can also generate methane from methionine and MT (Rimbault et al., 1988). However, in the S-series incubations, aerobic consumption of DMS was evident (Figure 5-9D), and because the BES-amended sample had the same concentration profile as the unamended samples, DMS may also be consumed by SRB or aerobic bacteria, but not by methanogens. Moreover, rare methanogens were cultured from some of the Lower Kane Cave microbial mats (Chapter 4), and low levels of methane were measured from the cave spring water (Table 2-1). During the A- and B-series, however, methane levels did not increase above the background, which is expected if methanogenesis or proteolytic sulfur amino acid breakdown processes were occurring (Figures 5-6G and 5-7G).

In conclusion, microorganisms living in sulfur-rich, subterranean habitats contribute to sulfur gas cycling, and the terrestrial subsurface represents both a source and sink for $\text{H}_2\text{S}_{(g)}$ and VOSC. This research demonstrates for the first time

that H₂S and VOSC are cycled by microbial communities in an aphotic freshwater habitat. Photochemical degradation processes are absent in the cave, so the microbial contributions to gas cycling can be studied in detail. Even if microbial production is balanced by consumption, sulfur gas cycling by microorganisms may be important in subsurface ecosystems by providing additional sulfur substrates for the microbial communities. The results from Lower Kane Cave are consistent with those from previous studies from marine and freshwater habitats with SRB (e.g., Stoner et al., 1994; Lomans et al., 1997; Visscher et al., 2003). One notable exception of this work is that methanogenesis does not appear to be a significant process by which VOSC are degraded in Lower Kane Cave. Less than 10% of the world's karst is associated with sulfidic waters (Palmer, 1991), and yet caves like Lower Kane Cave can serve as a proxy for larger sulfidic aquifers that may be inaccessible for study. As groundwater in non-karst areas can often have high concentrations of dissolved sulfide, especially in regions near hydrocarbon reservoirs (Ulrich et al., 1998; Nematy et al., 2001; Kodama and Watanabe, 2002; Elshahed et al., 2003), the contribution of subterranean sulfur gas cycling is potentially significant globally.

Table 5-1: Aqueous geochemical data, observed $C_{T\text{S}^-}$, and theoretical and measured $\text{H}_2\text{S}_{(\text{g})}$ volatilization flux. $C_{T\text{S}^-}$ and flux measurements were collected at different times over a three day time period, August 2003.

Chapter 6: Microbial Contributions to Cave Formation: New Insights into Sulfuric Acid Speleogenesis

ABSTRACT¹

The sulfuric acid speleogenesis model was introduced in the early 1970s from observations of Lower Kane Cave, Wyoming, and was proposed as a cave enlargement process resulting primarily from H₂S autoxidation to sulfuric acid and replacement of carbonate by gypsum on subaerially exposed cave-wall surfaces. This sulfuric acid speleogenesis type-locality was reexamined using uniquely applied geochemical and microbiological methods. Little H₂S escapes into the cave atmosphere, or is lost by abiotic autoxidation, and instead the primary H₂S loss mechanism is from consumption of reduced sulfur compounds by subaqueous sulfur-oxidizing bacteria. Filamentous “*Epsilonproteobacteria*” and *Gammaproteobacteria*, characterized by fluorescence in situ hybridization, colonize carbonate surfaces and generate sulfuric acid as a metabolic byproduct. The bacteria focus carbonate dissolution by locally depressing pH. These exceptional findings show that sulfuric acid speleogenesis occurs in the shallow subaqueous cave environment, and potentially at much greater phreatic depths in carbonate aquifers, thereby offering new insights into the microbial roles in subsurface karstification.

¹ A portion of this chapter was published in the paper “Microbial contributions to cave formation: new insights into sulfuric acid speleogenesis” by A.S. Engel, L.A. Stern, and P.C. Bennett, 2004, Geology, vol. 32 (5) p. 369-372.

INTRODUCTION

Karst landscapes form where soluble carbonate rocks dissolve by chemical solution, resulting in distinct geomorphic features including caves and conduit drainage systems (White, 1988; Ford and Williams, 1989). Karst comprises a significant percentage of the continental earth's surface, and karst formations are important resources for water, hydrocarbon energy, and tourism (see reviews by White, 1988; Ford and Williams, 1989; Palmer, 1991; Daoxian, 1998). The classic model for cave and karst development (speleogenesis) is one of carbonate rock dissolution by carbonic acid, generally at the water table or within the epikarst. Palmer (Palmer, 1991) estimates that <10% of karst globally has developed from hypogenic processes involving CO₂- or H₂S-rich fluids. Examples of extensive hypogenic karst include the caves of the Black Hills, South Dakota (Palmer and Palmer, 1989), the caves of the Guadalupe Mountains, New Mexico and Texas, including Carlsbad Cavern (Hill, 1996; Polyak et al., 1998), caves in Central Italy (Galdenzi and Menichetti, 1995), and the karst of the Caucasus Mountains (Shelley, 1956) and Turkmenistan (Maltsev, 1993). Many hypogenic caves are polygenic in origin (Hill, 1995; 1996), reflecting processes whereby mixing of meteoric water with waters enriched in CO₂ or H₂S has played a role in formational processes (e.g., Ford and Williams, 1989). Because of the complexity of speleogenesis processes, as well as the fact that many of these systems are no longer forming today, many of the mechanisms governing cave formation must be inferred.

Historically, several researchers have proposed that carbonates could dissolve by acids other than carbonic acid, including acids derived from inorganic or bacterial oxidation of sulfides or organic matter (Kaye, 1957; Howard, 1964). For many years, however, carbonate dissolution by sulfuric acid was considered insignificant, and more recently Lowe and Gunn (1995) suggest that sulfuric acid may be important for all nascent subsurface carbonate porosity generation. Palmer (1991; 1995) speculates that sulfuric acid dissolution, as a major cave formation process, is of more importance for the evolution of carbonate petroleum reservoirs than it is for the origin of caves. Indeed, sulfuric acid dissolution has been proposed for the karstification of significant hydrocarbon reservoirs, including the Lisburne field in Prudhoe Bay, Alaska (Jameson, 1994; Hill, 1995), and Mississippi Valley-type deposits (Hill, 1990). Recently, several active caves with hydrogen sulfide-rich groundwater, which discharges into the cave passages as springs, have been recognized (Hubbard et al., 1990; Galdenzi and Menichetti, 1995; Sarbu et al., 1996; Hose et al., 2000).

The process of sulfuric acid speleogenesis from the ‘replacement-solution’ process was proposed by Egemeier (Egemeier, 1981; Hill, 1990; Jagnow et al., 2000) from work in Lower Kane Cave, Wyoming. Dissolved hydrogen sulfide in the groundwater volatilizes into the cave atmosphere, where hydrogen sulfide oxidizes on moist, sub-aerial cave-wall surfaces to sulfuric acid;

The acid reacts with and replaces limestone with gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$),

which eventually dissolves into groundwater undersaturated with respect to gypsum. The net result is the removal of mass and an increase in void volume.

Hydrogen sulfide is a rich energy source for microorganisms, and sulfidic cave systems are often colonized by thick microbial mats (e.g., Angert et al., 1998; Hose et al., 2000; Engel et al., 2001). However, the potential role of sulfuric acid-generating microorganisms to cave formation has only been alluded to (Symk and Drzal, 1964; Hubbard et al., 1990; Hill, 1996; Angert et al., 1998; Hose et al., 2000; Vlasceanu et al., 2000; Engel et al., 2001). The present investigation reexamines the Lower Kane Cave sulfuric acid speleogenesis process by considering the presence of active microbial communities in subaqueous microbial mats, and in particular sulfur-oxidizing bacteria. Because only a small percentage of hydrogen sulfide volatilizes into the cave air, most of the dissolved sulfide is consumed within the subaqueous environment by microbial oxidation (refer to Chapter 5). This exceptional finding led to the hypothesis that speleogenesis within Lower Kane Cave occurs in the subaqueous environment, where sulfur-oxidizing bacteria directly contribute to carbonate dissolution.

MATERIALS AND METHODS

Aqueous Geochemistry

The focus of this chapter is on the Upper Spring transect and the 17 m of mat-filled outflow channel (Figure 1-2), although similar results were found at the other spring-stream complexes in the cave. Stream and gas chemistries were characterized seasonally over three years by standard field-based techniques, as well as by methods developed specifically for the cave environment. Unstable

aqueous parameters (pH, E_H , O_2 , temperature) were determined in situ by electrode methods every meter along the spring outflow channel. Low-level dissolved oxygen and total dissolved sulfide (C_{TS^-}) were measured in the field by colorimetric analysis on a field spectrophotometer using Rhodazine D and Methylene Blue complex (CHEMetrics, VA), respectively. Dissolved, moderate-level oxygen was measured in the field also by colorimetry using the Indigo-Carmine method (CHEMetrics). Other dissolved constituents were determined as previously described in Chapter 2. Stream water dissolved solute speciation and activity, equilibrium gas partial pressure, and saturation state with respect to mineral phases were calculated from the in situ temperature, dissolved solute concentration, pH, and ionic strength using the geochemical speciation model PHREEQC (Parkhurst and Appelo, 1999).

Atmosphere Gases

As a result of the unstable and fugitive nature of some sulfur gases, gas measurements and H_2S flux were performed in the cave by direct-inject field gas chromatography (refer to Chapter 5).

Calcite Field Chambers and Microcosms

Sterile and non-sterile field chambers (in situ microcosms) containing chips (0.5 to 1 cm^3) of Iceland Spar calcite (Wards Scientific) and native Madison Limestone (mineralogy confirmed by x-ray diffraction) were deployed to test whether microorganisms or the bulk stream water chemistry controlled carbonate dissolution. Microcosms were constructed from 2.5 cm wide by 5 cm long PVC-pipes with screw-caps on either end. Sterile microcosms had 0.1 μm -PVDF

hydrophilic filters on the end (similar to 'peepers'), while non-sterile microcosms had 0.5 mm polyethylene mesh on either end to allow for fluid flow, and also for microbial colonization of the chips. Paired sterile and non-sterile microcosms were placed throughout the cave in the stream and within microbial mats, and remained in the cave to react for 2 weeks to nine months (Figure 6-1). Additionally, a technique similar to the buried-slide technique (Parkinson et al., 1971) was used: polished chips (with the largest surface areas being 1-2 cm²) of limestone and pieces of Iceland Spar were surrounded by a 0.5 mm-mesh sack. At each microcosm site, a mesh sack was also deployed (which contained glass slides for structural support).

Electron Microscopy

When field chambers and mesh sacks were retrieved, the rock and mineral chips were processed separately and chips were preserved for microscopy, including conventional scanning electron microscopy (CSEM), environmental SEM (ESEM), and fluorescence in situ hybridization (FISH). Chips examined by ESEM were not preserved, but instead were frozen to -20°C. Unpreserved chips were examined using a Philips XL30 ESEM, with energy dispersive x-ray analysis system, and gaseous secondary and backscatter electron detectors. Chamber conditions were varied from 10%-95% relative humidity using a peltier cooling stage and variable water pressure (0.9 to 6.4 torr, with corresponding accelerating voltages from 4 to 20 kV). For CSEM, chips were fixed using a chemical critical-point drying method modified from Nation (1983). Chips were fixed in 2.5% glutaraldehyde, followed by dehydration in a series of ethanol washes to preserve

biological material on the surfaces. Air-dried samples were mounted on aluminum stubs, sputter-coated with gold for 30 sec, and examined using a JEOL JSM-T330A SEM with a 30 kV accelerating voltage.

Fluorescence In Situ Hybridization

Because filamentous sulfur-oxidizing bacteria are difficult to isolate or to grow in cultures, as well as to enumerate by standard culturing methodology, culture-independent phylogenetic characterization and quantification of microbial communities comprising the filamentous mats, including the construction of 16S rRNA gene sequence clone libraries (Chapter 2) and fluorescence in situ hybridization (FISH) using 16S rRNA-specific probes (Chapter 3; Engel et al., 2003), was done for Lower Kane Cave microbial mats. FISH probes were designed to target specific and dominant epsilonproteobacterial groups within the mats (Amann et al., 1995).

For fluorescence in situ hybridization (FISH), chips were fixed in two ways within 12 hr of collection: (i) with 4% paraformaldehyde for 3 hr, as described by Manz et al. (1996), and (ii) with 50% ice-cold ethanol according to Roller et al. (1994). Fixed chips were air-dried and dehydrated by sequential washes in 50, 80, and 100% ethanol for 3 min prior to hybridization. Previously synthesized oligonucleotide probes (LKC1006, GAM42a, and EUB338I-III mix; Chapter 3) were applied to the chips using hybridization and washing buffers. Refer to Chapter 3 for details. Probe LKC1006 (5'-CTCCAATGTTTCCATCGG-3') was designed to target one epsilonproteobacterial group (LKC Group II) from the microbial mats; this group was the most abundant by biovolume using FISH (Table 3-4). Probe

GAM42a (5'-GCCTTCCCACATCGTTT-3') targeted *Gammaproteobacteria*, including *Thiothrix* spp. (Manz et al., 1996). Probe EUB338I-III mix hybridized with *Eubacteria*, with equal concentrations of EUB338I (5'-GCTGCCTCCCGTAGGAGT-3') for *Eubacteria*, EUB338II (5'-GCAGCCACCCGTAGGTGT-3') specific for *Plantomycetes*, and EUB338III (5'-GCTGCCACCCGTAGGTGT-3') specific for *Verrucomicrobia* and other bacterial groups (Daims et al., 1999). A Leica TCS 4D confocal laser scanning microscope (CLSM) at the Institute for Cellular and Molecular Biology Core Facility, University of Texas at Austin, was used for three-channel simultaneous monitoring of fluorescence results. The CLSM was equipped with a Kr/Ar mixed gas laser and a UV laser, with DIC optics in an inverted microscope. The lasers supply the excitation wavelengths at 488, 568, and 647 nm. Examination was done using the 100x oil immersion objective. Image processing was done using software provided with the Leica instrument, with manual adjustment of contrast and brightness using Adobe Photoshop.

RESULTS AND DISCUSSION

Hydrogen Sulfide Transport and Reaction

Based on Egemeier's original work (Egemeier, 1973, 1981), it was hypothesized that subaerial replacement of limestone by gypsum was a significant mechanism for cave enlargement in Lower Kane Cave because most of the H₂S would quickly escape into the cave atmosphere. Volatilization was tested by measuring the dissolved and atmospheric gases, and by determining the actual flux of H₂S_(g) from the cave water to the atmosphere (Chapter 5), and subsequently the

available $\text{H}_2\text{S}_{(\text{g})}$ that could oxidize on the moist cave-wall surfaces (refer to Chapter 7 for additional information).

At the study spring (Upper Spring), anaerobic water has $34 \mu\text{mol}\cdot\text{L}^{-1}$ total dissolved sulfide ($\text{C}_{\text{T}}\text{S}^-$) at $20.5 \text{ }^\circ\text{C}$ and pH 7.2 (40% H_2S :60% HS^- ; $\text{pK} = 7.04$), (Table 6-1). The total flux of $\text{C}_{\text{T}}\text{S}^-$ at the Upper Spring, calculated from the stream velocity and the incoming concentration of sulfide, was $\sim 8700 \mu\text{mol}\cdot\text{min}^{-1}$, with an average $\text{H}_2\text{S}_{(\text{g})}$ flux of $44 \mu\text{mol}\cdot\text{m}^{-2}\cdot\text{min}^{-1}$ from the stream and microbial mats (Table 5-1 and 5-3). Therefore, over the entire length of the microbial mat at the Upper Spring, the transfer $\text{H}_2\text{S}_{(\text{g})}$ to the cave atmosphere represents less than 8% of the total discharged $\text{C}_{\text{T}}\text{S}^-$, suggesting that the bulk of $\text{C}_{\text{T}}\text{S}^-$ is lost by other mechanisms in the subaqueous environment. One of those loss mechanisms is abiotic autoxidation, but it was found to be very slow in the disaerobic proximal stream water (Zhang and Millero, 1983; Millero et al., 1987), representing only $\sim 0.014\%$ of the potential abiotic loss.

Therefore, the $\text{C}_{\text{T}}\text{S}^-$ loss rate was much faster than could be accounted for by volatilization and autoxidation. The distinctly concave-down concentration vs. distance profile (Figure 5-3) is unlike the characteristic concave-up first-order loss profile expected for both abiotic loss mechanisms. At the mat terminus, however, the increase in dissolved O_2 concentration corresponds to rapid biotic consumption of $\text{C}_{\text{T}}\text{S}^-$ (Figure 5-3). Near the Upper Spring mat terminus, both allochthonous and autochthonous (see Chapter 5) sulfide is consumed by subaqueous biotic consumption, evidenced by the extremely rapid decrease in $\text{C}_{\text{T}}\text{S}^-$. The high

background $[\text{SO}_4^{2-}]$ in the stream water (Table 6-1), however, makes it impossible to measure small changes in oxidation byproducts.

Subaqueous Microbial Carbonate Dissolution

The dominant mechanism for C_TS^- loss is subaqueous microbial oxidation, and most sulfur-oxidizing bacteria oxidize H_2S completely to sulfate with a substantial energy yield:

Others initially form elemental sulfur (S^0) as an intermediate that is stored intracellularly and further oxidized during periods of limiting sulfide:

As a result of two of these three energetic oxidation reactions (Equations 6-3 and 6-5), acidity is generated in the form of sulfuric acid, attacking the geologic matrix supporting the community and modifying their ecological surroundings. Although some sulfur-oxidizers are acidophiles (Johnson, 1998), most are neutrophilic. Colonization of carbonate surfaces, therefore, buffers excess acidity and maintains pH homeostasis (Engel et al., 2001).

The dominant microorganisms in Lower Kane Cave are phylogenetically grouped within the “*Epsilonproteobacteria*”, with lesser abundant sulfur-oxidizing communities of *Thiothrix* spp. (*Gammaproteobacteria*) and *Thiobacillus* spp. (*Betaproteobacteria*) (Chapter 2; Table 2-3). Although many “*Epsilonproteobacteria*”, including those identified from Lower Kane Cave, have not been obtained in pure culture, many cultured epsilonproteobacterial groups

oxidize reduced sulfur compounds using molecular oxygen (under microaerophilic conditions) or alternative electron acceptors (such as nitrate or metals) (e.g., Campbell et al., 2001; Madrid et al., 2001; Lopez-Garcia et al., 2002; Takai et al., 2003). On the basis of phylogenetic affiliation, habitat geochemistry, and sulfur isotope data (Chapter 2), I hypothesize that the “*Epsilonproteobacteria*” in Lower Kane Cave are also sulfur-oxidizers. Most cultured “*Epsilonproteobacteria*” do not store sulfur intracellularly, in contrast to *Gammaproteobacteria*, specifically *Thiothrix* spp. (Larkin, 1989; Nielsen et al., 2000).

Deeply corroded native carbonate fragments (pebble- to cobble-size limestone clasts) were observed in the cave stream, with dissolution effects only on surfaces exposed to stream water and the filamentous microbial mats (Figure 6-2A). Gypsum replacement of these clasts is obvious above the water surface (Figure 6-2B). Examination of these rock surfaces by CSEM and ESEM revealed a complex reacting environment with dissolving carbonate surfaces, secondary gypsum, and a thick cover of predominately filamentous bacteria and exopolysaccharide material (Figure 6-3). The observed carbonate dissolution and gypsum precipitation associated with a surface biofilm suggests that sulfuric acid speleogenesis occurs within a mineral surface microenvironment maintained by the microbial community, rather than being caused by changes in bulk aqueous geochemistry.

The water exiting the Upper Spring pool had a calculated equilibrium partial pressure of CO₂ (pCO₂) of 10^{-1.95} atm, was only slightly undersaturated with respect to calcite (SI_{cal} ~0.2), but was significantly undersaturated with respect to

gypsum ($SI_{\text{gyp}} \sim -1.5$) (Table 6-1). Within a few meters from the orifice, the cave waters became supersaturated with respect to calcite ($SI_{\text{cal}} = +0.06$), and at the end of the microbial mat $SI_{\text{cal}} = +0.2$ due to the volatilization of CO_2 and the contribution of alkalinity by dissimilatory sulfate reduction. The bulk waters were undersaturated with respect to gypsum ($SI_{\text{gyp}} = -1.54$ to -1.62) (Table 6-1).

Although the waters were in equilibrium or supersaturated with respect to calcite, SEM examination of the chamber calcite revealed etching localized where microbial filaments or biofilms were attached to the mineral surfaces (Figure 6-4A through 6-4E; Appendix E). Sterile calcite chips exposed to the stream water show no microbial colonization and no apparent dissolution (Figure 6-4F). Two filament types were observed on nonsterile calcite chips with ESEM, one containing sulfur globules and another without (Figure 6-5A). Dissolution trenches directly under filaments without sulfur (white arrows) were deeper than trenches associated with sulfur-containing filaments (black arrows) (Figure 6-5B). Differences in dissolution intensity at the microbial filament may correspond to the predominance of each of the two sulfide oxidation mechanisms (Equation 6-3 vs. Equation 6-4); greater localized acidity may be generated under the filaments that do not store sulfur (Equation 6-3).

FISH probes were used on the experimental chip surfaces to determine the identities of the filaments colonizing the surfaces. By using CLSM, the three FISH probes applied to rock and mineral surfaces showed positive hybridization signals to predominantly filamentous organisms (Figure 6-6). The topographic signal range was $\sim 25 \mu\text{m}$ from the native limestone and $5 \mu\text{m}$ on the Iceland Spar surfaces.

However, these topographic variations in the surfaces, presumably because of dissolution of the carbonate during the experiment, made it difficult to obtain one focal plane with the CLSM. Exceptionally bright hybridization signals for each of the probes indicated high rRNA content, suggesting metabolically active populations when the samples were retrieved (Amann et al., 1995). Nearly all observed filaments simultaneously hybridized with the EUB338I–III mix and LKC1006 probes on limestone surfaces (Figure 6-6A and 6-6B), and fewer filaments hybridized with the GAM42a and EUB338I–III mix probes (Figure 6-6A and 6-6C). The FISH results genetically identify the two filamentous sulfur-oxidizing bacterial groups that colonize subaqueous carbonate surfaces, consistent with the ESEM observations of filaments with and without intracellular sulfur (Figure 6-5A).

A New Model for Microbial Sulfuric Acid Speleogenesis

The rapid loss of sulfide from the stream, carbonate dissolution associated with microbial filaments, and the dominance of “*Epsilonproteobacteria*” on the experimental limestone surfaces support the hypothesis that these organisms have a direct role in sulfuric acid speleogenesis by oxidizing sulfide to sulfuric acid. The classic sulfuric acid speleogenesis model relied in part on $\text{H}_2\text{S}_{(\text{g})}$ volatilization from the cave stream to the cave atmosphere for replacement-solution processes to proceed (Egemeier, 1981; Palmer, 1991), yet negligible volatilization and abiotic autoxidation of $\text{C}_\text{T}\text{S}^-$ in the cave stream was measured in Lower Kane Cave (Chapter 5). Instead, $\text{C}_\text{T}\text{S}^-$ is consumed by subaqueous sulfur-oxidizing bacteria and cave enlargement occurs via microbially-enhanced dissolution of the cave

floor. In the cave stream, the system is very close to equilibrium, and the calcite dissolution rate is a function of $[\text{Ca}^{2+}]$, pCO_2 , and solution pH. The rate has a non-linear dependence on the degree of undersaturation (Ω) that can be described as the difference between the actual and equilibrium saturation pH ($\Delta\text{pH} = 0.5 \log \Omega$) (e.g., (Morse and Berner, 1972; Berner and Morse, 1974). At conditions of small Ω ($\Delta\text{pH} < 0.15$), such as found in the bulk stream water receiving diffuse proton input from abiotic sulfide oxidation, calcite dissolution is very slow with little effect from small changes in pH. In contrast, where bacterial filaments are in contact with carbonate, excess acidity is focused at the reacting surface (Equation 3) and local Ω increases. Although the stream water is near calcite equilibrium, the $[\text{Ca}^{2+}]$ increases along the stream region where microbial growth is greatest, whereas $[\text{SO}_4^{2-}]$ increases only slightly (Table 6-1). These observations show that sulfur-oxidizing bacteria colonize subaqueous carbonates, localize dissolution by generating acidity, and therefore are integral to sulfuric acid speleogenesis.

CONCLUSIONS

While a microbial role to cave formation has been alluded to for sulfidic caves (Hubbard et al., 1990; Hill, 1996; Angert et al., 1998; Hose et al., 2000; Vlasceanu et al., 2000; Engel et al., 2001), previous explanations for sulfuric acid speleogenesis assumed abiotic chemical and hydrologic controls. These controls operate predominantly near a shallow groundwater table because of oxygen requirements for abiotic processes (e.g., Palmer and Palmer, 2000) or subaerially after H_2S volatilization on the basis of extensive gypsum in these cave systems

(e.g., Egemeier, 1981; Hill, 1990; Galdenzi and Menichetti, 1995; Hill, 2000). This work reexamined Lower Kane Cave and confirmed that some $\text{H}_2\text{S}_{(\text{g})}$ does indeed volatilize into the cave atmosphere, and consequently subaerial speleogenesis does occur. However, the long-term rate is unknown. The $\text{H}_2\text{S}_{(\text{g})}$ volatilization flux today cannot explain modern speleogenesis processes, but the volatilization loss into the cave atmosphere represents the maximum potential proton transfer to the cave walls, which affects subaerial cave-wall speleogenesis processes (Chapter 7).

Almost all $\text{C}_\text{T}\text{S}^-$ in Lower Kane Cave is consumed by subaqueous sulfur-oxidizing bacteria. These bacteria drive sulfuric acid speleogenesis by their attachment to carbonate surfaces and generation of sulfuric acid, which focuses local carbonate undersaturation and dissolution. As the sulfur-oxidizing “*Epsilonproteobacteria*” can be metabolically active under low oxygen tensions, they can catalyze sulfide oxidation in environments where autoxidation is kinetically limited. Therefore, microbial catalysis extends the phreatic depths to which porosity and conduit enlargement could occur in carbonate systems, including oil-field reservoirs and aquifers. One such setting for future investigations, and a location to test the microbial dissolution model, is within the Edwards Aquifer, Central Texas, where it has been proposed that a portion of the karstic aquifer has formed from sulfuric acid speleogenesis (Grubbs, 1991). The metabolic and geologic consequences of an active microbial ecosystem fundamentally change the model for sulfuric acid speleogenesis in the deep subsurface, which may shed light on carbonate porosity development in large aquifers and petroleum reservoirs.

Chapter 7: Geochemistry and Interfacial Phenomena of Acidic Condensation Droplets on Cave-wall Surfaces: Implications for Authigenic Quartz Precipitation and Sulfuric Acid Speleogenesis

ABSTRACT

Volatilization of hydrogen sulfide in Lower Kane Cave, Wyoming, and sulfide oxidation to sulfuric acid on moist subaerial cave-wall surfaces causes carbonate rock dissolution and replacement by gypsum during sulfuric acid speleogenesis. A slight temperature gradient from the cave springs to the rock walls and high relative humidity contribute to condensation. Condensate forms on cave-wall surfaces, including gypsum and organic-rich reddish-brown crusts ($\delta^{13}\text{C} = -36.3\text{‰}$; $n = 11$, $1\sigma = 0.84\text{‰}$). The brown crusts discontinuously cover the gypsum throughout the cave and are composed principally of carbon, oxygen, and silicon. Average droplet pH is 1.7 ($n = 40$), ranging from pH 1.25 on brown crusts to 2.92 on gypsum. Droplets on crusts had pH values below the critical $\text{HSO}_4^-:\text{SO}_4^{2-}$ pK as a result of crust hydrophobicity and acid-producing bacteria; droplets with a pH < 2 were undersaturated with respect to gypsum, while droplets with pH > 2 were in equilibrium with gypsum, as a result of buffering by the bisulfate-sulfate weak acid/base pair (pK = 1.92) combined with the gypsum-sulfate. Microbial cells and filaments, although evident from nucleic acid staining, are metabolically inactive based on application of 16S rRNA-specific oligonucleotide probes. Low pH droplets were supersaturated with respect to quartz ($\text{SI}_{\text{quartz}} = +0.55$, $n = 4$), and euhedral quartz microcrystals were found in the crusts. The cave-wall environment enhances silica mobilization from acid dissolution of the limestone and liberation

of insoluble residues (clays and feldspars). Quartz precipitation may be accelerated by bacterial cells and organic material acting as nucleation points for crystal growth, especially for the very small crystals. Armoring of the cave walls by gypsum and organic biofilms fundamentally affects how the cave enlarges during sulfuric acid speleogenesis. Microbial colonization of the low pH, moist gypsum habitat forms an organic film that eventually becomes impermeable through time. Condensation droplets become separated from the underlying gypsum, thereby precluding diffusion of sulfuric acid through the gypsum to the limestone, limiting or shutting off sulfuric acid dissolution completely. Subaerial sulfuric acid speleogenesis, as the replacement of the limestone by gypsum, will commence only when fresh limestone is exposed.

INTRODUCTION

Tiny authigenic quartz crystals have been found in gypsum deposits from ancient caves formed by sulfuric acid speleogenesis, including several caves in Italy (Forti, 1994), Turkmenistan (Maltsev et al., 1997), and Carlsbad Cavern, Lechuguilla Cave, and others in the Guadalupe Mountains, New Mexico (Polyak and Provencio, 2001; Polyak and Güven, 2004). In Carlsbad Cavern, micrometer- to deci-micrometer quartz crystals are found in unconsolidated powders in association with gypsum and carbonate mineralization (Polyak and Provencio, 2001; Polyak and Güven, 2004). These cave systems did not form under hydrothermal processes, and therefore quartz precipitation in the caves occurred at low, earth-surface temperatures. Moreover, as most of these cave systems are no

longer active, there has been little explanation for how the quartz crystals originated.

Quartz precipitation at low temperatures is a perplexing chemical and kinetic occurrence (e.g., Chafetz and Zhang, 1998). Although quartz is one of the most abundant minerals on the Earth, it is kinetically unreactive at low temperatures and it is unlikely to precipitate (or dissolve) at any significant rate without a catalyst (Rimstidt and Barnes, 1980; Rimstidt, 1997). Quartz precipitation from solution is hindered by the presence of humic acids, Al, Fe, and Ca, and removal of these impurities is necessary for precipitation (Thiry and Millot, 1987). There is evidence that microorganisms, acting as potential nucleation sites, catalyze silica precipitation at low pH, by cell wall sorption of H_4SiO_4 ions (Fortin and Beveridge, 1997).

In Lower Kane Cave, Wyoming, a small system actively forming from sulfuric acid speleogenesis (Egemeier, 1981), quartz microcrystals are found in brown organic-rich crusts associated with gypsum cave-wall mineralization and acidic condensation droplets. Sulfuric acid speleogenesis in Lower Kane Cave is principally by subaqueous hydrogen sulfide oxidation to sulfuric acid by microbial catalysis. A small percentage of hydrogen sulfide does volatilize into the cave atmosphere (refer to Chapters 5 and 6), and it is subsequently oxidized on moist cave-wall surfaces. The sulfuric acid on exposed cave-wall surfaces creates an aggressive solution that rapidly corrodes the carbonate host rock and replaces it with gypsum, the replacement-solution process of Egemeier (1981):

To date, sulfuric acid speleogenesis has been linked to the development of <10% of the carbonate karst worldwide (Palmer, 1991), including the formation of some of the world's largest caves such as Carlsbad Cavern, New Mexico (Hill, 1996), and the Frasassi Caves, Italy (Galdenzi and Menichetti, 1995). In some cave systems that are actively forming from sulfuric acid speleogenesis, microbial communities colonize subaqueous and subaerial habitats, including acidic cave-wall surfaces (Hose et al., 2000; Vlasceanu et al., 2000; Engel et al., 2001). Microbial life at pH <4 in natural and artificial environments has been characterized, as studies of life in extreme environments has surged recently (e.g., Johnson, 1998; Bond et al., 2000).

Warm (22.6 °C) incoming sulfidic water and cooler (~21 °C) cave walls enhance condensation on subaerial cave-wall surfaces in Lower Kane Cave. I hypothesized that the chemistry of condensation on cave walls influences limestone dissolution, and gypsum and authigenic quartz precipitation reactions. Subaerial condensation is significant not just for cave formation mechanisms and speleothem alteration or precipitation (Dublyansky and Dublyansky, 1998), but also for microbial communities that may colonize the cave-walls. Condensation has been noted in many different caves (e.g., Eraso, 1969; Dublyansky and Dublyansky, 1998), and several studies of caves forming by carbonic acid dissolution describe aggressive condensate chemistries (Gergedeva, 1970; Pasquini, 1973; Dublyansky and Dublyansky, 1998), demonstrating that condensed waters are responsible for carving cave features and even wide-scale speleogenesis. Understanding cave-wall condensate properties is important because the nature of condensate and the

surfaces upon which they form affect the dissolving or precipitating ability of the solution, as well as its ability to entrain gas(es).

The role of condensation in sulfuric acid speleogenesis and cave-wall modification has not been previously investigated. Moreover, there has not been demonstrable evidence of quartz precipitation from a naturally acidic, microbially-active environment. Therefore, the goals of this study were to characterize the physical and chemical nature of the subaerial cave-wall surfaces from Lower Kane Cave in order to speculate about the formation of quartz in other caves formed from sulfuric acid speleogenesis. The quartz may also serve as a biomarker for an environment in these ancient caves where microorganisms once lived.

MATERIALS AND METHODS

Study Site

Several caves in the Bighorn Basin, Wyoming, formed from sulfuric acid speleogenesis, including Lower Kane Cave (Egemeier, 1981). Lower Kane Cave air temperatures average ~ 21 °C with a relative humidity of 99-100%. The spring waters average 22.6 °C, and have a pH of ~ 7.3 . Incoming total dissolved sulfide is ~ 34 $\mu\text{mol}\cdot\text{L}^{-1}$, and volatilization of $\text{H}_2\text{S}_{(\text{g})}$ is $<8\%$ of the total dissolved sulfide flux (refer to Chapter 5).

Crust and Gypsum Characterization

Moist and dry brown crusts and gypsum deposits were collected aseptically throughout Lower Kane Cave. Crusts were digested in warm HCl and HNO_3 for 4 hr and the acid solution was analyzed by inductively coupled plasma mass

spectroscopy (ICP-MS) for major cations and high pressure liquid chromatography (HPLC) for anions.

Crusts were fixed using a chemical critical-point drying method modified from Nation (1983); samples were washed overnight with 25% gluteraldehyde, and then dehydrated with a series of ethanol washes. Air-dried, preserved samples were mounted on aluminum stubs, sputter-coated with gold, and examined using a JEOL JSM-T330A scanning electron microscope (SEM) in conventional-mode (CSEM) at an accelerating voltage of 30 kV with electron dispersive analysis (EDS) system. A Philips XL30 SEM operated in environmental mode (ESEM) with EDS was used for visualizing hydrated crusts and EDS elemental mapping without gold-coating.

The brown crusts were HCl-acidified to ensure removal of carbonate mineral phases for carbon isotope ratio analysis. Most carbon isotope measurements were made by elemental analyzer interfaced with a continuous flow FinniganMAT Delta Plus mass spectrometer, but some measurements were also made by sealed tube combustion, vacuum purification, and dual-inlet VG Prism II mass spectrometer (refer to Chapter 2). Carbon isotope values are expressed in delta (δ) notation with respect to the international standard V-PDB.

Brown crusts were prepared with the stain 4',6-diamidino-2-phenylindole (DAPI) to visualize nucleic acids within the crusts. Some crust samples were also preserved in two ways with respect to the general requirements for successful fluorescence in situ hybridization (FISH) of various gram-negative and gram-positive bacteria: (i) with 4% (wt/vol) paraformaldehyde for 3 hr before final wash with saline phosphate buffer as described by Manz et al. (1992), and (ii) with one-

time 96% ice-cold ethanol according to Roller et al. (1994). Preserved crusts were attached to a thin agarose layer on Teflon-coated nonfluorescence slides and air-dried before dehydrating by sequential ethanol washes (refer to Chapter 3 for detailed FISH methodology). Hybridizations with multiple 16S rRNA-specific oligonucleotide probes to target specific taxa were performed as described by Manz et al. (1992) (Table 7-1); following hybridization, DAPI was applied to the crusts for cross-referencing cells. DAPI and FISH results were visualized on an Olympus BX41 phase-contrast microscope with a reflected fluorescence system, and a 100x oil-immersion objective.

Droplet Collection and Characterization

Condensation droplets were drawn into a sterile, plastic, and non-reactive syringe, whereby ~1 ml of droplet solution over a 5-10 cm² area of the same substrate was collected and homogenized. Droplets from brown crusts and gypsum were collected separately. Condensate solutions were filtered to remove gypsum crystals. Solution chemistry was determined by HPLC and ICP-MS, and pH was measured from an aliquot with a IQ150 pH/mV/temperature meter with a stainless steel micro pH electrode (IQ Scientific Instruments, Inc., San Diego, CA) calibrated to pH 4, 2, and 1.8. Dissolved solute speciation and activity and saturation state with respect to mineral phases were calculated from in situ temperature, dissolved solute concentration, pH, and droplet ionic strength using the geochemical speciation model PHREEQC (Parkhurst and Appelo, 1999). pH of individual droplets in the cave was measured using the IQ150 pH microelectrode.

Surface free energy affects the saturation state of a solution with respect to mineral stability. Condensation droplet morphology was measured in the cave and interfacial tension was determined from digital images by measuring the contact angles droplets on brown crust (n = 21) and on gypsum (n = 3; droplets on gypsum were rare). In order to reduce complications between advancing and receding edge contact angles, because droplets did not form on completely flat surfaces and the inclination of the solid can deform the droplet (Extrand and Kumagai, 1995), only droplets that appeared to be free-hanging on nearly horizontal cave walls (ceilings) were measured. Interfacial tension was determined from a modified Young's relationship,

$$\gamma_{LV} \cos\Theta = \gamma_{SV} - \gamma_{SL} \quad (7-2),$$

such that the surface forces are of a liquid (L) drop on a surface (S) in contact with air (V), and a definite contact angle, Θ , between the liquid and solid phase. If the contact angle can be estimated, then an equation-of-state approach that relates γ_S and γ_{LV} can be derived. Kwok et al. (1998) suggest that, for a contact angle- based surface analysis, the measure of contact angles of a single liquid drop would suffice for determination of the surface tension of the underlying solid,

$$\cos \Theta = -1 + 2 (\gamma_S / \gamma_{LV}) \quad (7-3)$$

Once the contact angle and γ_S are known, γ_{SL} can be calculated (Kwok et al., 2000). Using Equation 7-3 assumes a smooth, homogeneous, and incompressible solid, all aspects of natural systems that are difficult to quantify (e.g., solids are not completely smooth surfaces; adsorbed gas can reduce the solid-liquid interfacial

tension and smooth effective roughness at the solid surface). These calculations were used to estimate surface hydrophobicity, which would also serve as a measure for the potential reactions that could be occurring between the droplet and the underlying mineral or crust surface(s).

Quartz Separation and Cathodoluminescence Microscopy

Gypsum deposits and brown crusts were dissolved in dilute HCl to collect the insoluble residue phase. Gypsum was further dissolved by gentle shaking in distilled water with NaCl to complex free Ca^{2+} . Bedrock from several units within the Madison Limestone was digested with HCl and EDTA separately. Insoluble residues from the various digestions were centrifuged and the supernatants were removed by pipet. Residues from gypsum and the brown crusts were visually inspected by stereoscopic microscopy, and individual euhedral crystals were separated from quartz clusters. Residues from the limestone were analyzed by x-ray diffraction and quartz grains were separated.

Quartz crystals from the brown crusts, $\sim 30 \mu\text{m}$ long (the lower limit for manual manipulation using a stereo-microscope), were mounted individually in epoxy and polished flat to obtain cross-sections of the crystals at random orientations. Clusters were also mounted in epoxy in several orientations and polished. Crystal sections were imaged by cathodoluminescence (CL) microscopy using the ESEM with a Philips PanaCL detector and RGB (red/green/blue) filters. Digital images were processed in Adobe Photoshop for RGB color merging, and brightness and contrast alterations.

RESULTS

Cave-wall Crusts and Condensate Morphology

The walls of the cave are nearly all replaced by gypsum (Figure 7-1A), formed as a result of active sulfuric acid speleogenesis; limestone is rarely exposed. Discontinuous patches of reddish-brown crusts cover the gypsum (Figure 7-1B). Acid digestion of the brown crusts revealed they were composed of 56% carbon by dry weight. ESEM with elemental mapping of crusts supported this, demonstrating dominance by carbon (Figure 7-2A), with rare sulfur and isolated areas of silicon (Figure 7-2B). Calcium was not detected in the brown crusts using ESEM, although there was 14% calcium detected by dry weight.

Condensation droplets, averaging 2-3 mm in diameter, were observed on brown crusts, gypsum, and rarely on freshly exposed limestone. The highest abundance of droplets was on brown crusts in areas of the cave directly over flowing stream water (Figure 7-3). Where there was no flowing stream water, condensation was not observed on the walls, and the brown crusts appeared dehydrated (i.e., cracked and pulling away from the gypsum underneath). Contact angle estimates for condensation droplets on brown crusts were $>90^\circ$, with an average angle of 121.6° ($n = 21$; Table 7-2), and 20% of these droplets were noticeably cloudy. In contrast, the average contact angle of droplets on gypsum was 71° ($n = 3$) (Table 7-2).

The surface tension (γ_S) values for the brown crust were estimated using Equation 7-3, assuming that the γ_{LV} was pure water at $72.8 \text{ mJ}\cdot\text{m}^{-2}$ (although the ionic strength and the high concentration of sulfate-ions, speciated as sulfate and

bisulfate, would slightly decrease interfacial tension of the liquid (Zhou et al., 1998). For the crusts with contact angles $>90^\circ$, the mean interfacial tension was $17.3 \text{ mJ}\cdot\text{m}^{-2}$, while the average surface tension for droplets with contact angles $<90^\circ$ was higher at $47.5 \text{ mJ}\cdot\text{m}^{-2}$ (Table 7-2). The corresponding interfacial tension between the solid and water was $55.3 \text{ mJ}\cdot\text{m}^{-2}$ for droplets on brown crust, while droplets on gypsum had less γ_{SL} values, averaging $25.1 \text{ mJ}\cdot\text{m}^{-2}$ (Table 7-2). The small contact angles and tension estimates indicate that the brown crusts were more hydrophobic surfaces than the gypsum.

Condensate Geochemistry

Condensation droplets on brown crusts had a mean pH of 1.7 ($n = 40$), whereas gypsum droplets had pH values $\sim 2\text{-}3$. Higher pH droplets ($\sim \text{pH } 4$, $n = 20$) were measured from exposed limestone surfaces near the cave entrance. Condensation droplets were collected from fifteen locations for geochemical analysis. Table 7-3 summarizes overall droplet geochemistry.

Droplets with the lowest pH had the highest $[\text{SO}_4^{2-}]$ and ionic strengths. Sulfate (as $\text{C}_\text{T}\text{SO}_4^{2-}$) was speciated using dissociation constants for sulfate-bisulfate-sulfuric acid (Stumm and Morgan, 1996). There was up to 85 mM HSO_4^- for the lowest pH droplet (Figure 7-4). The concentrations of metals increased with decreasing condensate pH, including Si (Figure 7-5A). Total Al^{3+} (measured as $\text{C}_\text{T}\text{Al}$) was complexed as AlSO_4^+ and $\text{Al}(\text{SO}_4)_2^-$, at 0.047 and 0.011 mM , respectively (Figure 7-5B). Equilibrium calculations of condensate solutions showed that most droplets at $\text{pH} > 2$ were in equilibrium with gypsum, while the droplets at $\text{pH} < 2$ were undersaturated with respect to gypsum (Tables 7-3 and 7-4;

Figure 7-4). The droplets from gypsum that were not in equilibrium with gypsum have varying concentrations of Ca^{2+} in solution, and especially low concentrations. (Figure 7-4). Droplets on crusts and gypsum were undersaturated with respect to calcite (Table 7-4), but most of the droplets on brown crusts were supersaturated with respect to quartz (Table 7-4; Figure 7-5B).

Quartz

Quartz crystals observed from the brown crusts ranged in size from $<1\mu\text{m}$ to $10\mu\text{m}$ along the longest axis (Figure 7-6; Appendix F). Some crystals had organic debris covering them (Figure 7-6C), or were imbedded within a fibrous matrix (Figure 7-6E). The surfaces of the quartz crystals showed no evidence of abrasion or pitting common to detrital quartz. Crystal size ranged from $<0.5\mu\text{m}$ to $>19\mu\text{m}$, and the median crystal length of crystals observed by ESEM was $1.28\mu\text{m}$ ($n = 495$). All sizes fell within a statistically significant log-normal distribution (with four degrees of freedom) (Figure 7-7). Quartz crystals were also found within gypsum, in large complex clusters with odd morphologies; individual crystals could not be discerned (similar to Figure 7-6D). No euhedral quartz crystals were found in limestone, although chert fragments were identified and x-ray results showed a ‘quartz’ peak that most likely coincided with chert interference.

Fifteen quartz crystals or clusters $\sim 30\mu\text{m}$ or larger were examined using CL. It was not possible to examine thin sections of the averaged-size quartz crystals ($1.28\mu\text{m}$), and the larger crystal size distribution was not measured using ESEM. Therefore, the significance of this size range is not known. The smallest crystal

analyzed by CL (~10 μm in length) had only dark brown to black luminescence color, indicating an authigenic phase (e.g., Pagel et al., 2000; Ramseyer and Mullis, 2000). In contrast, larger crystals showed authigenic overgrowths on a quartz core with higher luminescence color (Figure 7-8). High luminescence color is characteristic of detrital quartz grains (light blue) (Ramseyer and Mullis, 2000). Depending on the sectioning of an individual crystal, the overgrowth rim width varied, but an average thickness was $<5 \mu\text{m}$. In Figure 7-8, the detrital grain is fractured and two stages of authigenic overgrowth precipitation events were observed, one brown layer and another purplish-black layer.

Brown Crust Microbiology

Eleven brown crust samples were analyzed for the carbon isotope composition in order to determine if there was a signature of biological activity. The brown crusts had carbon isotope values of -36.3‰ ($n = 11$; $1\sigma = 0.84\text{‰}$). The limestone had a carbon isotope composition of $+0.95\text{‰}$. The carbon isotope values for the crusts reflect significant discrimination against ^{13}C , typically exhibited by chemolithoautotrophic fractionation (Preuß et al., 1989).

DAPI inspection of the crusts indicated a variety of microbial cell morphologies throughout the brown crusts had, including thin filaments $\sim 1\text{-}2 \mu\text{m}$ wide and larger fungal hyphae with filament widths averaging $10 \mu\text{m}$, and small rods and cocci (Figure 7-9). However, FISH with 16S rRNA-specific oligonucleotide probes was not successful. After multiple attempts, no fluorescence signals were observed with any of the probes hybridized to the brown crusts.

DISCUSSION

Sulfuric Acid Speleogenesis and the Role of Cave-wall Surfaces

Lower Kane Cave formation mechanisms, including mineral alteration or precipitation reactions, are affected by the properties of the solids and liquids on cave-wall surfaces and microorganisms using the cave-wall surfaces as habitat. The cave walls are coated with gypsum, formed from the dissolution of the host limestone by sulfuric acid produced via sulfide oxidation (either biotic or abiotic):

If the condensate solution is in contact with the underlying gypsum, the solution will approach pH 2, but typically will not go below this pH due to the buffering by the sulfate-bisulfate weak acid/base pair:

and also from the gypsum-sulfate,

In contrast, droplets on brown crusts have pH values below the critical bisulfate-sulfate pKa, possibly as a result of sulfuric acid-producing bacteria, as well as crust hydrophobicity that physically separates the condensate from the gypsum and allows the pH to pass the bisulfate buffer point (Figure. 7-4). The γ_S values calculated for the brown crusts are as high as hydrophobic hydrocarbon or plastic surfaces (Stumm and Morgan, 1996).

Changes in surface tension resulting from the effects of solution pH and ionic strength have been previously investigated (Zhou et al., 1998). According to

Butkus and Grasso (1998), solution pH has two distinct effects on the interfacial energy between surfaces. pH indirectly affects hydration forces by changing surface charge, which also affects the magnitude of electrolyte adsorption. Additionally, solution pH changes surface functional group characteristics (Holmes-Farley et al., 1985). When the pH of water droplets decreased (as in the example provided by Holmes-Farley et al., 1985, from droplets on polyethylene carboxylic acid surfaces), there was an increase in the hydrophobicity of the surface and water contact angles increased due to the protonation of surface groups. This is further supported by the work of Hård and Johanson (1977) which demonstrated that the conjugate base of strong acids, and not the proton, may be responsible for decreases in surface tension, and that an increase in surface tension caused by the conjugate acid of a strong base is more pronounced than the decrease in surface tension caused by the conjugate base of a strong acid. In Lower Kane Cave, the droplets on brown crust had a lower pH and higher contact angles than those on gypsum, resulting in the crusts themselves being more hydrophobic than the gypsum. Ionic strength will also influence contact angle, and consequently surface tension. The experiments by Butkus and Grasso (1998) demonstrate that an increase in ionic strength results in an increase in contact angle, approximately 2-5° for a 10-fold increase in ionic strength. The highest ionic strength of the droplets with the lowest pH also had the lower surface tension value (Tables 7-2 and 7-3).

Speleogenetic Quartz Formation

At pH ~2 or less, total silica ($C_T\text{Si}$) was dominated by H_4SiO_4 . As pH decreased, $C_T\text{Si}$ increased, as did the SI with respect to quartz (Tables 7-3 and 7-4),

indicating that the observation of quartz crystals in the brown crusts is matched by the saturation state of the solutions on the surfaces. The log-normal distribution in quartz crystal sizes suggests that the crystals have not grown uniformly on the cave walls. These differences may be due to variable adsorption of silica from the bulk condensate solution, depending on the surrounding physical surface chemistry of the gypsum or organic crusts, as well as the presence of microorganisms. Parks (1990) describes that if a solution is supersaturated with respect to quartz, quartz is expected to precipitate, but unless particles of quartz are already present, precipitation begins with nucleation of very small particles (<5 nm) (Iler, 1979). At this size, quartz is very soluble (Parks, 1990) and amorphous silica will precipitate, not quartz. If the rate of dissolution of amorphous silica is larger than the rates of nucleation and growth of quartz, then amorphous silica will precipitate. Conversely, precipitation in the presence of seed quartz crystals larger than 5 nm should allow quartz to grow directly. Quartz overgrowths on large detrital quartz grains suggest that the latter is true (Figure 7-8). As the authigenic, euhedral crystals are also quartz, this suggests that nucleation of small particles may have also occurred (Figure 7-6).

Sources of Silica

Several hypothetical sources of dissolved silica are evaluated to examine what processes may have contributed to high silica saturation states in the condensate solutions. Sources of silica from meteoric water, dissolving silicates, and weathering of insoluble clays are discussed.

Influx of quartz-saturated meteoric water

Surface waters are often supersaturated with respect to quartz because the reaction kinetics of quartz precipitation are slow compared to the dissolution rate of, for example, feldspars at temperatures <80°C (Rimstidt and Barnes, 1980; Rimstidt, 1997). However, Egemeier (1981) proposes that there is little infiltration of meteoric water into Lower Kane Cave because of the depth of the cave in Little Sheep Mountain and the low precipitation rates in the northern Bighorn Basin (<20 cm·yr⁻¹). Additionally, abundant cave gypsum would most likely not be preserved if meteoric water, typically undersaturated with respect to gypsum, percolated into the cave. Meteoric influx has caused gypsum to dissolve in the caves of the Guadalupe Mountains (Polyak and Provencio, 2001), as well as the Frasassi system, Italy (Galdenzi and Menichetti, 1995). If quartz-saturated meteoric water did flow along fractures into the cave, quartz would most likely be precipitating at the contact between limestone and gypsum, which was not observed. Therefore, the source of silica in the condensation droplets on the cave walls most primarily results from condensation of water vapor, and not a source outside into the cave.

Silicates dissolution

Dissolution of feldspars by hydrolysis (e.g., KAlSi₃O₈),

or precipitation of secondary clay minerals such as kaolinite or illite on the cave-wall surfaces, could be occurring.

There is limited evidence of primary feldspar within the limestone or of significant

diagenetic clay precipitation within the gypsum deposits, as has been observed in Carlsbad Cavern (Polyak and Provencio, 2001). Clay minerals are most likely not forming because concentrations of accessory cations in condensate solutions are not high enough to reach mineral saturation, and SI values for various clays are extremely low. Therefore, the high silica concentrations in the cave condensate do not result from feldspar dissolution and precipitation of clays.

Weathering of insoluble (residual) clays

Dissolution of insoluble residues from the limestone during sulfuric acid speleogenesis could be occurring. Previous descriptions of the Madison Limestone suggest that the most dominant insoluble residues in the limestone units are clays, such as kaolinite and illite (Plummer et al., 1990). Clay solubility increases with decreasing pH, and as a result, silica could be released into solution (Nagy, 1995):

Aggressive condensate containing sulfuric acid would enhance clay mineral weathering. Organic acids and ligands may also increase clay dissolution by forming complexes with Al on the clay surface, weakening the Al-O-Si bonds (Nagy, 1995). Because rates of silica dissolution vary with changes in exposed surface area of a silicate mineral, and with changes in the volume of water reacting with the dissolving clays, the high surface area of dissolving clays would provide more silica to solution with constant reacting water volumes. For the Lower Kane Cave condensate solutions, liberation of Al during clay dissolution could inhibit the activity of silica (Iler, 1979). At pH values <4, Al exists as Al^{3+} , and in the lowest pH condensate solution, free Al^{3+} is almost completely complexed with sulfate

(Figure 7-5B). Therefore, of the possible silica sources, clay weathering during sulfuric acid dissolution of the host carbonates is the most likely.

Significance of Microorganisms to Cave Formation and Quartz Precipitation

Authigenic quartz formation at earth-surface temperatures is extremely slow, and not typically considered an important process. Kinetic barriers still must be overcome to precipitate quartz in the cave. Because metals (e.g., Ca and Al) that would otherwise poison quartz precipitation are complexed with sulfate, it is hypothesized that organic matter, and specifically microorganisms that once were metabolically active on the cave walls and formed organic biofilms, may have acted as catalysts for quartz precipitation.

Any microorganisms living on the cave-walls are most likely acidophilic bacteria. DAPI staining suggests that microbes are present in the wall crusts (Figure 7-9), but FISH might suggest that they are not metabolically active. As the FISH probes target rRNA, perhaps the lack of positive hybridization indicates the metabolic status (or lack thereof) of the organisms in the low-pH environment when the samples were collected and preserved (Amann et al., 1990; Amann et al., 1995). Previous investigations of 16S rRNA gene sequences retrieved from cave-wall biofilms in other active sulfidic caves demonstrated the occurrence of known sulfur-oxidizing bacteria, including *Thiobacillus* and *Sulfobacillus* (Vlasceanu et al., 2000), and *Thiobacillus* spp. and *Acidomicrobium* (Hose et al., 2000). However, the metabolic viability of these organisms was not established. Acidic biofilms also have been reported from mines, and cultures of *Leptospirillum*, *Acidomicrobium*,

Ferromicrobium acidophilus, and the Archaean *Thermoplasmales* have been obtained (Bond et al., 2000).

The occurrence of quartz within the organic crusts may not be coincidental. Acidophilic sulfur-oxidizing bacteria generate sulfuric acid, which is important for maintaining an acidic habitat, but cells may also function as nucleation sites for quartz precipitation. Fortin and Beveridge (1997) suggest that sorption of silicate ions (speciated as H_4SiO_4) onto acidophiles (e.g., *Thiobacillus* spp.) serves as a nucleation surface, possibly by templating, for the precipitation of *amorphous silica* at pH ~2 - 3. Metal-bridging of multivalent cations on bacterial cells also has been shown to promote aluminosilicate precipitation by enhancing silicate anion binding (Urrutia and Beveridge, 1993). Currently, however, there is no known relationship between microbes and quartz precipitation at any temperature range,

Microbes that colonization the subaerial cave-wall surfaces play a role in speleogenesis by forming a thick organic biofilm on the gypsum. These biofilms have high surface tensions relative to the gypsum, which eventually creates an impermeable surface layer on the cave walls. This hydrophobic surface precludes diffusion of sulfuric acid through to the gypsum and, consequently, to the underlying limestone.

CONCLUSIONS

Low-temperature euhedral quartz crystals found in caves formed from sulfuric acid speleogenesis indicate potentially microbially active acidic environments during periods of cave formation. While it is possible that the speleogenetic quartz precipitated in Lower Kane Cave prior to the cave formation,

it is more likely, based on condensate geochemistry and the association of the quartz with gypsum and brown crust, that the quartz formed since cave inception. The relationship between euhedral quartz and the cave-wall surfaces colonized by microorganisms (active or not) suggests that the rate of quartz precipitation might be enhanced by biologically active surfaces or microbially-produced ligands. This finding would be a fundamental discovery for both geomicrobiology and geochemistry. Identification of quartz, as a geologically stable signature of acid-sulfur bacterial metabolism, could then be used to identify such integrated bio- and geo- processes in ancient cave systems, or other more diverse terrestrial or extraterrestrial systems, modern or ancient.

Chapter 8: Conclusions

The subsurface is a major habitat for diverse microbial communities, as reactive rock surfaces and mineral-rich groundwater provide a variety of energy sources for microorganisms. Caves, although typically <50 m below the earth's surface, offer a valuable opportunity to examine biologic-geologic interactions under subsurface conditions. In Lower Kane Cave, Wyoming, groundwater bearing dissolved hydrogen sulfide, but negligible allochthonous carbon, discharges as springs into the cave passage. Both subaqueous and subaerial microbial communities inhabit this cave system, and the microbial ecology and geochemistry of both of these habitats were investigated.

The bulk of the subaqueous microbial mats has high sulfur content and expresses chemolithoautotrophic metabolism. 16S rDNA sequences retrieved from these mats indicate low overall taxonomic diversity, and the mats are dominated by several novel evolutionary lineages within the class "*Epsilonproteobacteria*". Lower Kane Cave represents the first non-marine natural system demonstrably driven by the metabolic activity of "*Epsilonproteobacteria*". The epsilonproteobacterial groups identified from Lower Kane Cave are not endemic to Lower Kane Cave, as molecular evidence suggests that these epsilonproteobacterial groups occupy a variety of terrestrial sulfidic habitats, both under photic and aphotic conditions. These results expand the geographic and ecological diversity of "*Epsilonproteobacteria*", suggesting that geographic isolation may not be a driving factor in speciation based on minimal genetic divergence among these groups.

Ecologically, the “*Epsilonproteobacteria*” are chemolithoautotrophic sulfur-oxidizing bacteria. As they diversify genetically and metabolically, they create habitats within the microbial mats for other bacterial groups. The biomass of the diverse anaerobic microbial groups, within the interior of the microbial mats, is substantially less than the total biomass of the microbial mat. Stream geochemistry and the spatial relationship of aerobic and anaerobic metabolic guilds allow for tight carbon and sulfur cycling constrained by redox boundaries within the mat environment. A significant component of autotrophically produced carbon is cycled through a detrital microbial loop, demonstrating the ecological importance of these anaerobes. The physical model of carbon and sulfur nutrient spiraling is based on the energy transfer between redox environments, and without aerobic and anaerobic metabolic complexity, nutrient spiraling would not occur. Specifically, chemoautotrophically-fixed carbon produced by the sulfur-oxidizers is degraded by the fermenting bacteria, as well as transported downstream. Fermenters produce a variety of breakdown products that are consumed by different sulfate-reducing bacterial groups, methanogens, and other microbial groups such as iron-reducers or denitrifiers. In turn, the sulfate-, sulfur- and fermenting bacteria generate autochthonous hydrogen sulfide and other volatile organosulfur gases that are consumed primarily by sulfur-oxidizers. Active VOSC cycling by microbial communities from an aphotic habitat has not been previously demonstrated. Sulfur gases produced in terrestrial subsurface habitats, such as sulfidic groundwater, can be important potential sources to the global sulfur cycle.

Almost all of the dissolved sulfide coming into the cave is consumed by subaqueous sulfur-oxidizing bacteria within the microbial mats, including the “*Epsilonproteobacteria*”, but also *Gammaproteobacteria* (e.g., *Thiothrix* spp.) and *Betaproteobacteria* (e.g., *Thiobacillus* spp.). These bacteria drive subaqueous sulfuric acid speleogenesis by attachment to carbonate surfaces and generation of sulfuric acid, which focuses local carbonate undersaturation and dissolution. As the “*Epsilonproteobacteria*” can be metabolically active under low oxygen tensions, these organisms can potentially catalyze sulfide oxidation where autoxidation would be kinetically limited, such as in deep anoxic aquifers. Prior to this work, sulfuric acid speleogenesis was considered a subaerial process (e.g., Egemeier, 1981; Hill, 1990; Galdenzi et al., 1995; Hill, 2000) or a process limited to shallow groundwater environments because of oxygen requirements for abiotic autoxidation mechanisms (e.g., Palmer, 2000). However, chemolithoautotrophy and microbial sulfur oxidation under microaerophilic conditions extend the phreatic depths to which porosity and conduit enlargement can occur in carbonate systems. Groundwater in karst and non-karst areas can often have high concentrations of dissolved sulfide, especially in regions near hydrocarbon reservoirs (Ulrich et al., 1998; Nemati et al., 2001; Kodama et al., 2002; Elshahed et al., 2003), making the contribution of sulfur cycling and microbially enhanced carbonate dissolution more significant globally. As “*Epsilonproteobacteria*” are the major microbial groups so far identified in many sulfidic habitats associated with carbonate caves and springs, these organisms may not only be responsible for sulfuric acid speleogenesis in Lower Kane Cave, but may also be important for carbonate porosity development

globally. The metabolic and geologic consequences of an active microbial ecosystem in the subsurface fundamentally change the model for sulfuric acid speleogenesis.

File SEM5201usm_b.doc
 Date May 2, 2001
 Sample upper spring white mat – bottom jelly mat
 Sample # LKB-O1M – OO3b (jelly mat)
 Description brown-golden to darkbrw mat under
white mats at Site 3
 Duration in place
 Date emplaced
 Date retrieved March 2001
 Method of preservation gluteraldehyde, frozen in N2,
Cracked, freeze-dried overnight
 Coating material gold
 Time of coating 2x 15 sec
 Accelerating voltage 30 kv
 Are bugs present? Singles? Groups?
 No. types present cocci rods branchy
 Radius of bugs Length
 Etching? Secondary minerals?
 EDAX File names
 No. photomicrographs 20 File names M2_upb2_*.tif

Comments: Pictures from two sample stubs

White mat – bottom jelly brown mat – slimy with some sediment (evidence of fine-grained stuff (50-100 um) stuff inside of mat). Lots of filaments on the mineral substrates – and it looks like the filaments are ordered structurally on the substrates – in a lattice structure. Really strange – thick filaments are oriented in one direction, with smaller ones in between them (1 um wide)- may be for nutrient acquisition (“closest- packing” arrangement)

Need to look for more of this

Saw spiky mineral (calcite?)- within the mats – maybe dissolving – maybe precipitating.... Other strange mineral forms – maybe sulfur globules

REALLY AWESOME spiral-guys... but very very very small (100-200 um wide) but long... free-floating in filament matrix but also adhered to substrates (last pic)

Comments:

White mat preserved in gluteraldehyde in field – collected from 203 m (same spot as always – Site 3)

Mat is very slimy and difficult to pull apart – had to cut sections to look at in freeze-dry and look at

Lots of filaments – very dense mat – size of filaments is generally the same (between 3 and 1 μ m). Larger filaments look a little rough on the outside, but smaller (around 1 μ m wide) are very smooth

See some minerals – like the spiky calcite and other rhombs within filament matrix

Sulfur globules

File SEM21301framdoc

Date 2-13-01

Sample Upper Spring Gray sediment – top layer

Sample # LKC-01M-004

Description gray sediment from U Spg orifice area

Duration in place

Date emplaced

Date retrieved March 2001

Method of preservation gluteraldehyde, N2frozen,

fractured w/ exacto, froze whole bottle in N2,

Then freeze-dried overnight (~ 15 hrs)

Coating material gold

Time of coating 2x 15 sec

Accelerating voltage 30 KV

Are bugs present? Singles? Groups?

No. types present 3 cocci rods branchy

Etching? Secondary minerals?

EDAX File names attached – peaks Fe and S (small peak)

Comments:

Gray sediment mat preserved in gluteraldehyde in field – collected from 189 m (pool bottom)

Sediment is very flocky

Lots of black specs – Fe-S stuff

Not many biological things – some filaments and cocci “sacks” – lots of framboids and crystallites

Comments:

Upper Spring orifice 189 m (Figure 1-6A). Most impt images were the first ones (esp the third in the 1st row), showing that a framboid is associated with limestone (Ca, and shows extensive dissolution). Perhaps the framboids ARE coming from the limestone.... Need to look at hostrock in SEM to see b/c thin sections show Fe present.... Some of the framboid crystals are "coated" compared to others, maybe they are being replaced?

Rest of the sample showed thick glycocalyx with lots and lots of cells (mostly cocci <1mm), but also with some rods 1-2 mm long. The biofilm is generally thin. Some evidence for filamentous cells, but could be sheaths - what is making the blood red color?

Saw lots of small framboids also encased in biofilm (looked for density/composition variation in TV with contrast turned way up.... Very dark objects were framboids!).

Comments:

Upper Spring orange film next to gray and red.

Really bad charging problems and the SEM was jumping all over the place drifting and jumping during picture-capture. Sample was really really porous.

For the most part, it looked like the samples from the red mats at Site 1, with sheaths. Didn't see any *Gallionella*-like stuff. There was a thick biofilm on solid particles (sediment?), with clumps of cocci, less than 1 μm across. Some indication of spirochetes.

Red stuff on right (whole picture ~ 0.75 m wide).

 EDAX just general , mostly Fe

Comments:

215 m red mats (Figure 1-8), thick goopy stuff – freeze-dried sample was very soft and porous, little bit of charging problem, but not too bad over all.

Lots and lots of sheaths (*Leptothrix*) – this sample didn't have as much of the bumpy stuff all over it like before (maybe too much gold before?) – clumps of cocci and rods in between sheaths. Sheaths have broken ends, but couldn't find growing tips. Sheaths approx 1µm across, and more than 20 µm long, avg about 10 µm, but this is probably a function of breaking them up.

Thin filaments, about 100 nm across, twisted around each other and sheaths (see image below!) – perhaps *Gallionella*... very nice twisty segments, no more than about 10 µm long, but could have been broken

Comments:

Pumpkin guts from stream channel at 72 m
 – charge a little, have to reduce spot size
 and brightness- concentrate on small areas,
 then move because of charge – need to
 coat better

Seems to be just a sheath matrix with balls
 (or cells) all around. Really cool stuff-
 oriented? Sheaths - look at mats under Epi
 or confocal to see (but might not stain...?)

EDS of ball material has Fe

Groups/clumps of stuff – mineral matter-
 mixed with
 Sheaths... don't know what it is?

Spiral sheaths – maybe *Gallionella* – but
 don't know because diameter is pretty
 small

Straight sheaths – *Leptothrix*-like

DESCRIPTION OF ADDITIONAL SAMPLING SITES FOR CHAPTER 3

Sulfidic Caves

Hellspont Cave, Big Horn County, Wyoming

This small cave (20 m long) is located along the Bighorn River downstream from Lower Kane Cave, but across the river (Figure 1-3; Figure B-1). Hellspont Cave has one spring orifice at the back of the cave (Egemeier, 1981), and microbial mat filament bundles are suspended in the stream water column discharging from the spring (~15 cm deep). There is a thick white microbial mat at the entrance of the cave. A gypsum crust of moist white gypsum and discontinuous patches of elemental sulfur cover the walls. Mat samples from inside the cave and at the entrance were collected on several occasions in 2000 through 2002.

Cesspool Cave, Allegheny County, Virginia

Cesspool Cave is a small opening (<20 m of passage) developed in a travertine-marl complex of Quaternary age located along the Sweet Springs Creek (Hubbard et al., 1986, 1990; Engel et al., 2001). A sulfidic, non-thermal spring discharges into a back pool, flows out of the cave, and resurges into a surface pond. The hydrogen sulfide is thought to originate from oil-field brine solutions that flow up-dip along local faults (Hubbard et al., 1990). Some incidental sunlight reaches the back pool area due to the limited passage length and large surface entrance. The white filamentous microbial mats in the cave and resurgent spring were previously sampled (Engel et al., 2001), and two groups of “*Epsilonproteobacteria*” were identified from 16S rDNA gene sequences. Both of these groups were closely

related to the Lower Kane Cave group I (Figure 3-1), and glycerol-preserved samples and samples stored at -80°C were used to verify that the LKC group I PCR primer could amplify this group.

Big Sulphur Cave, Trigg County, Kentucky

The only entrance to Big Sulphur Cave, near Cadiz, Kentucky, is as a resurgence spring, approximately 5 m above the south side of the Little River. Big Sulphur Cave is large, with 15,750 ft of passage. A very small side passage, with a sulfidic stream, feeds into the main cave trunk passage within approximately 100 m of the entrance. Sulfide is only detected in this small side passage, but $\text{H}_2\text{S}_{(\text{g})}$ can be smelled from the entrance and in the vicinity of the side passage within the main trunk passage. The side channel is relatively small (no more than 0.5 m wide x 1-0.3 m high) and white filamentous microbial mats are attached to cobbles in the stream. The mats are discontinuous along the stream bed, and first occur 5-6 m from the main trunk passage (Figure B-2). Due to passage constriction, it was not possible to see a spring orifice, if there is any, or even where the sulfidic water was originating from (e.g., a spring orifice or from a fissure in the stream bed). Collembolan, flatworms, crayfish and a significantly large population of isopods, were associated with the mats. Gypsum and elemental sulfur were observed on small exposed limestone cobbles in the sulfidic stream. Mat samples were acquired in 2002.

Surface-discharging Mesothermal Sulfidic Springs

Frasassi Caves and resurgence, Genga, Italy

The Frasassi Caves, including Grotta Grande del Vento, Grotta del Fiume, and Grotta Sulfurea, have been studied extensively by Italian speleologists, and Galdenzi and Menichetti (1995) suggest that the caves formed from sulfuric acid speleogenesis. An active sulfidic stream flows through lower levels of the system, originating beyond the passages in Grotta Grande del Vento. Abundant gypsum and sulfur accumulations occur throughout the entire cave system at all cave passage elevation levels. Subaqueous white microbial mats, as discontinuous patches of filaments and webs, have developed within an anaerobic, sulfidic cave stream in two different portions of the cave (Grotta del Fiume and Grotta Sulfurea), and filamentous mats again occur at the resurgence cave spring into the Sentio River (Figure B-3). Samples from the cave microbial mats were acquired in 1998 and frozen at -80 °C prior to DNA extraction. Resurgent spring samples were collected in 2001.

White Sulphur Springs, Schoharie County, New York

White Sulphur Springs is part of a circa 1805-1940s resort in Sharon Springs, New York. A sulfidic spring discharges from a large pool inside an unused bathhouse behind the White Sulphur Temple (Figure B-4), and the water overflows from the floor of the bathhouse, under the walls of the building, and into a small stream outside the building. Thin white filaments covered the outflow basin from the bathhouse. Other sampling locations included two cisterns, one that was covered and another that was open to sunlight; both had white filaments and web-

like microbial mats. Elemental sulfur deposits were common on surfaces above the water level and the cistern walls. Samples were collected in 2002.

Palmetto Spring, Gonzolas County, Texas

Sulfidic water discharges from an artificial (concrete) basin in the parking lot of a picnic area in Palmetto State Park, Texas (Figure B-5). A thin white filamentous mat forms over the concrete, and discontinuous white filament bundles occur ~ 5 m from the concrete basin, although green phototrophic material was also present. White mat samples were collected in 2003.

Surface-discharging thermal Sulfidic Springs

Thermopolis Hot Springs, Hot Springs County, Wyoming

Sulfidic water flows along faults in the Thermopolis anticline and emerge from the Madison Limestone, discharging into the Bighorn River within Hot Springs State Park, Thermopolis, Wyoming (Figure B-6). Water flows from one orifice at $7000 \text{ m}^3 \cdot \text{day}^{-1}$. Thick white microbial mats occur in the upper reaches of the spring before the water spills over travertine pools and dams. Samples were collected in 2002 and 2003.

Glenwood Springs, Garfield County, Colorado

The hot spring at Glenwood Springs, Colorado, is also known as Yampah Hot Springs, and feeds an extremely large swimming pool at the resort. Before reaching the pool there is a cooling pond, piping, a small cistern (referred to as the Drinking Spring), and more pipe work. Microbial mat samples were collected at the cistern (Figure B-7).

Pah Tempe, Washington County, and Fifth Water, Utah County, Utah

Sulfidic water at Pah Tempe Mineral Hot Springs discharges along the Hurricane Fault in Quaternary basalts near the Virgin River, Hurricane, Utah, and the water flows through underground faults. The resort was closed due to groundwater pumping along the river, and hot spring flow has diminished. Microbial mats form on the artificial (concrete) pool bottoms, as well as below breaks in the pool walls where a stream developed (Figure B-8). Mats are suspended on the water surface, supported by large bubbles. Megan L. Porter and Katharina de la Cruz-Dittmar, Brigham Young University (BYU), sampled the mats from these springs in 2002. M.L. Porter extracted total environmental DNA and amplified the epsilonproteobacterial groups using specific PCR primers; universal bacterial primers were also used. Springs at Fifth Water Hot spring, also known as Diamond Fork hot springs, in Utah County, Utah, were also sampled by M.L. Porter and used in this study.

Soda Dam Spring, Sandoval County, New Mexico

Numerous active fumeroles, hot springs, and mudpots attest to active thermalism in the Valles Caldera, associated with the Rio Grande rift (Rzonca et al., 2003). At the Soda Dam near Jemez Pueblo, water discharges from a fault where Precambrian granite juxtaposes Paleozoic carbonates (Madera Limestone, Pennsylvanian). Waters are characterized as Na-Cl-HCO₃ type with minor sulfate concentrations (Goff et al., 1982). A small outlet opposite the Travertine Dam has a small microbial mat (referred to here as Soda Dam Spring) (Figure B-9), which is mostly green from phototrophic organisms; thin patches of white filaments are

found closest to the orifice. Samples were collected in 2001 and 2003. Rzonca and Schulze-Makuch (2003) describe the microbiology of numerous spring waters from the region, finding evidence that an organism genetically related to the Lower Kane Cave groups were present in the water coming out at the spring, although the resulting sequence from the study has not been deposited into GenBank to verify taxonomic relatedness.

Lazio Volcanic Province

Hot springs in central Italy occur along the flanks of the Monte Cimino caldera near the city of Viterbo. Sulfidic waters emerge at the Bagnaccio, Bullicame, Paliano, and Le Zitelle Springs, where white and salmon-colored microbial mats and secondary travertine deposits are common (Figure B-10). Microbial mats from Le Zitelle were sampled in 2001, and were included in this study. Thick white microbial mats occur in the upper reaches of the spring before the waters spill over travertine pools and dams.

Figure B-1: (A) Entrance of Hellspont Cave, Bighorn Co., Wyoming, on the eastern side of the Bighorn River. (B) White filamentous microbial mats on bottom of stream. (C) Spring at back of cave. Full-face respirators are required because the concentration of H₂S is very high. (D) White filaments and phototrophs at entrance at river level.

Figure B-2: Microbial mats in Big Sulphur Cave, Trigg Co., Kentucky. (A) Very small side passage. (B) Microbial mats. (C) Closeup of mats and mud. (D) Flashlight next to mats for scale. Isopods are commonly found in the mats.

Figure B-3: Microbial mats at Frasassi Cave resurgence spring, Genga, Italy. (A) The spring discharges from a cave passages ~ 0.5 m high. (B) White microbial mats extend for 20 m inside the passage.

Figure B-4: (A) Microbial mats coating a concrete discharge pool from the Sulphur Temple bathhouse, White Sulphur Springs, Sharon Springs, Schoharie Co., New York. (B) The pipes running from the bathhouse were exposed under access panels. (C) Long filaments on concrete.

Figure B-5: Microbial mats associated with an artificial concrete mound at Palmetto Spring, Gonzales Co., Texas. White mats were also found ~3 m downstream in a small creek.

Figure B-6: (A) Microbial mats in stream channel discharging from one of the hot springs at Thermopolis Hot Springs, Hot Spring Co., Wyoming. (B) Floating organic matter with white filaments. (C) Thick white filaments on cobbles in stream.

Figure B-7: Drinking Spring cistern, Glenwood Springs, Garfield Co., Colorado. (A) Water discharges in the upper center (arrow) from a pipe under the platform and flows into a channel ringing the cistern pool. (B) Channel around pool with white filaments.

Figure B-8: Microbial mats consisting of webs and bubbles floating on the surface of the water at Pah Tempe hot Springs, Washington Co., Utah. (A) Sampling mats. (B) Filamentous mat where wading pool wall was broken. (C) Floating mat, webs and bubbles.

Figure B-9: Microbial mats at Soda Dam Spring, Jemez Co., New Mexico. (A) Small discharge hole (~2 in diameter) in travertine (arrow). (B) Closeup of white filamentous area (arrow) in mostly a phototrophic mat. (C) Small discharge hole (probably from a pipe) and minor rivulet with white filaments.

Figure B-10: Microbial mats at Zitelle mineral hot springs, near Viterbo, Italy. (A) Orifice with boiling spring. (B) Sampling white filaments on channel edge with travertine. (C) Channel below spring.

APPENDIX E

Chapter 6 Supplement

Appendix E Table of Contents	335
Scanning electron photomicrographs of calcite from in situ microcosms	336

File
 Date
 Sample
 Description
 Duration in place
 Date emplaced
 Date retrieved
 Method of preservation
 Coating material
 Time of coating
 Accelerating voltage
 Are bugs present? Singles? Groups?
 No. types present cocci rods branchy
 Radius of bugs Length
 Etching? Secondary minerals?

Comments:
 Pics from calcite chip from microcosm at 203 m

 Calcite chip deeply corroded and severely etched where filaments were covering surface

 Rare, strange quartz within biofilms.... Don't know if this is from the wall crusts that fell into mats and was incorporated into mat, or if the euhedral quartz formed within the mat authigenically (saw only 2 crystals within the mat)

Comments:
 Pics from calcite chip 2 from microcosm at 203 m
 Calcite chip deeply corroded and severely etched where filaments were covering surface
 Filaments covering surface- crosscutting cleavage surfaces – embedded filaments and cocci in dissolving calcite
 Two types of filaments – one with septa and another without. Cocci very small and attached to filaments, or embedding within glycocalyx – lot of slime on surfaces

Comments:
ESEM Pics from calcite chip 3 from microcosm at 203 m (aken by Phil and Libby)

Calcite chip corroded where filaments were covering surface

Filaments covering surface-crosscutting cleavage surfaces – embedded filaments in dissolving calcite

Dissolution under sulfur-filaments less than dissolution under non-sulfur-filaments

Two types of filaments – one with septa and another without, and one with intracellular sulfur and another without.

 File names File names

Comments:
 Problem with charging,
 so only took 2 pictures

Nice Si xtals – no
 etching or signs of
 weathering – no
 pitting... embedded in
 biofilm matrix. Most of
 the xtals are gypsum (Ca
 and S) – long tabular
 gypsum needles/xtals

Cells are mixed with
 matrix- if there are any
 real cells it's hard to tell

wall biofilm, no descrip (some cells)

gypsum (big xtal in back) and Si (nice xtal in front) with biofilm

Comments:
 Si xtals on and within biofilms. Biofilm made up of rods and filaments embedded in matrix (Ca,Si, Fe, S composition, see EDS). Quartz xtals range in size from 200 nm to about 5-10 um, and some xtals may be bigger (about 20 um). Most show nice clean surfaces, no etching or pitting... and very awesome euhedral shapes (see below).

 Cells hard to measure because the shapes are hidden in the biofilm matrix, but most cells appear to be about 1 um long, but others look like cocci (short and stubby)... Only a few "fat" rods >1 um

File SEM5701acid
 Date 5-7-01
 Sample wall mat, acid crust near Up Spg
 Sample # lkb-01m-007
 Description gyp and rusty-colored crust on wall, acid
 Date retrieved 3-01 trip
 Method of preservation glut
 Coating material gold
 Time of coating 30 sec
 Accelerating voltage 30 KV
 Are bugs present? Singles? Groups?
 No. types present cocci rods branchy
 Radius of bugs small, <1 μm Length 1 μm
 Etching? Secondary minerals? Quartz

Comments:

Acid wall crust, more pictures of beautiful quartz crystals... And strange thin filaments that grow around and near some of them (Folk thinks that it may be palygorskite?). Quartz ranges from about 1mm long to about 5 mm long, some having doubly-terminated ends (quite euhedral and longer than wide), while others are round. Some faces appear to be coated – maybe with a biofilm....

Cells few and far between, although where they are present, and are clumped in a biofilm – hard to get size, but avg 1 μm long as rods. The whole background substrate is a biofilm, bumpy with cells, and quartz is either resting on or struck through it.

Vita

Annette Summers Engel, born Annette Marie Summers in Akron, Ohio, on December 21, 1972, was the first child to Ronald Lee and Marie Alice Summers. After graduating from Marlinton High School in Alliance, Ohio, in 1991, she attended Wittenberg University in Springfield, Ohio, from 1991-1995. She majored in Geology, went caving nearly every weekend, and graduated *cum laude* with a Bachelor of Arts degree in May, 1995. Annette met Scott Allen Engel at a Wittenberg caving function, and they were married November 4, 1995. Scott and Annette moved to Cincinnati, Ohio, where Annette attended graduate school at the University of Cincinnati from 1995-1999. She received a Masters of Science from the Department of Geology in 1997, with the thesis "The Speleogenesis of Movile Cave, Southern Dobrogea, Romania," and followed that degree with a Masters of Science from the Department of Biological Sciences in 1999 for completing the thesis work entitled "The Geomicrobiology of Sulfidic Cave Systems." Annette entered the University of Texas at Austin in the Fall of 1999 where she began her doctoral research in the Department of Geological Sciences with Philip C. Bennett. She and Scott look forward to the future when they will have more time to explore wild places.
