ABSTRACT

We have started a new, deep multi-imaging survey of the Fornax cluster, dubbed the Fornax Deep Survey (FDS), at the VLT Survey Telescope (VST). In this paper we present the deep photometry inside two square degrees around the bright galaxy NGC 1399 in the core of the cluster. We found that the core of the Fornax cluster is characterized by a very extended and diffuse envelope surrounding the luminous galaxy NGC 1399: we map the surface brightness out to 33 arcmin (~ 192 kpc) from the galaxy center and down to $\mu_g \sim 31$ mag arcsec⁻² in the g band. The deep photometry allows us to detect a faint stellar bridge in the intracluster region on the west side of NGC 1399 and toward NGC 1387. By analyzing the integrated colors of this feature, we argue that it could be due to the ongoing interaction between the two galaxies, where the outer envelope of NGC 1387 on its east side is stripped away. By fitting the light profile, we found that there exists a physical break radius in the total light distribution at $R = 10$ arcmin (~ 58 kpc) that sets the transition region between the bright central galaxy and the outer exponential halo, and that the stellar halo contributes 60% of the total light of the galaxy (Section 3.5). We discuss the main implications of this work on the build-up of the stellar halo at the center of the Fornax cluster. By comparing with the numerical simulations of the stellar halo formation for the most massive bright cluster galaxies (i.e., $13 < \log M_{200}/M_\odot < 14$), we find that the observed stellar halo mass fraction is consistent with a halo formed through the multiple accretion of progenitors with stellar mass in the range 10^8 – $10^{11} M_\odot$. This might suggest that the halo of NGC 1399 has also gone through a major merging event. The absence of a significant number of luminous stellar streams and tidal tails out to 192 kpc suggests that the epoch of this strong interaction goes back to an early formation epoch. Therefore, different from the Virgo cluster, the extended stellar halo around NGC 1399 is characterized by a more diffuse and well-mixed component, including the intracluster light.

Key words: galaxies: clusters: individual (Fornax) – galaxies: elliptical and lenticular, cD – galaxies: halos – galaxies: photometry

1. INTRODUCTION

Deep and large-scale multiband imaging is crucial in studying the galaxy outskirts, out to hundreds of kiloparsecs, where the imprints of mass assembly reside: these are the regions of the stellar halos. Under the hierarchical accretion scenario, galaxies at the centers of the clusters continue to undergo active mass assembly, and their halos are still growing in the present epoch: stellar halos and diffuse intracluster light (ICL) result from the stripping of stars from the cluster members by minor mergers and dynamical harassment (Contini et al. 2014; Lucia & Blaizot 2007; Puchwein et al. 2010; Cui et al. 2014).

Observations show that stellar halos can be made of multiple stellar components and can have complex kinematics and host substructures in the form of shells and tidal tails, which indicate gravitational interactions, like merging or accretion, in the formation history of a galaxy (see Bender et al. 2015a; Longobardi et al. 2015a, and references therein). The light distribution of the stellar halos can appear as a different component at large radii with respect to the inner light profile, showing an exponential decrease (Seigar et al. 2007; Donzelli et al. 2011),

or, alternatively, they result as a shallower outer region of the whole light profile, which can be well fitted by a single Sérsic law with a high value of the n exponent, $n \sim 7$ – 8 (Bender et al. 2015a). The relics of the interactions, such as tails, shells, or streams, are also very faint, with a typical surface brightness below $\mu_V \sim 27$ mag arcsec⁻². Therefore, their detection requires very deep imaging and a careful data reduction, able to perform the sky subtraction with an accuracy of a few percent.

In the recent years, a big effort has been made to develop deep photometric surveys aimed at studying galaxy structures up to the faintest levels of surface brightness, which reveal low-luminosity structures and trace the stellar halos at very large distances from the galaxy center (Mihos et al. 2005; Janowiecki et al. 2010; Martínez-Delgado et al. 2010; Roediger et al. 2011; Ferrarese et al. 2012; van Dokkum et al. 2014; Duc et al. 2015; Muñoz et al. 2015; Trujillo & Fliri 2015). Recently, deep images of the Virgo cluster have revealed several faint ($\mu_V = 26$ – 29 mag arcsec⁻²) streams of ICL among the galaxy members and made it possible to map the stellar halos of the bright cluster galaxies (BCGs) at very large distances from the center (Janowiecki et al. 2010). In particular, the halo of M87 is

traced out to about 150 kpc (Mihos 2015). A steep color gradient toward bluer colors is measured in the halo regions, suggesting a significant contribution of metal-poor stars in its outskirts. In this context, the VEGAS survey, an ongoing multiband survey of early-type galaxies in the southern hemisphere (Capaccioli et al. 2015), is producing competitive results. In particular, for the cD galaxy NGC 4472 (in the Virgo cluster), genuine new results concern the detection of an ICL tail in the range $5R_e \leq R \leq 10R_e$ and in the range of surface brightness of $26.5\text{--}27.6 \text{ mag arcsec}^{-2}$ in the g band.

For galaxies in the local universe (≤ 30 Mpc), the properties of the stellar halos can also be addressed using discrete tracers such as globular clusters (GCs) and planetary nebulae (PNe). Observations show that the red GC populations have number-density profiles consistent with that of the stars in the parent galaxy, while the blue GCs are spatially more extended in the intracluster space and trace the metal-poor component of the halo (Forbes et al. 2012; Pota et al. 2013; Durrell et al. 2014; Cantiello et al. 2015; Hilker et al. 2015). In the Hydra cluster, the location of blue GCs coincides with a group of dwarf galaxies under disruption, suggesting a young stellar halo that is still forming (Arnaboldi et al. 2012; Hilker et al. 2015). In this case, this interpretation is further supported by kinematic measurements. In M87, the kinematics of PNe, their α parameter, and the shape of the luminosity function allow us to separate the halo component from the ICL population (Longobardi et al. 2015b). As stressed by Bender et al. (2015a), deep photometry alone is not enough to recognize the structure of the stellar halo, and kinematics measurements are necessary when possible. In particular, the possibility to infer the variation of the orbital distribution of stars, PNe, and GCs (e.g., Gerhard et al. 2001; Napolitano et al. 2009, 2011, 2014; Romanowsky et al. 2009; Pota et al. 2015) in the galaxy halos is a strong observational test for galaxy-formation scenarios that can be compared with predictions of hydrodynamical simulations (e.g., Wu et al. 2014).

From the theoretical side, semianalytic models combined with cosmological N -body simulations have become very sophisticated, with detailed predictions about the structure of stellar halos, the amount of substructure, the mass profiles, the metallicity gradients, and so on (e.g., Cooper et al. 2013; Pillepich et al. 2014) in various types of environments. Recent studies have demonstrated that the overall structure of stellar halos, their stellar populations, and the properties of their dynamical substructures directly probe two fundamental aspects of galaxy formation in the Λ CDM (cold dark matter) model: the hierarchical assembly of massive galaxies and their dark matter halos and the balance between in situ star formation and the accretion of stars through mergers (Cooper et al. 2013, 2015a, 2015b; Pillepich et al. 2015).

The rich environments, clusters, and groups of galaxies are the ideal laboratory to probe the physical processes leading to the formation of the stellar halos and the ICL. In this framework, we are performing a deep, multiband (u , g , r , and i) survey of the nearby Fornax cluster at the VLT Survey Telescope (VST), situated at the Paranal observatory of the European Southern Observatory (ESO). The Fornax Deep Survey (FDS) with VST aims to cover the whole Fornax cluster out to the virial radius (Drinkwater et al. 2001), with an area of about 26 square degrees around the central galaxy NGC 1399, including the region where NGC 1316 is located. The FDS will provide an unprecedented view of the structures of the cluster members, ranging from giant early-type galaxies to small spheroidal galaxies. The multiband,

deep images will allow us to map the light distribution and colors of cluster galaxies out to 8–10 effective radii in order to study the inner disks and bars, the faint stellar halo, including the diffuse light component, and the tidal debris as signatures of recent cannibalism events. Moreover, FDS will also give a full characterization of small stellar systems around galaxies, as GCs and ultracompact dwarf galaxies (UCDs).

A detailed description of the FDS observations, data reduction and analysis, and scientific goals is the subject of a forthcoming paper. In this work, it is urgent to present the first results of the FDS, focused on the bright cluster member NGC 1399, which is the cD galaxy in the core of the Fornax cluster. This galaxy has been studied in detail over a wide wavelength range, from radio to X-ray. NGC 1399 is characterized by a large number of compact stellar systems (GCs and UCDs), for which several studies have provided the number-density distribution and stellar population estimates (Dirsch et al. 2003; Mieske et al. 2004; Bassino et al. 2006; Schuberth et al. 2010; Puzia et al. 2014; Voggel et al. 2016).

The photometry and kinematics of the inner and brighter regions of the galaxy resemble those of a typical elliptical galaxy (Saglia et al. 2000). The two-dimensional light distribution of the central brightest regions of the galaxy appear very regular and round in shape (Ferguson 1989). The most extended light profiles were published by Schombert (1986) in the V band and by Caon et al. (1994) in the B band, mapping the surface brightness out to $R \sim 40$ arcmin (~ 230 kpc) and $R \sim 14$ arcmin (~ 81 kpc), respectively. The most extended kinematics of the stars (out to ~ 90 arcsec) was derived by Saglia et al. (2000): it shows a small rotation ($\sim 30 \text{ km s}^{-1}$) and a high stellar velocity dispersion in the center ($\sim 370 \text{ km s}^{-1}$), which decreases at larger radii and remains constant at $250\text{--}270 \text{ km s}^{-1}$. At larger radii, out to ~ 13 arcmin, the kinematics is traced by GCs and PNe (McNeil et al. 2010; Schuberth et al. 2010). The kinematics of red and blue GCs are distinct, with red GCs having velocity dispersions consistent with that of stars, while blue GCs are more erratic, showing a higher velocity dispersion, $300 \leq \sigma \leq 400 \text{ km s}^{-1}$ (Schuberth et al. 2010). The velocity dispersions of the PNe are consistent with the values derived by the star’s kinematics and with those for the red GCs (Napolitano et al. 2002; McNeil et al. 2010). The X-ray data have shown the presence of a hot gaseous halo associated with NGC 1399, which extends out to about 90 kpc (Paolillo et al. 2002). It appears very asymmetric, consisting of three components that dominate at different scales: the central bright part, coincident with the peak of light; the “galactic” halo that extends out to ~ 7 arcmin, which is offset toward the west with respect to the optical galaxy centroid; and, on larger scales, the “cluster” halo that is elongated in the opposite direction. The galactic halo is very inhomogeneous, showing the presence of several cavities and arc-like features (see Figures 3 and 6 in Paolillo et al. 2002). Different from the compact stellar systems and X-ray emission, the light distribution and colors in the faint outskirts of NGC 1399 are still unexplored. As part of the FDS, in this paper we present the analysis of the deep photometry performed in the g and i bands inside two square degrees around NGC 1399 in order to unveil the stellar halo of this galaxy at the largest galactocentric distances and in an unexplored range of surface brightness.

In the following, we adopt a distance for NGC 1399 of $D = 19.95$ Mpc (Tonry et al. 2001), which yields an image scale of $96.7 \text{ pc arcsec}^{-1}$.

Figure 1. Color composite mosaic (from the u , g , and i bands) of the central 2×1 degrees² in the core of the Fornax cluster. The central cD galaxy NGC 1399 is the brightest object on the left side. North is up and east is on the left.

2. OBSERVATIONS, DATA REDUCTION, AND ANALYSIS

The ongoing FDS observations are part of the Guaranteed Time Observation surveys *FOCUS* (P.I. R. Peletier) and *VEGAS* (P.I. M. Capaccioli, Capaccioli et al. 2015) being performed at the ESO VST. The VST is a 2.6 m wide-field optical survey telescope, located at Cerro Paranal in Chile (Schipani et al. 2012). The VST is equipped with the wide-field camera OmegaCam, spanning a 1×1 degree² field of view in the optical wavelength range from 0.3 to $1.0 \mu\text{m}$ (Kuijken 2011). The mean pixel scale is $0.21 \text{ arcsec pixel}^{-1}$.

The observations presented in this work were collected during a visitor mode run during 2014 November 11 to 23 (runID: 094.B-0496[A]). The images are in the u , g , r , and i bands. All images were acquired in dark time. They cover five fields of 1 deg^2 , one of them centered on the core of the Fornax cluster ($\alpha = 03^{\text{h}}38^{\text{m}}29^{\text{s}}.024$, $\delta = -35^{\text{d}}27'03''18$). Observations were obtained by using a *step-dither* observing sequence, consisting of a cycle of short exposures, one centered on the core of the Fornax cluster and others on three adjacent fields all around it ($\Delta = \pm 1^\circ$) on the SW and NW sides. This approach, already adopted in other photometric surveys (Ferrarese et al. 2012), allows a very accurate estimate of the sky background around bright and extended galaxies.

For each field, we have obtained 76 exposures (of 150 s each) in the u band, 54 in the g and r bands, and 35 in the i band, giving a total exposure time of 3.17 hr in the u band, 2.25 hr in the g and r bands, and 1.46 hr in the i bands. The average seeing during the observing run ranged between 0.6 and 1.1 arcsec.

The data reduction has been performed with the *VST-Tube* imaging pipeline: a detailed description of it, including calibrations and error estimates, is given by Capaccioli et al. (2015). The observing strategy adopted for this data set allows us to derive an average sky image from exposures taken as close as possible in space and time to the scientific ones. The average sky frame is derived for each observing night, and then it is scaled and subtracted from each science frame.

The color composite mosaic (from the u , g , and i bands) of the central 2×1 degrees² around the central cD galaxy NGC 1399 is shown in Figure 1. In this work we concentrate our analysis on the g - and i -band images of this region in order to study the light distribution of the stellar halo and the diffuse ICL component. In a forthcoming paper, where we will also present the full data set of the FDS observations, we will show the photometry and structure of all the bright galaxies in the whole mosaic, including the two-dimensional model of the light distribution (E. Iodice et al. 2016, in preparation).

2.1. Surface Photometry

One of the goals of the FDS is to map the surface brightness and color profiles out to the very faint outskirts of the cluster member galaxies (up to about 8–10 effective radii R_e). To this aim, the crucial step is to account for all of the effects that can contribute to the sky brightness with the highest accuracy. As mentioned in the previous section, data were acquired in completely dark nights. By looking at the $100 \mu\text{m}$ image available at the NASA/IPAC Infrared Science Archive, we have checked that the region of the Fornax cluster is almost devoid of cirrus clouds, so they do not contaminate the images. Other possible sources that can contribute to the sky brightness are the

Figure 2. Left panel: surface brightness profile (top) and intensity profile (bottom) in the g band in the outer regions of NGC 1399. The black points correspond to the values corrected for the background level ± 0.05 counts (continuous black line) estimated at $R \geq R_{\text{lim}}$ (long dashed line); see bottom panel. The open blue, magenta, and red points correspond to the surface brightness values for sky levels of 10%, 20%, or 50% lower or higher than our estimate of the background level, respectively. The dot-dashed vertical line indicates the break radius at $R = 12$ arcmin (~ 70 kpc); see text for details. In the bottom panel, the short dashed lines indicate the corresponding count levels of the residual sky for the above values. Right panel: total surface brightness profile in the g band (black circles) derived from the VST mosaic, compared with literature data (top panel). The blue triangles are magnitudes derived from Caon et al. (1994), green squares are from Dirsch et al. (2003), the red asterisks are the original data from Schombert (1986), and the open red circles are the same magnitudes corrected for a 30% higher value of the sky level.

extragalactic background light, the zodiacal light, and the terrestrial airglow (Bernstein et al. 2002). The zodiacal light decreases in intensity with distance from the Sun, and it is very faint at low ecliptic latitudes (Bernstein et al. 2002). Therefore, considering the ecliptic latitude of the Fornax cluster and the low airmass value during the observations (≤ 1.5), the contribution by the zodiacal light and also of the terrestrial airglow are very low. Given that, the small contribution by the smooth components listed above to the sky brightness is taken into account by the sky frame derived for each observing night and then subtracted from each science frame (see Section 2). Since each sky frame is taken on a field close in distance to the target and taken close in time, the average value of all the smooth sources listed above is estimated in a way that only a possible differential component could remain in the sky-subtracted science frame. To estimate any residuals after the subtraction of the sky frame that can also take into account such differential effects, we proceeded as follows. On the whole sky-subtracted mosaic in each band after masking all the bright sources (galaxies and stars) and background objects, we extracted the azimuthally averaged intensity profile with the IRAF task ELLIPSE. The fit is performed in elliptical annuli, centered on NGC 1399, with fixed position angle (P.A.) and ellipticity (ϵ), given from the isophotes at $R \sim 1$ arcmin, where P.A. = 6° and $\epsilon = 0.02$. The major axis increases linearly with a step of 100 pixels out to the edges of the frame, that is, out to about 100 arcmin, excluding the border, which is characterized by a larger noise. This method allows us (1) to measure any residual fluctuations¹⁰ in the sky-subtracted

images and then take them into account in the error estimate of the surface brightness and (2) to estimate the distance from the galaxy center where the galaxy’s light blends into the background at zero counts per pixel, on average. This method was first suggested by Pohlen & Trujillo (2006) to study the light profiles of spiral galaxies and also adopted by Iodice et al. (2014) on the deep VISTA wide-field images of NGC 253.

From the intensity profiles, we estimated the outermost radius from the center of the galaxy, where counts are consistent with those from the average background level. Such a value is the residual from the subtraction of the sky frame, so it is very close to zero. The radius where the galaxy’s light blends into this level sets the surface brightness limit of the VST light profiles and gives an estimate on the accuracy of the sky subtraction. In the bottom panel of Figure 2, we show the intensity profile in the g band, centered on NGC 1399 and extending out to the edge of the mosaic, as a function of the semimajor axis. We derived that for $R \geq 33$ arcmin (~ 192 kpc) we are measuring the residual fluctuations of the sky. The error on the average value is 0.11 counts. The fluctuations of the background level are less than 0.2 counts. The same approach is adopted in the i band, and it gives a limiting radius of $R \sim 27$ arcmin, an error with the average value of 0.2, and fluctuations of the background level that are less than 0.4 counts.

The isophotal analysis of NGC 1399 is performed by using the ELLIPSE task out to the limiting radii estimated above, where the semimajor axis length is sampled with a variable bin. We derived the azimuthally averaged surface brightness profiles (see Figures 2 and 3), as well as the ellipticity and P.A. profiles (see Figure 4), as a function of the semimajor axis. The surface brightness profiles extend down to $\mu_g = 31 \pm 2$ mag arcsec $^{-2}$ and $\mu_i = 28.6 \pm 2$ mag arcsec $^{-2}$ in the g and i bands, respectively. According to

¹⁰ The residual fluctuations in the sky-subtracted images are the deviations from the background in the science frame with respect to the average sky frame obtained by the empty fields close to the target. Therefore, by estimating them, we obtain an estimate of the accuracy of the sky-subtraction step.

Figure 3. Left panel: azimuthally averaged surface brightness profiles in the *u* (blue), *g* (light blue), *r* (green), and *i* (red) bands from the VST mosaic in logarithmic scale. Right panel: *g*- and *i*-band profiles plotted in linear scale. The effective radii are those derived by fitting the growth curves of the *g* and *i* total magnitudes. The continuous line is the resulting fit with an exponential (long dashed line) and a Sérsic (dotted line) law (see Section 3.5). In both panels, the small box is the enlarged portion of the outer regions where the light profiles become steeper for $R \geq 12$ arcmin (~ 70 kpc). This radius is indicated with the vertical short-dashed line.

Capaccioli et al. (2015) and Seigar et al. (2007), the error estimates¹¹ on the surface brightness magnitudes take the uncertainties on the photometric calibration (~ 0.003 – 0.006 mag) and sky subtraction (~ 0.11 – 0.2 counts) into account. We noticed that, for a large area of the mosaic (~ 50 to ~ 80 arcmin from the galaxy center), the fluctuations on the background level are not larger than 10% (see bottom panel of Figure 2), whereas, on a smaller range of radii, for $30 \leq R \leq 40$ arcmin and for $80 \leq R \leq 90$ arcmin from the galaxy center, the deviations from the average zero level of the background affect by about 20% the surface brightness for $\mu_g \geq 27$ mag arcsec $^{-2}$ and $\mu_i \geq 25$ mag arcsec $^{-2}$. Therefore, to adopt a conservative approach, the error estimate on the sky subtraction takes into account the largest values of about 20% in the residuals, even if it is worth stressing that this is an upper limit and that this value is smaller on average.

Before discussing the light profiles and the two-dimensional light and color distribution (see next section), we present here some tests on the reliability of our results.

We noticed that the light profiles show a change in the slope at $R = 12$ arcmin (~ 70 kpc) and at $26 \leq \mu_g \leq 26.5$ mag arcsec $^{-2}$ (see Figure 3). In a logarithmic scale this is quite evident. At this break radius the light profiles become steeper. The relatively high surface brightness level at which the change of slope is observed suggests that it should not be due to a wrong estimate of the sky level. Nevertheless, we have checked this as follows. In the left panel of Figure 2 we show how much the light profile changes by

¹¹ The uncertainty in the surface brightness is calculated with the following formula: $\text{err} = \sqrt{(2.5/(\text{adu} \times \ln(10)))^2 \times ((\text{err}_{\text{adu}} + \text{err}_{\text{sky}})^2) + \text{err}_{\text{zp}}^2}$, where $\text{err}_{\text{adu}} = \sqrt{\text{adu}/N - 1}$, N is the number of pixels used in the fit, err_{sky} is the rms on the sky background, and err_{zp} is the error on the photometric calibration (Seigar et al. 2007; Capaccioli et al. 2015).

Figure 4. Ellipticity (bottom panel) and P.A. (top panel) profiles for NGC 1399 derived by fitting the isophotes in the *g* (blue points) and *i* (red points) band images. The vertical dashed line indicates the break radius at $R = 12$ arcmin.

accounting for a sky level 10%, 20%, and 50% higher or lower than the average background level. Even if the average sky level was wrong by 20%, the change in the slope would still be present and only the outer points (at $R \geq 25$ arcmin) would be affected. To obtain a shallower profile from $R \geq 20$ arcmin of about more than 2 mag arcsec $^{-2}$, the sky level would have to be 50% lower. Anyway, also in this case, for $12 \leq R \leq 20$ arcmin a slope

Figure 5. VST image centered on NGC 1399 in the g band, plotted in surface brightness levels. The image size is 68.95×51.10 arcmin. The dashed black ellipse is the isophote at the limiting radius $R_{\text{lim}} = 33$ arcmin (~ 192 kpc). The surface brightness level contours in the range $30 \leq \mu_g \leq 31.2$ mag arcsec $^{-2}$ are shown in blue. The dashed black lines show the direction along which we extracted the radial profiles shown in Figure 9, and we observe a light excess. The black circles identify the whole sample of dwarf galaxies in the Fornax cluster observed in the DECam images published by Muñoz et al. (2015).

variation in the light profile is still evident. By looking at the bottom panel of Figure 2, this large difference can be excluded since the observed background level out to the edge of the mosaic is clearly higher.

A further check comes by comparing the light profiles obtained from the VST data with the literature data for NGC 1399. All of the light profiles from the literature were shifted to the g -band profile by using the transformations from Fukugita et al. (1996). The most extended light profiles published in the optical bands for NGC 1399 are from Schombert (1986), Caon et al. (1994), and Dirsch et al. (2003), and they are compared with the VST profile in the g band in the right panel of Figure 2. On average, the agreement is quite good. The light profile by Caon et al. (1994) extends out to 14 arcmin. It was obtained along the major axis of NGC 1399 in the B band, and this causes some differences between the two profiles that are evident for $1 \leq R \leq 6$ arcmin. A change in the slope is observed at the same radius ($R = 12$ arcmin) as the one derived from the VST g -band profile (see right panel of Figure 2). The light profile published by Dirsch et al. (2003) (in the R band) is not an azimuthal average, but it is derived by measuring the surface brightness around all targeted GC sources within an annulus between 8 and 11 arcsec. Compared to the VST profile, the agreement is very good. Even if it is less extended and

does not reach the same faint surface brightness levels as our data, a drop is still observed for $R \geq 10$ arcmin. The most extended light profile ($R \sim 40$ arcmin) available in the literature is that from Schombert (1986) in the V band. It is consistent with the VST profile out to $R \sim 10$ arcmin. As previously argued by Dirsch et al. (2003), the discrepancy between this profile and all the others might be due to an overestimated background or additional light from the bright objects close to NGC 1399 that was not completely masked. Indeed, if we correct the background level for the profiles published by Schombert (1986) by about 30%, it becomes fully consistent with the other results (see open red circles in the right panel of Figure 2).

3. RESULTS: LIGHT AND COLOR DISTRIBUTION OUT TO 192 KPC

In Figure 5 we show the sky-subtracted VST image in the g band centered on NGC 1399, plotted in surface brightness levels, where the outermost isophote at $R = 33$ arcmin (~ 192 kpc) is overlaid. In order to highlight the low surface brightness structures, we performed a Gaussian smoothing with a radius of 20 pixels.

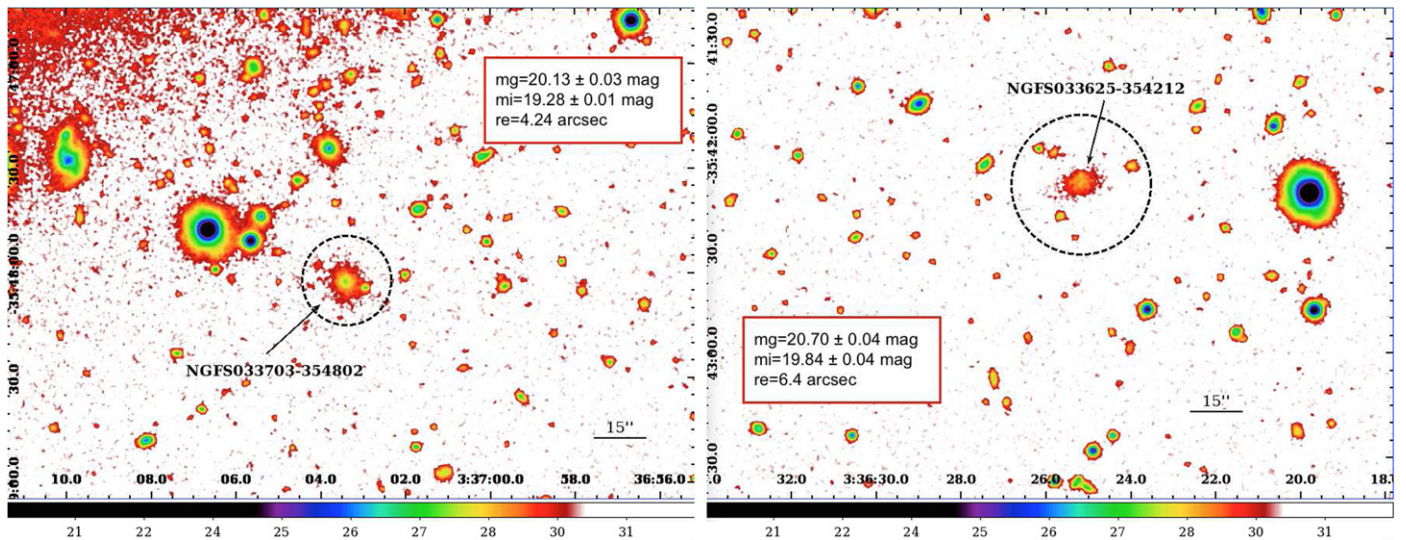

Figure 6. Enlarged portion of the mosaic where two dwarf galaxies among the faintest objects detected by Muñoz et al. (2015) are located. We selected two examples, one nucleated (left panel) and one nonnucleated (right panel) dwarf. The integrated magnitudes in the g and i bands were derived in a circular aperture with a radius of $2r_e$, where the effective radius r_e is the value given by Muñoz et al. (2015).

At these large distances we are mapping the faint stellar outskirts of NGC 1399, which encloses most of the bright galaxies in the core of the Fornax cluster. On this image we have identified the whole sample of the dwarf population in the Fornax cluster observed in the DECam images published by Muñoz et al. (2015). As an extra check of the detection limit of the VST data, we provide in Figure 6 the enlarged portion of the mosaic in the g band where two dwarf galaxies among the faintest and new objects discovered by Muñoz et al. (2015) are located. We selected two examples, one nucleated and one nonnucleated dwarf, which appear clearly detectable also in the VST.

3.1. The Low Surface Brightness Substructures in the Outskirts of NGC 1399

In the region between NGC 1399 and NGC 1387, we detect a “bridge-like” stellar stream. This feature is much more evident in the enlarged image shown in Figure 7 (top panel): it appears to be made of several filamentary structures that connect the two galaxies. They are about 5 arcmin long (~ 29 kpc) and cover an area of about 4.5 arcmin (~ 27 kpc). They have an average surface brightness of $\mu_g \sim 30$ mag arcsec $^{-2}$ ($\mu_B \simeq 30.6$ mag arcsec $^{-2}$). Also, the isophotes of NGC 1387 are not symmetric with respect to the galaxy center, appearing more elongated toward the SW.

The $g-i$ color map in the area of the stellar streams, shown in the bottom panel of Figure 7, shows that, on average, the stellar bridge is bluer than the two close galaxies. The asymmetry to the SW of NGC 1387 is a very extended arc-like region with redder colors. We derived the average $g-i$ colors in several regions covering the three main filaments in the stellar bridge (see boxes in Figure 7) and in the red arc on the west side of NGC 1387 (see red boxes in the bottom panel of Figure 7). The results are plotted in Figure 8. We found that in the middle region of the stellar bridge the $g-i \sim 0.9$ mag. This value is about 0.1–0.2 mag bluer than the average colors in the regions closer to NGC 1399 and NGC 1387, which are about 1.08 and 1.14 mag, respectively (see Figure 8). Given the very low level of the surface brightness, the stellar bridge and the features identified in the color map were unknown in the previous works.

The existence of a stellar stream toward NGC 1387 was already proposed by Bassino et al. (2006) based on their study of the projected distribution of the blue GCs (see Figure 9 of that paper) and recently confirmed by D’Abrusco et al. (2016) using our FDS data (see Figures 3 and 4 of that paper). The system of stellar streams detected in this work matches very well in space and size the bridge detected in the spatial distribution of the blue GCs.

Different from the GCs, the spatial distribution of the dwarf galaxies does not show any evident correlation with the stellar stream between NGC 1399 and NGC 1387 (see Figure 5). This cannot be considered as a definitive conclusion since we cannot exclude the presence of undetected faint and diffuse dwarfs inside the stellar streams (this aspect will be further investigated in a dedicated work on the FDS data).

The stellar bridge could be the sign of an ongoing interaction between the two galaxies. This aspect is discussed in detail in Section 4.

3.2. Isophote Analysis

The azimuthally averaged light profiles of NGC 1399 in the u , g , r , and i bands are shown in the left panel of Figure 3. The light profile in the g band is the most extended, out to 33 arcmin (~ 192 kpc) from the galaxy center, and the deepest, down to $\mu_g = 31 \pm 2$ mag arcsec $^{-2}$ ($\mu_B \simeq 31.8$ mag arcsec $^{-2}$). In the i band, we reach the faint level of $\mu_i = 29 \pm 2$ mag arcsec $^{-2}$ at $R \sim 27$ arcmin (see Figure 3). As pointed out in the previous section, the g -band light profile shows a slope variation at $R_{\text{break}} = 12$ arcmin $\sim 2R_e$ (~ 70 kpc) and at $26 \leq \mu_g \leq 26.5$ mag arcsec $^{-2}$ ($26.6 \leq \mu_B \leq 27.1$ mag arcsec $^{-2}$), which is quite evident when plotted logarithmically. This is a common feature in the light profiles of all other bands, where for $R \geq R_{\text{break}}$ they are steeper.

By integrating the growth curve of the azimuthally averaged profiles, the total magnitudes inside 33 arcmin in the g band and 27 arcmin in the i band are $m_g = 8.57 \pm 0.14$ mag and $m_i = 7.53 \pm 0.10$ mag ($m_B \simeq 9.17$ mag), respectively. The values were corrected for the Galactic extinction by using the absorption coefficients $A_g = 0.035$ and $A_i = 0.018$ derived according to Schlegel et al. (1998). The absolute magnitude in the g band is

Figure 7. Top panel: enlarged image of the core of the Fornax cluster in the VST g band shown in Figure 5, on the western regions of NGC 1399. The arrow indicates the regions of the streams between NGC 1399 and NGC 1387. Dashed boxes correspond to the regions where an average $g - i$ color is derived. Bottom panel: $g - i$ color map in the same region shown in the top panel. Darker colors correspond to redder $g - i$ values. Boxes correspond to the regions where an average $g - i$ color is derived for the streams (blue) and in the halo of NGC 1387 (red). The image size is 31.1×14.3 arcmin.

$M_g = -22.93$ mag, so the total luminosity is $L_g \simeq 1.66 \times 10^{11} L_\odot$. The effective radii are $R_e = 5.87 \pm 0.10$ arcmin in the g band and $R_e = 5.05 \pm 0.12$ arcmin in the i band. These values for the effective radii are larger than that given by Caon et al. (1994), which is $R_e = 2.17$ arcmin: this is the effect of a more extended light profile in the VST g -band images (see right panel of Figure 2). We derived the effective radius integrating the grow curve out the last data point in the Caon et al. (1994) profile, that is, $R = 14$ arcmin, and we have obtained $R_e = 2.28$ arcmin, which

is consistent with the already-published value. According to the R_e estimates given above, the surface brightness profiles in the g and i bands extend out to about $6R_e$ (see right panel of Figure 3).

The P.A. and ellipticity ($\epsilon = 1 - b/a$, where b/a is the axial ratio of the ellipses) of the isophotes change toward larger radii (see Figure 4). Inside 0.5 arcmin, the isophotes are almost round ($0.06 \leq \epsilon \leq 0.12$) and the P.A. is constant at about 22° . For $0.5 \leq R \leq 1$ arcmin, a large twisting is observed: the P.A.

Figure 8. Average $g - i$ colors derived in the regions covering the streams (blue points) between NGC 1399 and NGC 1387 (see Figure 7 plotted as a function of the distance from the center of NGC 1387). The red point indicates the average value of the $g - i$ color in the halo of NGC 1387. For comparison, the average value of $g - i$ derived for NGC 1399 at 10 arcmin from its center is also shown.

decreases by about 20° . At larger radii, for $R \geq 1$ arcmin, the ellipticity increases and reaches a maximum of $\epsilon \sim 0.25$ in correspondence to the break radius, while the P.A. remains constant at $\sim 8^\circ$ and also shows a peak (P.A. $\sim 18^\circ$) at $R = R_{\text{break}}$. Thus, for $R \geq 1$ arcmin, the light distribution tends to be more flattened and elongated toward the SW direction than in the inner regions.

3.3. Light Profiles at Several P.A.s

The steeper behavior of the outer profile is confirmed by the light profiles extracted along several position angles: at P.A. = 98° , which corresponds to the major axis of the outer component (for $R \geq R_{\text{break}}$, see Figure 4), and three other intermediate directions at P.A. = 30° , P.A. = 40° , and P.A. = 120° . The surface brightness is computed in a sector ten degrees wide and corrected for the flattening. The results are shown in Figure 9. Profiles on the NE side at P.A. = 30° and on the SE side at P.A. = 30° are not included in the plot since most of the regions out to 5 arcmin fall in the masked areas.

We found that the light distribution of the fainter outskirts at $R \geq R_{\text{break}}$ has on average the same light profile at different position angles. In particular, even taking into account the larger scatter than the azimuthally averaged profile, at all P.A.s the light profiles show a change in the slope for $R \geq R_{\text{break}}$. On the west side, for $15 \leq R \leq 30$ arcmin, an excess of light is measured at P.A. = 98° , where $27 \leq \mu_g \leq 28 \text{ mag arcsec}^{-2}$ ($27.6 \leq \mu_B \leq 28.6 \text{ mag arcsec}^{-2}$), which is two magnitudes brighter than the light at the corresponding radii on the east side. This region is the intracluster area among NGC 1387, NGC 1379, and NGC 1381, where D’Abrusco et al. (2016) also find an excess of intracluster GCs. On the same side, at P.A. = 120° (NW), a peak in the surface brightness is observed at $R \sim 20$ arcmin with $\mu_g \sim 28 \text{ mag arcsec}^{-2}$ ($\mu_B \simeq 28.6 \text{ mag arcsec}^{-2}$): on the image, this is the region between NGC 1381 and NGC 1380B. Similar features are observed on the SW side, at P.A. = 40° , with $27 \leq \mu_g \leq 28 \text{ mag arcsec}^{-2}$ ($27.6 \leq \mu_B \leq 28.6 \text{ mag arcsec}^{-2}$) for $15 \leq R \leq 20$ arcmin, almost one magnitude brighter than the NW profile at the same radii: at this distance from NGC 1399 we are mapping the light between NGC 1389 and NGC 1387. As discussed in Section 2.1, at this faint surface brightness, small fluctuations of the residual sky level could account for such an effect, which might become even more significant in a smaller area than in a large elliptical annulus. Even if no definitive

conclusion can be drawn at this point, since we are mapping regions where the surface brightness values are comparable with the sky fluctuations, it is important to note that such “excess” light is measured on the west side of the cluster core where most of the galaxies are located, while, on the east side, inside the same radius, only the dwarf irregular galaxy NGC 1427A is present (see Figures 1 and 5).

In a forthcoming paper, we show the analysis of the light distribution for all the bright galaxies in the core of the Fornax cluster so, after modeling it and subtracting off from the whole image, we can address whether those light excesses are still present in this region or, alternatively, they are just the overlapping stellar halos of these galaxies.

3.4. Color Profiles and Color Map

The $u - i$, $g - r$, and $g - i$ color profiles are shown in Figure 10. The center of the galaxy is red, with $g - i \sim 1.3$ mag and $g - r \sim 0.8$ mag. A strong gradient toward bluer values is observed in the $u - i$ color profile, where $3.2 \leq u - i \leq 2.7$ mag for $1 \leq R \leq 10$ arcmin. In the same range of radii, the difference in the $g - r$ and the $g - i$ values is only ~ 0.1 mag. Close to the break radius, all the color profiles show a bump of about 0.1–0.2 mag redder than the central values.

For $R > R_{\text{break}}$, $g - r$ has almost the same value as the inner radii: $g - r \sim 0.8$. The $g - i$ colors seem to be bluer since $1.3 \leq g - i \leq 1.1$ mag, while the $u - i$ are redder up to 1 mag. This effect can be explained as a gradient in metallicity (see, e.g., Peletier et al. 1990).

In Figure 11, we show the $g - i$ color map centered on NGC 1399. In the inner regions, at $R \sim 3$ arcmin from the center, there is an extended red tail ($1.1 \leq g - i \leq 1.3$ mag) on the west side of the galaxy. This could be a sign of a recent, minor merging event. At the same distance from the center ($R \sim 3$ arcmin) and on the same side (west), Cocato et al. (2013) found asymmetries in the kinematics traced by GCs: a recent accretion of a dwarf galaxy was given as a possible explanation of this feature. For $R \leq R_{\text{break}}$, the color map appears asymmetric with respect to the center, and it is more extended and redder on the SW side, where $g - i \sim 1.0$ – 1.2 mag. By comparing the X-ray density contours to the $g - i$ color map, we found a surprising correspondence between the morphology and extension of the “galactic” X-ray halo (see Paolillo et al. 2002) on the west side of the galaxy and the color asymmetries observed in the stellar light. In particular, the X-ray contours match the shape of the red tail observed in the inner regions of the galaxy on the west side.

3.5. Profile Fitting: The Exponential Halo around NGC 1399

As pointed out in Section 1, several recent works have shown that the light profiles of BCGs are not uniquely and well fitted by a single Sérsic profile, where the intensity $I(R) \propto R^{1/n}$, but in several cases a second component is needed to fit the outer stellar halo (Seigar et al. 2007; Donzelli et al. 2011; Arnaboldi et al. 2012). For NGC 1399, Schombert (1986) tried to fit the light profile with a single component using de Vaucouleur’s law: the best fit matches very well only the inner and brighter regions of the galaxy for $R \leq 10$ arcmin. As discussed above, the azimuthally averaged light profiles of

Figure 9. Surface brightness profiles in the g band extracted along several P.A.s (green and magenta triangles) compared with the azimuthally averaged profile (black asterisks). The vertical dashed line indicates the break radius at $R = 12$ arcmin.

Figure 10. Azimuthally averaged color profile as a function of the radius. The dashed line indicates the break radius $R = 12$ arcmin (~ 70 kpc).

NGC 1399 (in both the g and i bands) have an extended, steeper behavior for $R \geq R_{\text{break}}$ (see right panel of Figure 3), which clearly requires a fit with two components. Therefore,

we adopted a Sérsic law (Sérsic 1963) given by the equation

$$\mu(R) = \mu_e + k(n) \left[\left(\frac{R}{r_e} \right)^{1/n} - 1 \right], \quad (1)$$

which accounts for the inner and most luminous part of the galaxy, plus an outer exponential function given by

$$\mu(R) = \mu_0 + 1.086 \times R/r_h. \quad (2)$$

In the above formulae, R is the galactocentric distance, r_e and μ_e are the effective radius and effective surface brightness, respectively, $k(n) = 2.17n - 0.355$ (see Caon et al. 1993), and μ_0 and r_h are the central surface brightness and scale length of the exponential component.

We performed a least-squares fit of the azimuthally averaged surface brightness profile in the g band for $R \geq 0.1$ arcmin to exclude the power-law core of the galaxy. The structural parameters that give the best fit are the following: $\mu_e = 21.5 \pm 0.3$ mag arcsec $^{-2}$ ($\mu_e^B \simeq 22.1$ mag arcsec $^{-2}$), $r_e = 49.1 \pm 0.7$ arcsec (~ 4.7 kpc), $n = 4.5 \pm 0.7$, $\mu_0 = 23.4 \pm 0.1$ mag arcsec $^{-2}$ ($\mu_0^B \simeq 24$ mag arcsec $^{-2}$), and $r_h = 292 \pm 4$ arcsec (~ 28 kpc), and the results are shown in the right panel of Figure 3. The total g -band magnitude of the exponential component, corrected for the galactic extinction (see Section 3), is $m_{\text{tot}}^{\text{halo}} = 9.13$ mag. Thus, compared to the total magnitude of the whole system (see Section 3), it contributes about 60% of the total light, where the ratio is $L_{\text{exp}}/L_{\text{gal}} = 0.60 \pm 0.03$.

Figure 11. $g - i$ color map centered on NGC 1399. The image size is 31.24×21.22 arcmin. The continuous black contours are the X-ray levels from Paolillo et al. (2002).

The above parameters are within the range of values derived by Donzelli et al. (2011) for the 205 BCGs having double component profiles. In particular, the scale length of the exponential component measured for NGC 1399 is comparable with the average value of 25 kpc found for this large sample of galaxies.

From the best fit, we derived the total luminosity of the Sérsic component and of the exponential one as a function of the radius. In Figure 12 are plotted the relative fractions of the two components with respect to the total light profile: the inner Sérsic component dominates the light distribution inside ~ 1 arcmin ($\leq 0.3R_e$), where the contribution to the total light is about 90%. At $R = 10$ arcmin, the two components contribute 50% to the total light. This is consistent with the previous fit performed by Schombert (1986), where de Vaucouleur’s law reproduces very well the light distribution inside 10 arcmin. The exponential component in NGC 1399 is the dominant one for $R > 10$ arcmin, that is, outside $2R_e$.

The striking result of this analysis is that the break radius, identified by a “visual inspection” of the light profiles, is a physical scale separating the regions where the main galaxy and the stellar halo dominate. We had already commented that the transition between the two components occurs at the same radius where the ellipticity and P.A. of the isophotes become flattened and misaligned (see Figure 4). Hence one can argue

Figure 12. Fraction of the Sérsic (red line) and exponential (blue line) components with respect to the total contribution of both of them as a function of the galactocentric radius.

that the bright inner regions are almost spherical and the exponential component is more flattened, implying a different formation mechanism.

4. DISCUSSION: TRACING THE BUILD-UP HISTORY OF THE EXTENDED HALO AT THE CENTER OF THE FORNAX CLUSTER

We have obtained a new, deep mosaic of the Fornax cluster with VST in the u , g , r , and i bands, which covers an area of about 3×6 square degrees around the central galaxy NGC 1399 (see Figure 1). In this paper we focused on the light distribution in the g and i bands inside 2 square degrees around NGC 1399. The large mosaic obtained with the 1 deg^2 field of view pointings of OmegaCam and the large integration time allow us to map the surface brightness out to 33 arcmin (~ 192 kpc) from the galaxy center in the g band (see Figure 3). At these large distances we are mapping the faint outskirts of NGC 1399, down to $\mu_g = 31.2 \pm 2 \text{ mag arcsec}^{-2}$ ($\mu_B \simeq 31.8 \text{ mag arcsec}^{-2}$): the stellar envelope, the central galaxy plus ICL, encloses most of the bright galaxies in the core of the Fornax cluster (see Figure 5).

The main results given by the analysis of the light distribution down to the above levels of surface brightness are the following:

1. We detected a “bridge-like” stellar stream in the region between NGC 1399 and the nearby early-type galaxy NGC 1387 (see Figure 7). It is very faint, with $29 \leq \mu_g \leq 31 \text{ mag arcsec}^{-2}$ ($29.6 \leq \mu_B \leq 31.6 \text{ mag arcsec}^{-2}$), and it is about 5 arcmin wide (~ 29 kpc). Given the very low level of the surface brightness, this structure was unknown in the previous works.
2. The azimuthally averaged light profile in the g band is consistent with the presence of two main components: the bright central part of NGC 1399, which contributes about 90% of the light inside 1 arcmin (i.e., $\leq 0.3R_e$) and is well fitted by a Sérsic law with $n = 4.5$, and an exponential outer component from $R \geq 10$ arcmin, which contributes about 60% to the total galaxy light and extends out to about $6R_e$ (see Figure 3). The break radius at $R = 10$ arcmin is a physical scale separating the regions where the two components dominate.

In this section we discuss the main implications of these results on the build-up history of the center of the Fornax cluster.

4.1. What about the Origin of the Bridge-like Stellar Stream in the Halo Region between NGC 1399 and NGC 1387?

Stellar streams of comparable low surface brightness and extension as detected in the outskirts of NGC 1399 are also observed in the halo of several galaxies. The results from the pilot survey of tidal streams published by Martínez-Delgado et al. (2010), as well as those detected around galaxies in the SDSS DR7 archive by Miskolczi et al. (2011), suggest that several morphologies exist for such faint stellar structures, like great circles, spikes, very long tails, or also mixed types of streams. The morphology and stellar population of the stellar streams are strictly related to which kind of gravitational interaction makes them and the nature of the galaxies involved. As discussed by Duc et al. (2015), the material expelled from a galaxy, which is interacting with a companion massive enough

to perturb it, produces a tidal tail having age and metallicity (i.e., colors) similar to those measured in the parent galaxy. On the other hand, when a low-mass galaxy is disrupting the halo of a massive object, it produces a tidal stream made of material different from that in the massive galaxy. The system of NGC 2698/99 in the ATLAS^{3D} sample is an example of a tidal interaction producing tails, which also shows a luminous bridge of stars between the two galaxies (see Figure 21 in Duc et al. 2015).

As mentioned in Section 3, the stellar bridge-like structure detected between NGC 1399 and NGC 1387 could be the sign of an ongoing interaction between the two galaxies. The deep images taken at VST show that NGC 1387 has asymmetric isophotes at low surface brightness levels ($29 \lesssim \mu_g \lesssim 31 \text{ mag arcsec}^{-2}$), which appear more elongated toward the west side. These features are quite evident in the $g - i$ color map, where the galaxy shows a red arc-like structure on this side (see bottom panel of Figure 7). The projected distribution of the blue GCs by Bassino et al. (2006) also shows a bridge between NGC 1387 and NGC 1399 that is very recently confirmed by D’Abrusco et al. (2016) on the VST data. These features match very well in space and size the bridge of stellar streams detected in the light distribution.

Bassino et al. (2006) claimed that the observed stream of the blue GCs might be caused by a tidal stripping from the outer envelope of NGC 1387 by NGC 1399. This idea was supported by the low number of blue GCs around NGC 1387 with respect to that of red GCs. According to this scenario, the east side of NGC 1387’s envelope is stripped away by NGC 1399 and creates the stellar bridge observed between the two galaxies. The red arc on the west side of the galaxy is the surviving part of that envelope. A hint in favor of this hypothesis comes from the comparison between the average colors measured in the stellar bridge and in the halo of NGC 1387. We found that the average $g - i$ color in the middle region of the stellar bridge is only ~ 0.2 mag bluer than the average colors in the arc on the west side of NGC 1387, where $g - i = 1.14$ mag (see Figure 8). Taking into account the uncertainties on the color estimates at these levels of surface brightness (see Figure 10), the values derived above are all consistent. Anyway, the color difference between the surviving red part and the blue stripped part might mean a difference in their origin. Kinematics and numerical simulations will shed light on the interaction between these two galaxies.

4.2. Which Kind of Physical Structure Is the Outer Exponential Component in NGC 1399?

The light profiles derived for NGC 1399, out to about 192 kpc from the center, resemble those typically observed for disk galaxies, having a very bright $R^{1/n}$ central component and an outer exponential one (see Figure 3). In this case, NGC 1399 would be a giant S0-like galaxy with a very faint and diffuse face-on disk ($\epsilon \sim 0.2$, see Figure 4), never known in the literature. In order to prove such a hypothesis, it is necessary to gather observational and dynamical characteristics for this structure and check if they are consistent with a stellar disk. To do this, we used the photometry presented in this work and the published kinematical data. By the best fit of the light profile in the g band, the exponential component has a central surface brightness $\mu_0 = 23.4 \pm 0.1 \text{ mag arcsec}^{-2}$ ($\mu_0 = 22.6 \pm 0.1 \text{ mag arcsec}^{-2}$ in the r band) and a scale length $r_h = 292 \pm 4 \text{ arcsec}$ (~ 28 kpc). By comparing these values with the typical ones

obtained for a large sample of disk galaxies from the SDSS data, in the $\mu_0 - r_h$ plane, they are located along the slope of the constant disk luminosity but in the void region of very low surface brightness galaxies and with a very large disk (see Figure 1 in van der Kruit & Freeman 2011 and references therein). In particular, disk galaxies with a mass comparable to that of NGC 1399, $\sim 10^{12} M_\odot$, have an average scale length of 5.7 ± 1.9 kpc, and the central surface brightness in the r band is in the range $18 \leq \mu_0 \leq 21.8$ mag arcsec $^{-2}$. Thus, the “disk” in NGC 1399 would be one magnitude fainter and 10 times more extended than any other observed disk in the local universe.

The photometry alone is not enough to exclude the “disk” nature for this component because we need to prove that such a very faint and enormous disk should be dynamically stable. According to Toomre’s criterion (Toomre 1964), the stability of a galactic disk depends on the stellar velocity dispersion σ , the epicyclic frequency k , and the local surface density Σ , where the parameter $Q = \sigma k / 3.36 G \Sigma > 1$. The most extended stellar kinematics for NGC 1399 reaches a distance of $R = 97$ arcsec (~ 9.4 kpc) (Saglia et al. 2000), so it does not map the regions of the exponential component. At these large radii, the kinematics is traced by GCs and PNe out to ~ 13 arcmin (McNeil et al. 2010; Schubert et al. 2010), thus almost out to the region of the break. The kinematics of red and blue GCs are distinct. The kinematics of the red GCs is consistent with that of the stars in the inner regions of NGC 1399, while blue GCs are more erratic, showing a higher velocity dispersion ($300 \leq \sigma \leq 400$ km s $^{-1}$) than the red GCs (Schubert et al. 2008, 2010). Schubert et al. (2008) analyzed the GC kinematics and their irregularities out to 35 arcmin: they found an increase of the velocity dispersion of the blue GCs beyond 20 arcmin. The maximum rotation velocity of stars was about 40 km s $^{-1}$ inside 9.4 kpc, while that for blue GCs is about 110 km s $^{-1}$ at $R \sim 60$ kpc. Therefore, the blue GCs are the only traces of the kinematics in the region of the exponential component. Assuming as an average value of the rotation velocity $V_{\text{rot}} \sim 180$ km s $^{-1}$ (corrected for inclination) and as velocity dispersion $\sigma \sim 300$ km s $^{-1}$ for the blue GCs, we estimate the Q parameter at the break radius $R = 10$ arcmin (~ 58 kpc), where the exponential component starts to dominate the light, and at the last measured point in the surface brightness profiles $R = 33$ arcmin (~ 192 kpc). The local surface density is derived by the surface brightness profile at these radii by using a mass-to-light ratio $M/L = 32 M_\odot/L_\odot$ at $R = 10$ arcmin and $M/L = 42 M_\odot/L_\odot$ at $R = 33$ arcmin. These are derived by using the total mass given by the GC dynamics (see Figure 19 in Schubert et al. 2008) and the total luminosity integrated at the same radii from the VST g -band profile. Given that, we find $Q[R = 10] \sim 0.85$ and $Q[R = 33] \sim 4 \times 10^{-5}$, so $Q < 1$ over the whole extension of the exponential component. This analysis allows us to conclude that such a faint and large exponential component cannot be a dynamically supported disk. Therefore, we associate the light of the inner component with the bright cluster member NGC 1399 and the extended outer component with its stellar halo. The system *galaxy plus halo* has a total magnitude in the g band of 8.57 mag (see Section 3), so it has total luminosity $L \sim 2 \times 10^{11} L_\odot$. According to the M/L ratio at 192 kpc estimated above, we found that this system has a total mass $M \sim 7 \times 10^{12} M_\odot$.

Figure 13. Overview of the surface-density profiles of the blue and red GCs (blue and red circles), by Bassino et al. (2006), and X-ray (magenta asterisks), by Paolillo et al. (2002), compared with the surface brightness profile in the g band (black circles), as a function of the galactocentric radius for NGC 1399. The surface-density profiles are arbitrarily shifted in the ordinate scale. The dotted line indicates the “transition” region where the blue GCs and the X-ray density profile show a different slope with respect to the inner regions. The dashed line indicates the distance of 10 arcmin, where the contribution of the inner component and stellar halo to the light distribution is about 50% (see Section 3.5 for details).

4.3. What Is the Vision from Other Dynamical Tracers in the Halo Region?

The large-scale study of the GCs in NGC 1399 published by Dirsch et al. (2003) and Bassino et al. (2006) provides the color and spatial distribution up to the projected distance of 52 arcmin. They found that the blue GCs dominate in the outer regions, and their radial distributions show a slope change at $R \sim 7$ arcmin, while the red GCs have a single power-law profile on the entire range of radii (see Figure 13). The radial distribution of the red GCs follows the slope of the surface brightness out to the break radius, while the blue GCs do not seem to match the steep light profile for $R \geq R_{\text{break}}$, being shallower.

The X-ray halo of NGC 1399 extends out to about 90 kpc, and it is very asymmetric; Paolillo et al. (2002) noted the presence of several components: the “galactic” halo extends out to ~ 7 arcmin and is offset toward the west with respect to the optical galaxy centroid, while on larger scales the “cluster” halo is elongated in the opposite direction. The transition between the “galactic” and “cluster” X-ray density profile occurs at $R \sim 7$ arcmin, which is consistent with the value where the blue GC radial distribution starts to dominate over the red GC component, and it is a few arcminutes smaller than the break radius identified in the light distribution (see Figure 13).

As a conclusion of the cross-analysis with different tracers, we find that there is a “transition” region (very close in radius) where the light distribution, the blue GCs, and the X-ray density profile show a different slope with respect to the inner

regions (see Figure 13). In correspondence with this region, the kinematics of blue GCs is different from that of the red GCs, which is consistent with that of the stars in the inner regions, while the analysis of the X-ray-emitting gas supports the presence of different dynamical components. Moreover, as pointed out in Section 3, the two-dimensional density distributions of stars, blue GCs, and X-rays consistently show an asymmetry on the west side, toward the nearby early-type galaxy NGC 1387.

The above results confirm those derived by Hilker et al. (1999), who adopted a similar approach. By comparing the light distribution in NGC 1399, down to about 24 mag arcsec⁻² in the V band, with the surface density of GCs and X-ray and with the surface brightness of *dE/dS0* galaxies, they found that the profile slopes of the blue GC population, the X-rays, and the cD halo light are very similar in extension and slope. As suggested by Hilker et al. (1999), the agreement in the above properties might suggest that these components share a common history.

4.4. What Do Theoretical Studies on Halo Formation Predict for the Shape of the Light Profile?

According to Cooper et al. (2013), the *break radius* in the total stellar mass density sets the transition region in the galaxy halo between the stars formed in situ to those captured from accretion events. The shape of the light profile for $R \geq R_{\text{break}}$ could be indicative of which kind of accretion mechanism shaped the galaxy halo in the past. As discussed by Deason et al. (2013), when plotted in logarithmic scale, some outer light profiles are steeper, named as “broken,” in contrast to others that show an “excess of light” at large radii. The broken profiles are generally associated with short and more recent accretion, possibly unmixed as they trace the orbit of the accretion, while the shallower profiles could result from minor merging events taking place over long timescales, showing a larger degree of mixing. To produce such a broken profile, simulations found that the accreted material from satellites has similar apocenters or, alternatively, results from the accretion of a massive satellite (Deason et al. 2013). As investigated by Deason et al. (2013), the Milky Way also shows a broken profile of its stellar halo, and a break is detected at about 20–30 kpc from the center. On the other hand, no break is detected in the halo profile of M31. The kinematics can discriminate between the two cases because, if a massive satellite was accreted, the metal-rich population of the accreted stars shows a peak in the velocity dispersion at $R \geq R_{\text{break}}$.

In the case of NGC 1399, the light profile deviates from a smooth Sérsic profile, with $n \simeq 4$, for $R_{\text{break}} \geq 10$ arcmin, showing a steeper exponential profile with a scale length $r_h \simeq 4.8$ arcmin (~ 28 kpc; see right panel of Figure 3). Similar to NGC 1399, the BCGs studied by Seigar et al. (2007) also have a stellar halo with an exponential light profile. Different from NGC 1399, the light profile of M87 is shallower with increasing radius, and it was reasonably well fitted by either a single Sérsic law or a double $r^{1/4}$ (Janowiecki et al. 2010). As found by Bender et al. (2015a), the light distribution of the cD galaxy NGC 6166 in Abell 2199 is also well fitted by a single Sérsic law with a high value of the exponent ($n \sim 8$), so it appears shallower toward outer regions. According to the theoretical predictions, the differences in the halo profiles can reflect a different assembly history of this component in the BCGs. In NGC 1399, as discussed above, the regions after the

break radius are purely explored with any kinematical tracers. The only information is close to the break radius and indicates that a peak in the velocity dispersion is observed in the metal-poor blue GCs (Schuberth et al. 2008), but this is not enough to draw any conclusion on this point.

Therefore, based only on the new, deep photometry, we might address some points useful for the interpretation in the context of the stellar halo formation scenarios, which are not conclusive and need to be confirmed by a kinematical analysis.

First, one should take into account that the exponential stellar halo in NGC 1399 is the dominant component almost everywhere outside the $2R_e$, and it contributes about 60% of the total light. Thus, it might be reasonable to think that the material forming this component could be stripped by a massive satellite during a close passage around NGC 1399. Previous observational studies on NGC 1399 strongly suggest that the core of the Fornax cluster underwent merging events, which led to the accretion of the majority of blue GCs (Schuberth et al. 2010). If any kind of gravitational interaction happened in a recent epoch, we should find signs of it, in the form of tidal tails or streams, in the light distribution. Therefore, the frequency and the spatial distributions of such a features are strong constraints on the timescale and orbits of the accretion event, respectively.

Different from the Virgo cluster, the deep images of the core of the Fornax cluster do not reveal bright and extended structures of this type, except for the red tail detected at $R \sim 3$ arcmin and the faint streams toward NGC 1387 (see Section 3, Figure 7). This remains valid even considering that the Virgo cluster is about 3 Mpc closer, so the faint structure in the light distribution detected in the Fornax cluster would have an absolute magnitude only ~ 0.3 mag brighter. On the other hand, at the same faint level of surface brightness, around the giant bright galaxies M49, M86, and M87, several tidal tails are detected, some of them very extended, up to 100 kpc (Mišos et al. 2005; Janowiecki et al. 2010; Rudick et al. 2010; Capaccioli et al. 2015; Longobardi et al. 2015a). This observational fact might suggest that we are tracing two different epochs of the halo assembly in the two clusters: the Fornax cluster could be in a more dynamically evolved phase (Grillmair et al. 1994; Jordán et al. 2007), where most of the gravitational interactions between galaxies have already taken place and streams and tails are already dispersed into the intracluster medium or are below the observable surface brightness level.

4.5. Stellar Halo Mass Fraction in NGC 1399: Observations versus Theoretical Predictions

By fitting the light profile, we found that there exists a physical break radius in the total light distribution at $R = 10$ arcmin (~ 58 kpc) that sets the transition region between the bright central galaxy and the outer exponential halo, and that the stellar halo contributes 60% of the total light of the galaxy (Section 3.5).

In order to estimate the stellar mass fraction of the halo for NGC 1399, we need to account for the stellar mass-to-light ratio values for both the central galaxy and the halo. The color profiles shown in Figure 10 suggest that the stellar halo (for $R \geq 10$ arcmin) has $g - r$ color similar to that measured in the central galaxy, so we can assume a similar stellar M/L for both components. According to an average $g - r \sim 0.8$, from the stellar population synthesis model (Ricciardelli et al. 2012;

Figure 14. Stellar halo mass fraction vs. total stellar mass of the galaxy. The triangle indicates the value derived for NGC 1399, and the circles are for other BCGs from the literature (Seigar et al. 2007; Bender et al. 2015a). The dashed red region indicates the average predictions from theoretical models by Cooper et al. (2013). The blue region indicates the average predictions from the Illustris hydrodynamic simulations by Rodriguez et al. (2015).

Vazdekis et al. 2012) using a Kroupa IMF, $M/L \sim 4$. Therefore, the total stellar mass of the whole system, galaxy plus halo, is $M_{\text{tot}} \simeq 6.6 \times 10^{11} M_{\odot}$, while the stellar mass in the halo is $M_{\text{halo}} \simeq 4 \times 10^{11} M_{\odot}$. The stellar mass fraction is the same we found for the light, which is 0.58 ± 0.03 . As shown in Figure 14, this value is comparable with those derived for other BCGs with total stellar mass similar to NGC 1399, which varies from 0.47 to 0.9 for the galaxies in the sample studied by Seigar et al. (2007), and it is about 0.65 for the bright BCG NGC 6166 (Bender et al. 2015a).

The observed halo mass fractions for NGC 1399 and for other published data are compared with the predictions from numerical simulations by Cooper et al. (2013), for galaxies with a dark halo virial mass within the range $13 < \log M_{200}/M_{\odot} < 14$, and from the *Illustris* hydrodynamic cosmological simulations by Rodriguez et al. (2015). According to the dynamical models performed by Schuberth et al. (2010), the virial mass for NGC 1399 is in the range 5×10^{12} to $7 \times 10^{13} M_{\odot}$. On average, taking into account the uncertainties in the M/L estimate, the stellar mass fraction derived for the halo of NGC 1399 fully agrees with those predicted by the *Illustris* simulations, whereas it is at the lower limits of those by Cooper et al. (2013). The stellar mass fractions of the halos in the less luminous BCGs studied by Seigar et al. (2007) are more consistent with simulations, except for NGC 4874, where deviations could be due to a wrong estimate of the M/L ratio or of the halo stellar mass fraction. On the other hand, the brightest galaxy of the selected sample, NGC 6166, is far from the theoretical predictions: this could be due to unexplored regions in the simulations because Figure 12 in Cooper et al. (2013) shows that there are no values for a halo stellar mass larger than $10^{12} M_{\odot}$. We noticed that the region of the stellar halo mass fraction larger than 0.8 seems

devoid of observed stellar halos. The same effect seems to be also present in the same diagram obtained by Trujillo & Fliri (2015) (see Figure 12 of that paper), where the stellar mass fractions derived for less massive galaxies (in the range $12 < \log M_{200}/M_{\odot} < 12.5$) occupy the bottom half of the region given by the theoretical predictions. In both cases, this could be due to an incomplete sample. Anyway, this aspect needs to be further investigated on both the observational and theoretical sides.

Assuming that the stellar halo has been formed by accretion, then we find consistency with simulations. This means that 60% of the total light we measured in the core of the Fornax cluster for $R \leq 192$ kpc is formed via multiple accretion events. According to Cooper et al. (2013), the stellar mass of accreted satellites for halos of the most massive galaxies (i.e., $13 < \log M_{200}/M_{\odot} < 14$) varies in the range 10^8 – $10^{11} M_{\odot}$. While the lower limit of this interval is consistent with the typical mass for ultracompact dwarf galaxies (Chilingarian et al. 2011), the upper limit is that of a brighter and larger object. This might suggest that the halo of NGC 1399 has also gone through a major merging event. Given the absence of any tidal tail in the deep VST images, the epoch of this strong interaction goes back to an early formation epoch. For comparison, the total stellar mass of NGC 1387, which is interacting with NGC 1399 (see Section 4.1), is about $8 \times 10^{10} M_{\odot}$, assuming an M/L similar to that derived for NGC 1399, or even higher considering that NGC 1387 has on average redder colors than NGC 1399 (E. Iodice et al. in preparation).

The *Illustris* hydrodynamic cosmological simulations by Rodriguez et al. (2015) also predict a *transition radius* at which the halo component starts to dominate over the stars formed in situ. Such a radius is a function of the total mass of the galaxy, ranging from ~ 4 – 5 effective radii for medium-sized galaxies ($M_{\text{star}} \sim 10^{10}$ – $10^{11} M_{\odot}$) to a fraction of the effective radius for very massive galaxies ($M_{\text{star}} \sim 10^{12} M_{\odot}$). For NGC 1399, the total stellar mass is $M_{\text{tot}} \simeq 6.6 \times 10^{11} M_{\odot}$, and the break radius in terms of the effective radius of the light distribution is $R_{\text{break}} = 1.7R_e$ (see Section 3.2). Such a value is comparable with the predictions from *Illustris* simulations on the break radius, which vary from $\sim 0.2R_{\text{half}}$ for the most massive galaxies (stellar masses $\sim 10^{12} M_{\odot}$) to $\sim 3.5R_{\text{half}}$ for galaxies with stellar masses of $\sim 10^{11} M_{\odot}$.

4.6. Halo versus ICL

The presence of ICL in nearby clusters was established by several works in recent years (see Zibetti 2008 as review). As mentioned in Section 1, the extended stellar halo in BCGs and the intracluster stellar component overlap, so it is hard to separate each contribution by deep photometry alone. Surface photometry indicates that the ICL surface brightness is detected in the range between ~ 26 and ~ 32 mag arcsec $^{-2}$ in the r band, and it declines more steeply than the light profile of the galaxies in the cluster. The contribution of the ICL to the total light of most clusters is about 30% (Gonzalez et al. 2005; Zibetti et al. 2005). On average, this component is more elongated than the BCG, and the major axes of BCGs and the ICL are almost aligned ($\Delta\text{P.A.} \leq 10^\circ$), even if higher degrees of misalignment are also measured in some cases. The deep imaging of the Virgo cluster shows that, other than the numerous thin ICL streams, part of this component is in a more

diffuse form, locked in the extended halo around M87, traced up to 150 kpc (Mihos 2015).

For NGC 1399, the deep VST photometry allows us to map the surface brightness levels typical for the ICL contribution. The azimuthally averaged surface brightness profile derived in this work shows a steeper exponential decline for $\mu_g \geq 26.5 \text{ mag arcsec}^{-2}$ (i.e., $\mu_r \geq 25.65 \text{ mag arcsec}^{-2}$ since $g - r \sim 0.85$), and it reaches $\mu_g = 31.2 \text{ mag arcsec}^{-2}$ at $\sim 192 \text{ kpc}$ from the analysis (see Figure 3). As discussed in detail in the previous sections, this component is the stellar halo around NGC 1399, which is very extended and contributes to about 60% of the total light. We may suppose that part of this huge amount of light comes from the contribution of the ICL, which could vary from 10% to 30%, as was estimated in other clusters of galaxies (Gonzalez et al. 2005; Zibetti et al. 2005).

A hint for extra light is detected from the light profiles extracted at several P.A.s, in the regions between galaxies on the west side (see Section 3 and Figure 9), in the range of surface brightness of $27 \leq \mu_g \leq 28 \text{ mag arcsec}^{-2}$ and for $15 \leq R \leq 20 \text{ arcmin}$. At fainter levels of surface brightness, the stellar bridge between NGC 1399 and NGC 1387 is about $1\text{--}1.5 \text{ mag arcsec}^{-2}$ brighter than the average value of the diffuse component ($\mu_g \sim 31 \text{ mag arcsec}^{-2}$; see Figure 8). As found in other BCGs (Gonzalez et al. 2005; Zibetti et al. 2005), the ellipticity and P.A. profiles of the stellar envelope show that it is flatter with respect to the inner galaxy light, and both are misaligned by about 10° (see Figure 4).

However, photometry alone does not allow us to separate the gravitationally bound part of NGC 1399's very extended stellar halo from that of the ICL. There is a hint from the kinematics of the GCs for a higher velocity dispersion of the blue population at large radii of about 20 arcmin (Schuberth et al. 2010), but this point needs further confirmation with new data. Therefore, at this stage, no definitive conclusion can be drawn, and kinematical studies are crucial to disentangling the bound and unbound components in the stellar halo of NGC 1399.

5. SUMMARY

In conclusion, the most important and first results of the FDS with VST can be summarized as follows:

1. Deep photometry allowed us to detect the faint stellar counterpart of the blue GC stream in the intracluster region on the west side of NGC 1399 and toward NGC 1387. By analyzing the integrated colors of this feature, we claim that it could be explained by the ongoing interaction between the two galaxies, where the outer envelope of NGC 1387 on its east side is stripped away.
2. In the core of the Fornax cluster, a very extended envelope surrounding the luminous galaxy NGC 1399 is present. This component, which is well fitted by an exponential law, comprises 60% of the total integrated light out to 192 kpc, including the ICL fraction.
3. The surface brightness profile of NGC 1399 shows a physical break radius in the total light distribution at $R = 10 \text{ arcmin}$ ($\sim 58 \text{ kpc}$), that is, $1.7R_g$, that sets the transition region between the bright central galaxy and the stellar halo. Such a value is comparable with the predictions from *Illustris* simulations on the break radius for galaxies in the range of stellar masses $10^{11}\text{--}10^{12} M_\odot$.

4. Comparing with the numerical simulations of stellar halo formation for the most massive BCGs (i.e., $13 < \log M_{200}/M_\odot < 14$), we found that the observed stellar halo mass fraction is consistent with a halo formed through the multiple accretion of progenitors having stellar masses in the range $10^8\text{--}10^{11} M_\odot$. This might suggest that the halo of NGC 1399 has also been through a major merging event.
5. The absence of a significant number of luminous stellar streams and tidal tails between the galaxies in the core of the Fornax cluster suggests that the epoch of this strong interaction goes back to an early formation epoch. Thus, the extended stellar halo around NGC 1399 is characterized by a more diffuse and well-mixed component, including the ICL, with respect to that of M87 or M49 in the Virgo cluster (Mihos et al. 2005; Capaccioli et al. 2015). This is an indication that the Fornax cluster could be in a more dynamically evolved phase than the Virgo cluster.

This work is based on visitor mode observations taken at the ESO La Silla Paranal Observatory within the VST GTO Program ID 094.B-0496(A). The authors wish to thank the anonymous referee for his or her comments and suggestions that allowed us to greatly improve the paper. The authors wish to thank ESO for the financial contribution given for the visitor mode runs at the ESO La Silla Paranal Observatory. Enrichetta Iodice wishes to thank the ESO staff of the Paranal Observatory for their support during the observations at VST. EI is also very grateful to T. de Zeeuw, M. Arnaboldi, O. Gerhard, and I. Trujillo for the discussions and suggestions on the present work. Michele Cantiello acknowledges financial support from the project EXCALIBURS (PRIN INAF 2014, PI G. Clementini). Nicola R. Napolitano and M. Paolillo acknowledge the support of PRIN INAF 2014 ‘‘Fornax Cluster Imaging and Spectroscopic Deep Survey.’’
