Abstract

Continuous glucose monitoring (CGM) systems have great potential for real-time assessment of glycemic variation in patients with hepatic glycogen storage disease (GSD). However, detailed descriptions and in-depth analysis of CGM data from hepatic GSD patients during interventions are scarce. This is a retrospective in-depth analysis of CGM parameters, acquired in a continuous, real-time fashion describing glucose management in 15 individual GSD patients. CGM subsets are obtained both in-hospital and at home, upon nocturnal dietary intervention (n = 1), starch loads (n = 11) and treatment of GSD Ib patients with empagliflozin (n = 3). Descriptive CGM parameters, and parameters reflecting glycemic variation and glycemic control are considered useful CGM outcome parameters. Furthermore, the combination of first and second order derivatives, cumulative sum and Fourier analysis identified both subtle and sudden changes in glucose management; hence, aiding assessment of dietary and medical interventions. CGM data interpolation for nocturnal intervals reduced confounding by physical activity and diet. Based on these analyses, we conclude that in-depth CGM analysis can be a powerful tool to assess glucose management and optimize treatment in individual hepatic GSD patients.

1 | INTRODUCTION

Hepatic glycogen storage diseases (GSD) are rare inherited disorders of carbohydrate metabolism that can be classified according to the enzyme deficiency and organ distribution. An important biochemical hallmark of hepatic GSD is hypoglycemia, either with (GSD 0, III, IV, VI, IX, and XI) or without hyperketonemia (GSD Ia and Ib), that can lead to acute and chronic complications.^{1,2} A strict diet, self-management and self-monitoring of glucose homeostasis are the cornerstone of treatment and aim to maintain euglycemia and prevent secondary metabolic derangement.³

Traditionally, metabolic control during dietary treatment is monitored based on symptoms and signs, clinical parameters (weight, height, and liver size) and circulating biomarkers, such as glucose, ketones, lactate, triglycerides, total cholesterol, and uric acid,⁴⁻⁹ as well as urinary tetrasaccharide.¹⁰ Interpretation of these markers can be challenging due to heterogeneity between patients, and interference by medication, diet and time of sampling. Furthermore, in-hospital or out-patient evaluations of GSD patients are expensive, invasive, time, and labor intensive and not a good reflection of everyday life at home. The recent international priority setting partnership for patients with hepatic GSD emphasized the importance of improving minimally and non-invasive monitoring modalities of metabolic control.¹¹

Continuous glucose monitoring (CGM) and flash glucose monitoring (FGM) systems are novel techniques for real-time assessment of glucose management. Benefits of CGM include the generation of large quantities of data at home, to improve home site self-monitoring and self-management, and thereby patient empowerment.¹² CGM and FGM are recommended by several (inter)national guidelines¹³⁻¹⁷; depending on the country, their use is approved and reimbursed for (subgroups of) diabetes mellitus (DM) patients. CGM is a safe and effective monitoring modality in DM patients by improving glucose management and reducing HbA1c.¹⁸ For DM patients experiencing a high risk of hypoglycemia, real-time CGM can help to prevent hypoglycemia and contribute to improved quality of life.¹⁹ In addition, CGM has proven to be a valuable monitoring modality in dietary and medical intervention trials with DM patients.²⁰

CGM is increasingly recognized as a monitoring modality for hepatic GSD patients. Previous studies have shown that CGM can uncover asymptomatic (nocturnal) hypoglycemia and can be used for monitoring of glycemic variation in individual hepatic GSD patients.²¹⁻²⁴ There is good concordance between CGM and self-monitoring of blood glucose, which adds to the validity of the technique for home-site monitoring.²⁵ However, despite many safety issues related to fasting intolerance,¹ unfortunately, the costs for CGM are currently not generally reimbursed for hepatic GSD patients.

In-depth analysis of CGM datasets is rapidly emerging in the DM related literature²⁶⁻²⁸ and clinically meaningful CGM outcome parameters have been identified, such as time under range (TUR), time in range (TIR), and time above range (TAR).²⁹ These parameters have been included as person-centered outcomes for DM, as recently prioritized by a multidisciplinary panel of academics, healthcare professionals and patients.³⁰ Furthermore, in-depth data analysis methods such as Fourier analysis have been applied to assess glucose management in DM patients.²⁶

Previous GSD guideline publications have not included recommendation for CGM outcome parameters and, there is paucity of the literature describing in-depth CGM analysis for assessment of glucose management in individual GSD patients. We previously reported cumulative sum (CUSUM) analysis on lifelong triglyceride concentrations for assessing longitudinal metabolic control within individual GSD Ia patients.⁵² Here, we present a retrospective in-depth analysis of CGM parameters, obtained in a continuous, real-time fashion during different dietary and medical interventions, assessing glucose management in 15 individual GSD patients.

2 | METHODS

2.1 | Ethical approval

The Medical Ethical Committee of the University Medical Center Groningen (UMCG) confirmed that the Law on Medical Scientific Research involving Human Beings (WMO) did not apply to the current study (MEC 2019-119).

2.2 | Study design

This was a monocenter, retrospective, observational study of CGM data obtained in a real-time fashion in three subsets of hepatic GSD patients who underwent dietary and medical interventions at the UMCG, Groningen, the Netherlands.

2.3 | Subjects

Hepatic GSD patients at the UMCG received CGM to support GSD clinical and home evaluations and as safety measure during in-hospital dietary or medical interventions. The first CGM dataset was obtained from a single GSD Ia patient in whom multiple dietary interventions were performed, including exchanging nocturnal continuous gastric drip feeding (CGDF) for a nocturnal uncooked cornstarch (UCCS) regimen, both in-hospital and at home. The second CGM dataset was obtained from 11 GSD patients during in-hospital starch load tests that were part of the GLYDE trial (NCT02318966). In brief, this was a prospective, randomized, double-blind, crossover trial of Glycosade vs UCCS in which the first part consisted of two (blinded) 12-hour starch load tests. For the current study, we compared the CGM data obtained from UMCG patients during both starch loads; results on the GLYDE trial will be published elsewhere. The third CGM dataset was obtained from three GSD Ib patients during the in-hospital initiation and at home follow-up of the off-label treatment with empagliflozin for neutropenia and neutrophil dysfunction associated symptoms and signs.³¹

2.4 | Continuous glucose monitoring systems

The Dexcom CGM Systems are mostly applied in DM and they are approved for children of 2 years and older on the abdomen and lower back. The first and the third CGM subsets were obtained using Dexcom G6 (Dexcom, San Diego, California). The second CGM subset was obtained using Dexcom G4. Whereas both systems allow real-time CGM measurements, the Dexcom G6 additionally supports real-time online data sharing. Both Dexcom G4 and G6 have a relatively high accuracy of measurements in hypoglycemic range and sensitivity for detecting hypoglycemia in DM patients.^{32,33} Herbert and co-workers described a strong correlation between Dexcom G4 CGM values and standard capillary blood glucose measurements in patients with hepatic GSD, also in the range <3.9 mmol/L.²⁵

The CGM device consists of a wireless receiver, a transmitter and a sensor. The sensor is inserted in the

subcutaneous tissue in the interstitial space. The sensor coated with glucose oxidase reacts with glucose, producing an electrical current every 5 minutes (288 measurements per day). The blood glucose concentration is derived from the subcutaneous glucose concentration with computer-driven algorithms, where after the measurement is transmitted to the wireless receiver. For Dexcom G4, the sensor requires calibration twice a day by capillary glucose measurement, whereas Dexcom G6 is factory calibrated.

2.5 | Outcome parameters and data analysis

From the medical files, additional baseline and demographic patient information was collected on GSD type, mutation, gender, age, type of dietary treatment before and after intervention, medication, and parameters of metabolic control.

The raw data files were retrieved from the Dexcom CLARITY Clinical Portal (<https://clarity.dexcom.eu/professional/patients>) and stored anonymously as CSV-files before analysis.^{34,35} The Dexcom CGM System is validated for glucose concentrations above 2.2 mmol/L (>40 mg/dL). If the CGM sensor indicated a low value, the lowest possible CGM value of 2.2 mmol/L was used, since omitting these values would bias the descriptive statistics.

Statistical analysis was performed using IBM SPSS Statistics 23. In the second CGM dataset, group differences were calculated by paired *t*-test. *P*-values lower than .05 were considered significant (two-tailed).

Primary outcomes from the CGM dataset included descriptive outcomes (median, minimum, maximum, range), outcomes of glycemic variation (SD, variance, coefficient of variation [CV, calculated as SD divided by the mean]) and outcomes of glycemic control such as TUR as glucose ≥ 3.0 mmol/L and < 3.9 mmol/L (ie, level 1 hypoglycemia), as glucose < 3.0 mmol/L (ie, level 2 hypoglycemia) and as level 3 hypoglycemia (ie, a severe event characterized by altered mental and/or physical status requiring assistance), TIR as either more physiological CGM values ≥ 3.9 and ≤ 7.8 mmol/L or ≥ 3.9 and ≤ 10.0 mmol/L, and TAR as either CGM values > 7.8 mmol/L or CGM values > 10.0 mmol/L, defined according to the American Diabetes Association 2020.¹⁵ We assumed that diurnal variations of the actual diet and physical activity are confounding factors of glucose homeostasis. To correct for these factors, the CGM values between 1:00 and 5:00 AM. were analyzed separately for subsets I and III.

Secondary outcomes included the following:

1. CGM glucose concentrations directly derived from the Dexcom CLARITY Clinical Portal.
2. Descriptive statistics of glucose concentrations of the interval between 1:00 and 5:00 AM.
3. The first order derivative (change over time) calculated as $glucose' = \frac{dglucose}{dt}$.
4. The second order derivative (speed of change over time) calculated as $glucose'' = \frac{d^2glucose}{dt^2}$.
5. To display subtle variations for repeated measurements, CUSUM graphs were constructed of the time interval 1:00-5:00 PM. based on two methodologies. Method A has been described previously⁵², and the CUSUM for serial measurements was calculated as $CUSUM_t = \sum_{i=1}^t glucose_i - mean\ glucose_i$. Method B corrected for first and second order derivatives, and the CUSUM was calculated as $CUSUM_t = \sum_{i=1}^t glucose_{calculated}_i - glucose_i$, where $glucose_{calculated}$ was determined using a hypercube regression analysis based on the average numerical dataset per individual patient that correlated absolute glucose values to first and second order derivatives.
6. Fourier analysis is a technique to visualize complex (homeostasis) patterns of CGM data and was performed as described previously²⁷ by mathematically transforming the CGM data with a Fast Fourier Transformation (FFT) and expressing the data as one or

more sinusoidal curves. The amplitude is calculated as a representation of the phase of the CGM signal as $Amplitude = 2 * abs(\frac{FFT_Result}{n})$. From the mathematical transformation, a spectrogram is constructed that identifies three outcome parameters that have implications for glucose management: the frequency (the number of cycles per night), the number of frequencies (a glucose pattern can consist of one frequency or multiple patterns) and the amplitude of each identified frequencies. Good glucose management is characterized by a low frequency, a low number of frequencies and a small amplitude.

3 | RESULTS

Table 1 presents the general characteristics of the 15 included hepatic GSD patients (3 GSD Ia, 3 GSD Ib, 4 GSD IIIa, 3 GSD IX α , 2 GSD IX). We analyzed CGM data from 11 male and four female patients, ages ranged from 2 to 22 years.

3.1 | CGM subset I: nocturnal dietary interventions

This nine-year-old male GSD Ia patient was referred to our clinic for GSD evaluation. He suffered from recurrent hypoglycemia on his former dietary regimen and UCCS

FIGURE 1 CGM subset I from the Dexcom Clarity Clinical Portal of the in-hospital evaluation of P-I-1. The 5 days of in-patient evaluation of P-I-1. Day 1 the current treatment of *Nutridrink Juicy Style* was evaluated. Days 2 and 3 the Maltodextrin (metaX—Institut für Diätetik GmbH) intervention is evaluated. Days 4 and 5 the UCCS intervention was evaluated. P, patient; UCCS, uncooked cornstarch

intolerability was reported, leading to diarrhea. He was treated with daytime frequent feeds with either a meal or nasogastric tube feed based on short-acting carbohydrates (*Frebini* original fiber). During daytime, he used 25 g of UCCS every 3 hours. At night, he received CGDF (*Nutridrink Juicy Style* of 47 kcal/hour, 10.4 g/hour or 4.6 mg/kg/minutes of carbohydrates), whereas without GSD, his calculated, predicted endogenous glucose production (EGP) would approximate 4.2 mg/kg/minutes and 3.7 mg/kg/minutes at his current weight of 37.4 kg³⁶ and age,³⁷ respectively. Metabolic control was summarized by his biometry (BMI: +3.8 SDs; Weight-for-height + 5.2 SDs), high serum triglyceride (9.4 mmol/L) and total cholesterol (6.9 mmol/L) concentrations, and severe hepatomegaly assessed by abdominal ultrasound (26 cm maximal craniocaudal distance; normal range 9 to 11 years: 7.5 to 13.5 cm³⁸). After several attempts to monitor and adjust dietary treatment at home including reducing nocturnal CGDF, it was decided to perform an in-patient evaluation because of persisting hypoglycemia and excessive weight gain.

Figure 1 illustrates the Dexcom graphs, directly exported from the Dexcom CLARITY Clinical Portal, presenting the CGM data obtained during the in-hospital evaluation. Table 2 presents the CGM data analysis per intervention. After baseline assessment of the existing dietary regimen on the first day (and night) of in-hospital stay, caloric intake was restricted during the second and third night by changing to a MaltoCal 6 solution (metaX—Institut für Diätetik GmbH; 34.6 kcal/hour,

8.6 g/hour, 3.9 mg/kg/minutes of carbohydrates). Despite the reduction in carbohydrate intake after introduction of MaltoCal 6, a strong decrease of TUR could already be observed. During the fourth night, instead of nocturnal CGDF, an UCCS regimen was introduced of 45 g at 20:00, 0:00 and 4:00 (40 kcal/hour, 9.9 g/h, 4.4 mg/kg/minutes). The nocturnal UCCS regimen (days 4 and 5) stabilized CGM profiles and further reduced the amount of TUR. The variables of glycemic variation (variance, SD, and CV) also strongly decreased, presumably indicating episodes of hyperinsulinism. After a week at home, the nocturnal UCCS doses were lowered to 40 g (35 kcal/hour, 8.8 g carbohydrates/hour, 3.9 mg glucose/minutes/kg).

After 9 months of follow-up, during an outpatient visit, improvements were observed in biometry (BMI: +2.4 SDs; weight-for-height + 3.7 SDs), hyperlipidemia (serum triglyceride 5.4 mmol/L; total cholesterol 6.0 mmol/L) and hepatomegaly (19 cm craniocaudal distance). Evaluation of 13 days of home-site CGM data showed a low percentage of time spent in hypoglycemia, with limited variance and SD of the data (Table 2).

3.2 | CGM subset II: starch loads

In Table 3, the grouped results of the starch load tests with either UCCS or Glycosade are presented. In general, the Glycosade starch loads showed lower maximum glucose concentrations and which occurred later with a

Note: The first intervention included baseline measurements. * UCCS was given at 20:00, 0:00 and 4:00. ** Follow-up was performed 9 months after the initial visit and the CGM data was collected in an outpatient setting.

Abbreviations: CI, confidence interval; CV, coefficient of variation; Max, maximum; Min, minimum; TAR, time above range; TIR, time in range; TUR, time under range; UCCS, uncooked cornstarch; Var, variance; %, percent; #, number of measurements; <, below; >, above.

TABLE 3 CGM subset II of uncooked cornstarch and glycosade starch loads per group

Starch load	Median (mmol/L)	Min (mmol/L)	Max (mmol/L)	Range (mmol/L)	SD (mmol/L)	Var (mmol ² /L ²)	CV (%)	Initial glucose value (mmol/L)	Time to max (min)	End time (min)	Slope 0 to max (mmol/L/h)	Slope max to end (mmol/L/h)	AUC (mmol*h)
UCCS	4.9	3.3	8.8	5.5	1.3	1.8	25.1	4.6	69	576	4.8	-0.6	49
Glycosade	4.9	3.7	7.9	4.3	1.0	1.1	19.9	5.1	80	584	3.0	-0.5	51
P-value	0.859	0.321	0.038	0.036	0.107	0.190	0.177	0.298	0.369	0.757	0.008	0.099	0.895

Note: In the crossover design, patients were randomized to either UCCS or Glycosade starch loads first. *A P-value <.05 is considered significant. Values per starch load are calculated as means of all patients. The Glycosade intervention of P-II-2 and P-II-3 was excluded in group analyses due to incomplete CGM data.

Abbreviations: AUC, area under the curve; cm, centimeter; CV, coefficient of variation; F, female; kg, kilogram; Max, maximum; min, minutes; Min, minimum; M, male; P, patient; UCCS, uncooked cornstarch; Var, variance; y, years; #, number of measurements.

smaller range as compared to the UCCS starch loads. Additionally, the initial, increasing slope of the graph from the start to the maximum glucose concentration was less steep with the Glycosade starch load suggesting a more gradual intestinal glucose absorption. There is a trend toward smaller glycemic variation in response to the Glycosade starch load. Table 4 presents the CGM data from individual GSD patients, in response to different products, which may depend on different factors, such as GSD subtype, age, and gender.

3.3 | CGM subset III: empagliflozin in GSD Ib patients

Figure 2 illustrates the in-depth CGM data analysis of three GSD Ib patients treated with empagliflozin. In these patients, CGM is mainly used for safety reasons to detect possible hypoglycemia as a potential side effect of empagliflozin-induced glucosuria. The case history of P-III-1 was reported elsewhere.³¹ Table 5 presents details of descriptive data per intervention. Although glucose concentrations remained <4.0 mmol/L for a longer period of time in all three patients after initiation of empagliflozin, no symptoms of hypoglycemia are reported.

For P-III-1, the CGM concentrations during the day were more stable after start of empagliflozin (intervention 1), but variability initially increased during the night as indicated by the higher first and second order derivative and a decrease in the CUSUM (Figure 2A). Furthermore, the Fourier analysis showed an increase in the number of frequencies, indicating a less stable glucose pattern. Fecal calprotectin increased from 190 (day 4) to 750 mg/kg (day 10) upon empagliflozin treatment reflecting improved neutrophil function. After a few days of treatment, CGM values increased after which the empagliflozin dose was doubled. Paradoxically, the CUSUM increased steadily after the increase in dose in parallel to decreasing fecal calprotectin (255 mg/kg; day 19) and clinically, more solid and less frequent stools were observed. Additionally, Fourier analysis showed a decrease in the number of frequencies, indicating a more stable glucose pattern. Together, these results suggest improved gastro-intestinal absorption as a result of empagliflozin treatment. After the initiation nocturnal UCCS treatment instead of CGDF (intervention 3), there was less variation in absolute glucose concentrations and the first and second order derivatives were smaller. Additionally, the Fourier analysis illustrated a strong and sudden decrease in frequency (number of cycles per night) and the amplitude. In parallel, fecal calprotectin values normalized (55 mg/kg

on day 33). After lowering the dose of granulocyte colony-stimulating factor (day 33), the variation of CGM data decreased even further.

For P-III-2, a week after initiation of empagliflozin treatment, the CGM values and defecation pattern improved. UCCS was introduced (intervention 2), reducing the amount of CGDF during the day and night.

Afterwards, the CGM values increased further and the first and second order derivatives decreased (Figure 2B). In parallel, the Fourier analysis showed that the frequency of the CGM data decreased, indicating less glycaemic variability during the night. The stepwise increase in empagliflozin dose (interventions 3, 4, and 5) was paralleled by higher nocturnal CGM values. Interestingly,

^aUnit = mmol/L.

^bSecond dose of Empagliflozin given at 20:00 instead of 16:00.

^cPart of the CGM data was acquired in a home-setting.

Fourier analysis identified several clinically relevant moments. At day 12, the patient experienced a relative hypoglycemia (3.4 mmol/L) accompanied by diarrhea after which an additional feed was given. Fourier analysis registered the event with an increased amplitude. On days 28-30, the parents of the patient tried different new snacks, and glucose concentrations were relatively low (3.7 mmol/L) with multiple frequencies indicating less stable glucose homeostasis. The Fourier analysis revealed

an increase of the number of frequencies and a higher amplitude. From the additional follow-up data from home, the CGM values remained stable and the CUSUM increased further.

For P-III-3, empagliflozin was titrated over a period of 7 days. After initiation of empagliflozin (intervention 1), the absolute CGM values increased, as also illustrated by a rise in the CUSUM. After the increase of the empagliflozin dose (intervention 2), the CGM values did

not change significantly and fecal calprotectin levels remained low (<40 mg/kg feces).

4 | DISCUSSION

This is the first study that employs in-depth CGM dataset analysis to evaluate these outcome parameters for glucose management in hepatic GSD patients during different dietary and medical interventions. The combination of first and second order derivatives, CUSUM analysis and Fourier analysis (the frequency, number of frequencies, and amplitude of each frequency) identified both subtle and sudden changes in glucose homeostasis that cannot be easily detected alone when focusing on pre-prandial glucose concentrations or measuring at symptomatic hypoglycemia. Additionally, data interpolation of nocturnal intervals provides a useful strategy to limit confounding of glucose homeostasis by physical activity and diet.

The first case description illustrates how CGM data can be interpreted in a case-oriented fashion together with clinical domain knowledge, such as traditional parameters of metabolic control. The nocturnal dietary intervention with UCCS reduced time spent in hypoglycemia and glycemic variation for this GSD Ia patient. In DM types I and II, these parameters associate with risk of severe hypoglycaemia.^{39,40} Although glycemic variation appears to be smaller in hepatic GSD patients than in DM type 1 patients, fasting intolerance and risk of hypoglycemia are nevertheless strong arguments to limit glycemic variation by dietary interventions.⁴¹

The second CGM subset demonstrates that Glycosade may lead to less glycemic variation compared to UCCS (Table 3). However, as there is large heterogeneity in ages and GSD subtypes of these individual patients, the cumulative data should be carefully evaluated, emphasizing the importance to analyze the data in a case-oriented, personalized manner (Table 4). This is also displayed in the third CGM subset, in which, after an initial period of lower CGM concentrations, glycemic variation decreases with possibly better uptake of dietary macronutrients and UCCS by improved gastro-intestinal absorption after empagliflozin.

Several limitations of this study need to be addressed. First, there is as of yet no reference CGM data for GSD patients and no comparison with healthy subjects has been made. Therefore, in clinical practice and in our study, patients serve as their own control. Prospective and validation studies are warranted to determine reference values for CGM outcome parameters and to correct for intra-patient comparisons. Second, the retrospective study design introduced information and selection bias. Third, it is currently unknown how many measurements

are minimally required to obtain a reliable profile of glucose management in hepatic GSD patients. In DM patients, it has been recommended to collect 14-day CGM data to adequately predict glycemic variability over a three-month period.^{42,43} Advanced CGM systems may allow for glucose concentration measurements with higher frequency (ie, one reported measurement per minute), thereby accelerating adequate prediction of glycemic variability. Fourth, it should be mentioned that glucose management as assessed with CGM should be balanced against psychosocial well-being and quality of life.⁴⁴⁻⁴⁶ Fifth, there are several limitations to the use of CGM technology and the interpretation of interstitial fluid glucose levels. There is a delay of 10 to 15 minutes in both diffusion from capillary blood into interstitial fluid and the sensor as well as sensor signal processing time.⁴⁷ The combination of measurement errors and physiological differences between these compartments affects CGM accuracy. Finally, the amount of subcutaneous fat impacts the accuracy of CGM, which is especially important in infants and patients with increased BMI. Therefore, to limit variability of CGM sensor location on data interpretation we advise to place the CGM sensor in the same location on either upper arm or abdomen in each individual patient.

In DM, the potential of machine learning approaches for detection of glucose abnormalities, prediction of glucose concentrations, clinical decision making, and patient education is increasingly recognized.⁴⁸ Real-time machine learning of CGM data in DM accurately predicts glycemic fluctuations 1 hour in advance.⁴⁹ In theory, accumulation of big personal health data from physiological monitoring wearables offers opportunities for augmented intelligence and machine learning to improve patient self-management and remote monitoring by healthcare providers.⁴⁸ Supervised CGM machine learning algorithms with CUSUM and Fourier data analysis may allow for prediction of glycemic variation and outcomes in GSD patients, detecting conditions such as dietary undertreatment, overtreatment, nocturnal hypoglycemia and inflammatory bowel disease (IBD) exacerbations in GSD Ib patients. Current limiting factors include the lack of interoperability and data exchange between CGM software, hospital electronic health records, and personal digital health environment systems, to integration of multiple datasets, such as CGM data, dietary information, symptoms and signs, clinical parameters (weight, height, and liver size) and biomarkers.

The in-depth analysis of CGM data described in this study is crucial for future application of CGM systems as clinical trials with novel medical (gene therapy and mRNA therapy) and dietary treatments for GSD patients are emerging rapidly. For mRNA therapy in hepatic inborn errors of metabolism, the route of administration is

by multiple intravenous injections.⁵⁰ For adeno-associated virus vector-mediated gene therapy, the duration of efficacy after a one-time infusion is currently under clinical investigation. Corticosteroids are often used to manage presumed capsid-triggered immune response but are also known to interfere with glucose homeostasis. To date, blood glucose levels (NCT03665636), invasive, in vivo starch load tests (NCT02318966) and controlled fasting challenges (NCT03517085) are considered relevant outcome parameters in clinical trials for GSD patients. The insights from the current study emphasize that CGM can be used as minimally invasive outcome parameter to assess safety and efficacy during intervention trials in GSD patients.

In conclusion, this study demonstrates the potential of in-depth CGM data analysis for hepatic GSD patients during both dietary and medical interventions. Most CGM outcome parameters can be easily calculated from the raw export data from the CGM software system and can be used by any healthcare professional. CGM should be co-interpreted with clinical domain knowledge, such as symptoms and signs, information on dietary intake and markers of metabolic control, to monitor dietary and medical interventions. The authors summarized recommended indication for CGM monitoring and CGM outcome parameters in Table 6.

ACKNOWLEDGMENTS

We would like to acknowledge Shanlin Tong and Willemijn F. Boonstra for their respective TTT-project and Pilot Project for the University Medical Center Groningen Junior Scientific Masterclass; Tom de Wit of energQ for his help with the CGM analyses; Boelo G.F.D. Boelens and H.H. van der Wal, MD for their perspectives and critical review of the manuscript. The University Medical Center Groningen Junior Scientific Masterclass granted an MD/PhD project to Fabian Peeks and Terry Derks (MD-PhD 16-24).

CONFLICT OF INTEREST

The authors declare no potential conflict of interest.

AUTHOR CONTRIBUTIONS

All authors substantially contributed to the work and were involved in (a) conception and design of the study and/or analysis and interpretation of data, and (b) revising the article critically for important intellectual content. All authors approved the final manuscript as submitted and agree to be accountable for all aspects of the work. All authors confirm the absence of previous similar or simultaneous publications. Fabian Peeks collected and analyzed the data, wrote the first version of the manuscript, drafted and wrote the final version of the

manuscript. Terry G. J. Derks initiated this study, wrote the first version of the manuscript, drafted, and critically reviewed the later versions of the manuscript.
