ABSTRACT

Objective To assess a broad range of factors associated with pre-pregnancy nutritional status, a key step towards improving maternal and child health outcomes, in Ethiopia.

Design A baseline data analysis of a population-based prospective study.

Setting Kilite-Awlaelo Health and Demographic Surveillance Site, eastern zone of Tigray regional state, northern Ethiopia.

Participants We used weight measurements of all 17 500 women of reproductive age living in the surveillance site between August 2017 and October 2017 as a baseline. Subsequently, 991 women who became pregnant were included consecutively at an average of 14.8 weeks (SD: 1.9 weeks) of gestation between February 2018 and September 2018. Eligible women were married, aged 18 years or older, with a pre-pregnancy weight measurement performed, and a gestational age ≤ 20 weeks at inclusion.

Outcome measures The outcome measure was pre-pregnancy nutritional status assessed by body mass index (BMI) and mid-upper arm circumference (MUAC). Undernutrition was defined as BMI of $< 18.5 \text{ kg/m}^2$ and/or MUAC of $< 21.0 \text{ cm}$. BMI was calculated using weight measured before pregnancy, and MUAC was measured at inclusion. Linear and spline regressions were used to identify factors associated with pre-pregnancy nutritional status as a continuous and Poisson regression with pre-pregnancy undernutrition as a dichotomous variable.

Results The mean pre-pregnancy BMI and MUAC were 19.7 kg/m^2 (SD: 2.0 kg/m^2) and 22.6 cm (SD: 1.9 cm), respectively. Overall, the prevalence of pre-pregnancy undernutrition was 36.2% based on BMI and/or MUAC. Lower age, not being from a model household, lower values of women empowerment score, food insecurity, lower dietary diversity, regular fasting and low agrobiodiversity showed significant associations with lower BMI and/or MUAC.

Conclusion The prevalence of pre-pregnancy undernutrition in our study population was very high. The pre-pregnancy nutritional status could be improved by advancing community awareness on dietary practice and gender equality, empowering females, raising agricultural productivity and strengthening health extension. Such changes require the coordinated efforts of concerned

Strengths and limitations of this study

- One of the strengths is measuring weight in a distinct period before starting the inclusion of women.
- Including a relatively large sample of women and collecting information on many possible confounders can be considered strengths.
- As for limitations, mid-upper arm circumference (MUAC) was measured at inclusion, unlike body mass index, but as MUAC is insensitive to change over time, it can safely represent the pre-pregnancy status.
- Finally, seasonal variation was not considered in dietary diversity measurements.

governmental bodies and religious leaders in the Ethiopian setting.

INTRODUCTION

Undernutrition continues to be a public health problem in developing countries.¹ For women, undernutrition not only directly affects their current health, but it can also lead to additional health problems when they get pregnant. Maternal undernutrition is related to pregnancy complications like anaemia and hypertension, and also to adverse birth outcomes such as low birth weight and preterm birth.²⁻⁷ These adverse outcomes, in turn, are related to short-term and long-term adverse health outcomes of the mothers and their offspring.^{1 8-11} Clearly, pre-pregnancy undernutrition, defined as low body mass index (BMI) of $< 18.5 \text{ kg/m}^2$ and/or mid-upper arm circumference (MUAC) of $< 21 \text{ cm}$, contributes to the vicious cycle of transgenerational malnutrition and its subsequent effects.^{1 11}

Pre-pregnancy undernutrition is widespread in developing countries.¹²⁻¹⁵ According to a recent review, nearly 32% of pregnant women were undernourished

(MUAC: <21 cm) in Africa.¹⁶ Since MUAC is relatively insensitive to short-term change, this could also reflect pre-pregnancy nutritional status.^{17,18} In Ethiopia, the prevalence of undernutrition among non-pregnant women of reproductive age was 22% in 2016.¹⁴ The problem may be even more profound in Tigray, a region in northern Ethiopia repeatedly hit by drought and war.^{14,19} According to a study among non-pregnant women of reproductive age in the Kunama population, a minority group in Tigray, the prevalence of undernutrition was about 48%.¹⁹ These studies support the significant importance for public health of pre-pregnancy undernutrition and indicate substantial regional variation in developing countries like Ethiopia.

Factors that may influence pre-pregnancy nutritional status include socioeconomic,^{13,19–22} reproductive and obstetric conditions, food and dietary habits,^{19,23,24} and psychosocial characteristics. Few studies have investigated the factors associated with pre-pregnancy nutritional status in low-income countries like Ethiopia in detail.^{19,22} The previous studies also did not control potential confounders like implementing a health extension package, fasting, agrobiodiversity and psychosocial characteristics.^{25–27} Likewise, the role of women's empowerment, the process by which women who have been denied the ability to make strategic life choices acquire such an ability, expressed by their economic, socio-familial and legal empowerment, did not get attention yet.²⁸

Furthermore, other studies focused on specific population subgroups only, such as urban residents who may not represent the large majority of the population living in rural conditions²² or population groups with different socioeconomic and cultural characteristics.¹⁹ Knowledge about factors associated with pre-pregnancy nutritional status among women of reproductive age, the target population for interventions to achieve improvement, is, therefore, limited in countries like Ethiopia. The present study aimed to assess a wide range of factors associated with pre-pregnancy nutritional status, a key step towards identifying possible targets for intervention and support to improve maternal and child health outcomes in rural and urban areas of northern Ethiopia.

METHODS

Study design, setting and population

The present study, a baseline analysis of an ongoing population-based prospective study, the KIllite-Awlaelo Tigray Ethiopia (KITE) cohort, was conducted in KIllite-Awlaelo Health and Demographic Surveillance Site (KA-HDSS) between February 2018 and September 2018. The KITE cohort was designed to assess maternal nutrition prior to and during pregnancy, adverse birth outcomes and child growth. KA-HDSS is located in the eastern zone of the Tigray region of northern Ethiopia. The surveillance site consists of 10 rural and 3 urban kebeles (the smallest administrative units) spread across three districts: KIllite-Awlaelo, Wukro and Atsbi-Wonberta. Climatic conditions,

rural–urban composition, altitude and disease burden were considered in selecting the kebeles to represent the population of the Tigray region.

The total population of the KA-HDSS is 113 760. With 24% of the population being women of reproductive age, about 4550 pregnancies are expected per year within the KA-HDSS. Most of the population lives in rural settings, and agriculture is the primary source of income. Ethiopia has a three-tier healthcare system with health posts at the forefront of primary care. Each kebele has one health post staffed by two to three health extension workers (HEWs). Health posts provide promotional and preventive services under the umbrella of the 'health extension package' mainly at a household level. The health extension package consists of 16 components, including maternal health, family planning, nutrition and sanitation.²⁵

Pregnant women living in the study area, whose expected date of delivery lay before the end of January 2019, were the study population. Married women, aged 18 years or older, whose pre-pregnancy weight was measured and who completed ≤ 20 weeks of gestation, were eligible to be included in the study. The sample size was calculated to address the objectives of the KITE cohort. The critical assumption included a 5% α level (two-sided) and 80% power to find a difference of 24.6% low birth weight among women with MUAC of ≥ 23.0 cm versus 32.6% among women with MUAC of < 23.0 cm.⁷ Taking an estimated 10% dropout rate into account, the total sample size was calculated at 1100. With this sample size, effect sizes > 0.2 SD for continuous outcomes could also be detected.

Different methods were applied to identify pregnant women, including a community-based survey by HEWs through the 'Women Development Army', a network of health information workers reaching individual households around the health posts. The records of the nearby antenatal clinics and the KA-HDSS database were also used. In addition, we identified pregnant women through two ongoing projects in Ethiopia. The first project concerns a Productive Safety Net Programme that is being implemented, aiming to improve food security through the participation of households in community asset building projects and earn a wage either in cash or in-kind. Also, households are expected to participate in soil and water conservation activities at least 20 days per year for free. In both cases, pregnant women are exempted on reporting their pregnancy status to the HEWs, allowing us to identify them for participation.

Furthermore, a campaign offering trachoma treatment was taking place during the data collection period. As the treatment is contraindicated in the first trimester of pregnancy, women had to report their pregnancy status to HEWs. The opportunity was, therefore, used to identify pregnant women. All eligible pregnant women identified during the study period through any of the methods mentioned above were visited at their homes, invited for the study and included consecutively.

Measurements

The pre-pregnancy weight of women of reproductive age (N=17 500) living in the study area was measured between August 2017 and October 2017 using a Seca scale to the nearest 100 g at a community level in collaboration with the district health and KA-DHSS offices. Subsequently, the identification and inclusion of pregnant women took place. At inclusion, data were collected by interviewer-administered questionnaire, anthropometric measurements as per standard techniques²⁹ and extracting data available in the KA-DHSS database. The questionnaire was adapted from the literature^{7 14 30–34} and pretested on 55 pregnant women selected based on their accessibility in Tahtay-Maychew, central zone, Tigray region. Data including the pre-pregnancy weight were collected by qualified HEWs, and the data collection included the following.

Socioeconomic variables

Age in complete years, residence (urban or rural), religion (Orthodox, Catholic, Muslim or others), educational status (no formal education, primary education or secondary education and above), occupation (farmer, housewife, employed or others), husband educational status (no formal education, primary education or secondary education and above), husband occupation (farmer, employed, daily labourer or others), family size, that is, the number of people living in the same household, and wealth index were extracted from the KA-DHSS database. The surveillance site updates the database every 6 months except for wealth index. The last update for wealth index was done in 2015 in most of the kebeles and in 2017 in two kebeles that were included into the surveillance site recently. Therefore, adjustment was made at inclusion when there was a change since the last update.

Wealth index was assessed by asking about housing characteristics, access to improved drinking water and sanitation facilities, and ownership of household assets, land and livestock. First, the dichotomised socioeconomic proxy indicator variables were standardised using principal component analysis, and factor coefficient scores were created. Then, the indicator values were multiplied by the factor scores and summed to produce a standardised wealth index value. Finally, using the factor scores with the largest proportion of the variance, the wealth index was categorised into quintiles designating the lowest to the highest economic status.³⁵ Access to improved drinking water sources refers to access to piped water on-premises, public taps or standpipes, tube wells or boreholes, protected dug wells, protected springs and/or rainwater collection. Similarly, access to an improved sanitation facility is defined as access to an unshared toilet facility, pit latrine with a slab, ventilated improved pit latrine or flush toilet.³⁶

Furthermore, time to fetch water was collected at inclusion by asking, 'What is the time needed to fetch improved drinking water from the nearest source in minutes?'. Then, it was dichotomised at a cut-off point of

30 with the time needed not exceeding 30 min showing better service.³⁶ Likewise, access to health service was measured at inclusion by asking the time needed to go to the nearest health facility and back home, with ≤ 1 hour indicating better access. Also, implementation of the health extension package was assessed by checking if the women's households were certified as model households or not at inclusion. A model household was defined as a household that received short-term training on the health extension package as described above and subsequently implemented the package.^{25–27} Moreover, history of pre-pregnancy illnesses were recorded at inclusion.

To assess work burden, women were asked to rate their work as easy, moderate or difficult at inclusion. Moreover, physical activity data were obtained at inclusion using the International Physical Activity Questionnaire short form,^{34 37} by asking women about the kinds of physical activities—vigorous, moderate and walking—they did in the preceding week. Also, they were probed for how many days and how long per day they did each activity. Then, the data were summarised as low, moderate or high physical activity using the algorithm described in the scoring protocol.³⁷

Reproductive and obstetric conditions

Gestational age at inclusion was estimated from self-reported last menstrual period, fundal palpation and/or ultrasound. The latter two were extracted from antenatal records. Gravidity, that is, the number of previous pregnancies, parity, history of abortion, and stillbirth were extracted from the KA-DHSS database. Also, age at first marriage, age at first birth, previous inter-birth spacing in months, history of preterm birth, delivery by Caesarean section and severe perinatal haemorrhage were collected by interview at inclusion. Based on this information, a history of adverse pregnancy outcomes was defined as having experienced one or more of the following: abortion, stillbirth, preterm birth, severe perinatal haemorrhage or delivery by Caesarean section. Furthermore, self-reported information on intimate partner violence was obtained using the four-item Hurt, Insult, Threaten and Scream Questionnaire at inclusion. Each question was rated from 1 to 5, and a total score of >10 was used as a cut-off for the presence of violence.³⁸

To assess women empowerment, participants were asked nine questions addressing five domains at inclusion: (1) earning and control over income (relative income to husband, control over men's income and control over women's income); (2) decision-making on household purchases; (3) mobility and healthcare autonomy (decision-making on family visits and women's health); (4) attitude towards domestic violence and (5) ownership of assets (farmland and house).^{14 23 39} By coding each positive response as 1 and adding the responses, a women empowerment score ranging from 0 to 9 was obtained. Also, assigning each domain an equal weight (1) to be shared by the indicators within the respective

domains, women who scored $\geq 80\%$ or at least 4 out of 5 were considered as empowered.⁴⁰

Food and diet

Self-reported agrobiodiversity, harvest volume, food insecurity, dietary diversity, number of meals per day, fasting and frequencies of vegetables, fruits, animal-source food, alcohol and coffee intake were obtained at inclusion. Fasting is abstaining from animal-source foods such as meat, dairy products and egg for religious reasons. Christians fast almost every Wednesday and Friday weekly throughout the year, in addition to the long fast times. The longer fasting periods include the 40-day Christmas fast, the 55-day Lenten fast, the 14-day Apostles fast and the 14-day Dormition fast. Data on fasting were collected by asking women if they fast weekly and adhere to the long fast times. Finally, women were categorised as fasting if they fasted both the weekly and the long fasting times.

To assess agrobiodiversity, women were queried using a list of crops and livestock products and were asked to indicate whether their households produced any of these in the preceding year by 'yes' or 'no' options. Products from the list were grouped into eight categories: cereals, roots and tubers; pulses; oilseeds; fruits; vegetables; dairy; egg; and meat and poultry. A total agrobiodiversity score from 0 to 8 was calculated based on each category's answers.⁴¹ Also, the amount of produces of each crop in quintals was asked, and total harvest volume was calculated by adding all.

Dietary diversity was assessed by asking women about consuming a list of foods over a 24-hour period with 'yes' or 'no' as the answer options.³³ The list was organised into 10 groups: grains, white roots and tubers; pulses; nuts and seeds; dairy; meat, fish and poultry; egg; dark green leafy vegetables; other vitamin A-rich fruit and vegetables; other fruit; and other vegetables. Consumption of foods from 5 or more groups was defined as adequate dietary diversity.³³

Household Food Insecurity Access Scale was used to collect data concerning food security status.³² First, women were asked nine occurrence questions eliciting a 'yes' or 'no' response. Next, each positive response was followed by a frequency-of-occurrence question asking how often the reported food insecurity condition happened in the previous month. Response options were (1) rarely, (2) sometimes or (3) often. The sum of the frequency-of-occurrence questions across all nine questions yielded a food insecurity score ranging from 0 to 27. A household was classified as food secure if the response to all occurrence questions was 'no' or if the only 'yes' response concerned the question, 'did you worry that your household would not have enough food' and the frequency of occurrence was 'rarely'. All other households were classified as food insecure.³²

Psychosocial characteristics

Partner support was measured by the 5-item Turner Support Scale at inclusion, with each item scored from 0

to 3. A sum score of < 10 was defined as low.⁴² Also, social support from other social sources was assessed using the Oslo-3 Social Support Scale at inclusion, with total scores ranging from 3 to 14 and ≤ 8 being considered low.⁴³ Totalling the two measures of support, a total social support score was created, and low total social support was defined as low support from partner and other social sources.

Moreover, anxiety, depression and stress were collected at inclusion. The 10-item Edinburgh Postnatal Depression Scale and the 7-item anxiety subscale of the Hospital Anxiety and Depression Scale with each item rated from 0 to 3 were used to measure depression and anxiety. Cut-off points of ≥ 13 and ≥ 8 were applied to indicate high symptoms of depression and anxiety, respectively.^{44 45} For stress, the Perceived Stress Scale was used, with a score for each of the 4 items ranging from 0 to 4 and a cut-off of ≥ 8 showing high symptoms of stress.⁴⁶ Summing depression, anxiety and stress scores, a total distress score was obtained. Also, the presence of high symptoms in one, two, or three domains of distress, that is, anxiety, depression or stress, was considered to indicate the level of distress.

Anthropometrics

Height and MUAC to the nearest 0.1 cm were measured at inclusion using a height-measuring board and MUAC-measuring tape. Also, weight was measured as described earlier. All were measured twice and averaged. Based on pre-pregnancy BMI in kg/m^2 calculated from pre-pregnancy weight and height at inclusion, women were classified as undernourished (BMI: $< 18.5 \text{ kg}/\text{m}^2$), normal weight (BMI: $18.5\text{--}24.9 \text{ kg}/\text{m}^2$) or overweight (BMI: $\geq 25.0 \text{ kg}/\text{m}^2$). Likewise, MUAC $< 21.0 \text{ cm}$ was used to define undernutrition.⁴⁷

Data quality control

Data collection was supervised by health extension supervisors (BSc). Data collectors and supervisors were trained on the protocol for 1 day. Besides regular supervision, 10% of the completed questionnaires were selected at random to be checked by asking the women again. Also, some of the data were cross-checked with antenatal records.

Statistical analysis

Data were entered into EpiData V.3.3, verified by re-entering a random selection of 20% of the completed questionnaires, and analysed with STATA (V.11, Stata Corporation, College Station, Texas, USA). Proportion, mean with SD or median with IQR were used to summarise the characteristics of the participants.

Non-linear associations between pre-pregnancy BMI and MUAC as continuous dependent variables, and the independent variables were investigated, and linear spline regression was applied if indicated (Stata `adjust_rcspline` package). Non-linearity was initially tested with one-way analysis of variance (ANOVA) comparing mean BMI and mean MUAC by categories of each independent variable.

Table 1 Anthropometric measures by pre-pregnancy BMI categories of women (n=991) from the Tigray region, northern Ethiopia, 2018

Anthropometric measures	Undernourished (BMI: <18.5 kg/m ²)		Normal (BMI: 18.5–24.5 kg/m ²)		Overweight (BMI: ≥25.0 kg/m ²)		Total	
	Mean (SD)	Range	Mean (SD)	Range	Mean (SD)	Range	Mean (SD)	Range
Height, cm	157.01 (0.1)	135.2–175.8	157.80 (0.1)	132.6–181.2	158.82 (0.1)	152.3–168.6	157.52 (0.1)	132.6–181.2
Pre-pregnancy weight, kg	43.84 (4.3)	31.8–54.0	51.87 (5.7)	33.3–72.9	64.10 (5.3)	58.9–71.8	49.02 (6.6)	31.8–71.8
Weight at inclusion, kg*	46.09 (4.3)	34.2–57.1	54.43 (5.9)	36.6–75.7	66.58 (5.5)	60.3–73.0	51.44 (6.7)	34.2–75.7
MUAC at inclusion, cm	20.67 (0.9)	17.5–22.0	23.61 (1.4)	18.4–27.8	28.44 (1.1)	26.8–29.6	22.57 (1.9)	17.5–29.6
Proportion, n (%)	359 (36.2%)		627 (63.3%)		5 (0.5%)		991 (100%)	

*One woman had inconsistent data and was excluded.
BMI, body mass index; MUAC, mid-upper arm circumference.

If this test suggested non-linearity as apparent by statistically significant deviation from linearity ($p < 0.05$), two new continuous variables were created by partitioning each independent variable at the knot value (K) into two using linear spline regression. The coefficient for the first variable represented the effect of the variable below the knot value. The coefficient for the second variable reflected the effect at values greater than or equal to the knot value.⁴⁸ The knot value for each variable was roughly estimated by viewing the linear spline regression curves. Subsequently, the knot value resulting in the best fitting linear spline model, that is, a model with the lowest mean squared sum of errors, was determined by testing different values. Then, after regressing the two new variables and their respective intercepts against the corresponding dependent variable (reg BMI in₁ X<K in₂ X≥K, robust), we tested if the slopes of the two variables were different (test X<K=X≥K). If the test showed that the slopes were significantly different ($p < 0.05$), we concluded that the association was non-linear. Finally, after comparing linear spline, quadratic and cubic models, the model that had the best fit, as apparent by the lowest root mean squared sum of errors, was considered in the final analysis. In case linear spline model had the best fit, the two new variables with their intercepts were included in the analysis.

Following the linearity test, linear regression with robust standard errors was used to identify factors associated with pre-pregnancy BMI and MUAC. In the final adjusted linear regression models, relevant variables as per the literature with a statistically significant association ($p < 0.05$, two-sided) in the unadjusted analysis were included. Beta-coefficients with their corresponding 95% CIs were computed. Residence, occupation, parity and harvest volume were highly correlated with other variables and had a lower correlation with BMI and/or MUAC than their correlates. Thus, they were not included in the final models. As for model diagnostic tests, multicollinearity was checked using the variance inflation factor, and the normality of residuals was checked with histograms, normal probability plots and quantile–quantile plots. Also, specification error and omitted variable bias were tested using the linktest and ovtest commands.

Additionally, Poisson regression with robust variance was used to identify factors associated with pre-pregnancy undernutrition, defined as BMI of <18.5 kg/m² and MUAC of <21.0 cm as measured by MUAC. Independent variables significantly associated with pre-pregnancy undernutrition in the unadjusted analysis examined by the χ^2 test were included in the final model. Incidence rate ratios with 95% CI were computed.⁴⁹ All continuous variables were modelled as categorical variables to enhance data convergence and interpretation. Model selection was made based on Akaike and Bayesian Information Criteria.

Patient and public involvement

There was no patient or public involvement.

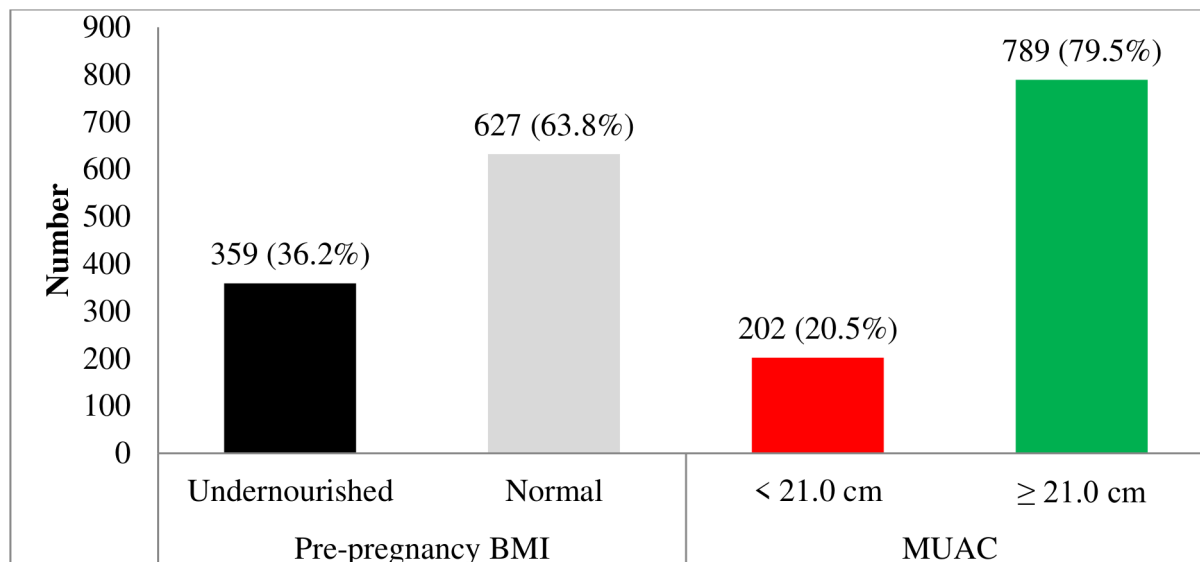

Figure 1 Pre-pregnancy nutritional status as assessed by BMI and MUAC of women, northern Ethiopia, 2018. BMI, body mass index; MUAC, mid-upper arm circumference.

RESULTS

A total of 991 eligible women were identified and included in the study. [Table 1](#) summarises the anthropometric measures of the participating women by pre-pregnancy BMI categories. The mean pre-pregnancy nutritional status of the women assessed by BMI and MUAC was 19.7 kg/m² (SD: 2.0 kg/m²) and 22.6 cm (SD: 1.9 cm), respectively. Overall, 36.2% (95% CI: 33.3 to 39.3) were undernourished (BMI: <18.5 kg/m²) before pregnancy. According to MUAC, the prevalence of undernutrition (MUAC: <21 cm) was 20.5% (95% CI: 18.0 to 23.0) (see [figure 1](#)).

The socioeconomic characteristics of the participants are presented in [table 2](#). On average, the women were 29.3 years old (SD: 6.5 years old) at inclusion. Most women lived in rural areas (65.3%), received primary education or below (69.4%), and were farmers (54.6%). As for their respective household characteristics, 242 (24.4%) were model households. Also, the majority (89.6%) had access to an improved drinking water source, whereas only 135 (13.6%) had access to an improved sanitation facility. In the unadjusted analysis, better socioeconomic circumstances were associated with higher BMI and MUAC.

[Table 3](#) depicts the reproductive and obstetric conditions, food and dietary as well as psychosocial characteristics. At inclusion, the mean gestational age was 14.8 weeks (SD: 1.9 weeks). The median parity of the women was 2, and 208 (21.0%) had a history of an adverse birth outcome. As for women empowerment, only 114 (11.5%) were empowered. Additionally, the prevalence of intimate partner violence among women was 16.2%. In the unadjusted analysis, higher women empowerment was associated with higher BMI and MUAC, whereas higher intimate partner violence was associated with lower BMI and MUAC.

As shown in [table 3](#), most women's food and dietary characteristics were poor. In total, 518 women (52.3%)

had adequate dietary diversity. With reference to dietary habits, most women (70.0%) fasted. Additionally, 392 women (39.6%) did not have adequate food security. In the unadjusted analysis, higher dietary diversity and agrobiodiversity showed significant associations with higher BMI and MUAC. However, fasting and food insecurity were associated with lower BMI and MUAC.

Furthermore, psychosocial problems were widespread among the women, as indicated in [table 3](#). More than one in five (21.9%) women had high symptoms of distress in one of the three domains of distress. Concerning social support, 75 women (7.6%) reported low social support. In the unadjusted analysis, a higher total distress score was associated with lower BMI and MUAC, whereas higher total social support score was associated with higher BMI and MUAC.

Results of the unadjusted and adjusted linear regression analyses are given in [table 4](#). In the adjusted model, age <30 years (coefficient: 0.08, 95% CI: 0.03 to 0.14), being from a model household (coefficient: 0.40, 95% CI: 0.15 to 0.66) and women empowerment score ≥6 (coefficient: 0.35, 95% CI: 0.18 to 0.53) were positively associated with BMI. From the food and dietary domain, higher dietary diversity (coefficient: 0.13, 95% CI: 0.05 to 0.22) was associated with higher BMI. Additionally, fasting (coefficient: -0.26, 95% CI: -0.50 to -0.02), food insecurity (coefficient: -0.07, 95% CI: -0.10 to -0.05) and agrobiodiversity score <2 (coefficient: -0.62, 95% CI: -1.07 to -0.16) were negatively associated with BMI. In total, the model explained 39.5% of the variation.

All variables that were associated with pre-pregnancy BMI were also associated with MUAC. Of these variables that had a larger effect, being from a model household (coefficient: 0.38, 95% CI: 0.13 to 0.63) and women empowerment score ≥6 (coefficient: 0.30, 95% CI: 0.13 to 0.48) were positively associated with MUAC. However, fasting (coefficient: -0.27, 95% CI: -0.51 to -0.03)

and agrobiodiversity score < 2 (coefficient: -0.61, 95% CI: -1.07 to -0.15) were negatively associated with MUAC. The model explained 38.5% of the variation in MUAC.

Results of Poisson regression analysis are given in table 5. Not being from a model household (incidence rate ratio (IRR): 1.61, 95% CI: 1.26 to 2.06), not being empowered woman (IRR: 2.68, 95% CI: 1.58 to 4.52), food insecurity (IRR: 1.65, 95% CI: 1.38 to 1.97) and inadequate dietary diversity (IRR: 1.66, 95% CI: 1.38 to 2.00) were associated with higher incidence rate ratio of pre-pregnancy undernutrition defined as BMI of <18.5 kg/m². All these variables were also associated with pre-pregnancy undernutrition, defined as MUAC of <21.0 cm.

DISCUSSION

We performed a population-based study to determine factors associated with pre-pregnancy nutritional status in 991 pregnant women in northern Ethiopia. A considerable part of the women included in the study did not have optimal nutritional status. Overall, nearly one-third were undernourished before pregnancy. These numbers are higher than the national prevalence (22%) but comparable to data reported as the regional prevalence in Tigray (32%)¹⁴ and for Africa as a whole (32%).¹⁶ In the present study, we were able to identify a wide range of factors that contribute to the persistence of highly prevalent pre-pregnancy undernutrition. Our findings signal that the identified opportunity to curb the trans-generational cycle of malnutrition before pregnancy is not effectively used in developing countries like Ethiopia. Our results may also offer directions and possibilities for targeted interventions to improve the situation.

Age until 29 years was positively associated with pre-pregnancy nutritional status and negatively but insignificantly after 29 years. This finding implies an association between lower age and lower pre-pregnancy nutritional status. Lower schooling, socioeconomic status and dietary practice could partly explain the relation between lower age and lower nutritional status. Similar finding has been reported by studies in Ethiopia.^{50 51}

Being from a model household, a proxy for implementing the so-called health extension package, was positively associated with pre-pregnancy nutritional status. A model household received short-term training on the health extension package, comprising several

components, including maternal health, family planning, nutrition and sanitation. After the training, implementation of the package was required to be labelled as a model household. In addition, HEWs educate women, individually at their home and in a group at a health post, on maternal health, including nutrition during their pregnancy. Therefore, it is likely that the observed association between implementation of the health extension package and better nutritional status is at least in part explained by the effect of the training on dietary practices and the impact of implementing the package on the overall health of the women.^{52–55} This promising finding suggests that strengthening the health extension programme may be a good approach to improving maternal nutritional status.

Moreover, a higher women empowerment score was associated with higher pre-pregnancy nutritional status in the present study, which is in line with the literature.^{23 56 57} This may be partly explained by the effect of women empowerment on access to food, dietary practice and seeking healthcare.^{58–64} Therefore, the observed association reflects the importance of considering women empowerment in confronting maternal undernutrition and its consequent effects. In short, finding a means for improving the women's social, economic, political and legal strength, ensuring equal rights for women and making them confident enough to claim these rights, such as purchasing resources they want and using healthcare they need, may be helpful.

In congruence with the literature, we observed a positive association between dietary diversity and pre-pregnancy nutritional status.^{19 65 66} As dietary diversity is seen as a proxy of dietary quality, higher dietary diversity can translate to better nutritional status.⁶⁷ Likewise, the negative association found between food insecurity score and pre-pregnancy nutritional status, consistent with the literature,^{19 68 69} could be explained by inadequate dietary intake or quality due to lack of access to food.^{70–73} Also, a lower agrobiodiversity score was negatively associated with pre-pregnancy nutritional status. Though previous findings are mixed, as shown in a recent review,⁷⁴ the observed association may suggest that a slight change in agrobiodiversity is not enough to positively impact maternal diet and nutrition. Moreover, it may be related to the opportunity costs of farm specialisation due to the foregone gains from diversification.

†Represent the two continuous variables below and greater than or equal to the knot value, respectively. BMI, body mass index; MUAC, mid-upper arm circumference.

Our study also revealed that fasting was negatively associated with pre-pregnancy nutritional status, which corresponds with a previous study among lactating women.⁵⁰ Almost all the women involved in our study were Orthodox Christians, and in this religion, more than half of the days in a full year are fasting times. This includes regular fasting days almost every Wednesday and Friday throughout the year. The long fasting periods include the 40-day Christmas fast, the 55-day Lenten fast, the 14-day Apostles fast and the 14-day Dormition fast. People are expected to abstain from animal-source foods for religious reasons during these times. This could result in poor dietary quality and poor nutritional status.^{75 76}

This finding highlights the importance of considering nutrition-sensitive religious practices as part of the efforts to improve maternal nutrition.

The present study's findings indicate that coordinated and considerable efforts of different bodies and functions might be needed to address pre-pregnancy undernutrition. For instance, involving the agricultural sector in mounting better access to food and involving the justice sector in tackling domestic violence may be helpful. Also, though the Orthodox Church nowadays shows flexibility on fasting during pregnancy, most pregnant women still adhere to fasting for religious reasons. Maintaining this practice will counteract other measures to solve pre-pregnancy undernutrition. Moreover, physical work like farming activities is not allowed on almost half of the days in a year, that is, all saints days and the weekends, which may worsen food insecurity and dietary quality. Thus, involving religious leaders to improve pre-pregnancy maternal nutrition could be supportive.

Strengths and limitations

Our study has some strengths and limitations. Using weight measured during a distinct period before starting recruitment of pregnant women, including a relatively large sample of women, and collecting information on many possible confounders can be considered strengths. As for limitations, MUAC was measured at inclusion, unlike BMI. However, as MUAC is relatively insensitive to change over time, it can safely represent the pre-pregnancy status.^{17 18} Additionally, seasonal variation was not addressed in the dietary diversity measurements. However, agrobiodiversity and food insecurity have been assessed, and adjusting for these variables may account for the bias that can be introduced due to the seasonal variation. Therefore, we do not believe that these limitations have seriously affected the generalisability of our findings. Finally, our study might not have been free of type one error due to the multiple hypothesis testing.

Conclusions

Pre-pregnancy undernutrition was prevalent in the women living in the study area. The findings of the present study suggest that considerable improvements could be made by advancing community awareness related to dietary practice and habits, also in the area of gender equality.

Empowering females, raising agricultural productivity and broader implementation of the health extension package are all factors that may improve maternal nutritional status. In the Ethiopian setting, this would require the coordinated efforts of concerned bodies, including religious leaders.
