CHAPTER 2

Computational analysis of the human HSPH/HSPA/DNAJ family and cloning of a human HSPH/HSPA/DNAJ expression library

Jurre Hageman and Harm H. Kampinga

Abstract

In this manuscript, we describe the generation of a gene library for the expression of HSP110/HSPH, HSP70/HSPA and HSP40/DNAJ members. First, the HSP genes were collected from the gene databases and the gene families were analyzed for expression patterns, heat inducibility, subcellular localization and protein homology using several bioinformatics approaches. These results can be used as a working draft model until data are confirmed by experimental approaches.

In addition, we describe the generation of a HSPA/DNAJ overexpression library and tested the effect of different fusion tags on HSPA and DNAJ members using different techniques for measuring chaperone activity. These results show that we have cloned a high quality heat shock protein expression library containing most members from the HSPH, HSPA, DNAJA and DNAJB families which will be useful for the chaperone community to unravel the function of the highly diverse family of human molecular chaperones.

Introduction

All organisms except some hyperthermophilic archaea contain the family of HSP110/ HSPH, HSP70/HSPA and HSP40/DNAJ chaperones (1). HSPA and DNAJ proteins function as molecular chaperones to assist in processes such as translation and transport of proteins across membranes.

The HSPA machine consist of the core HSPA protein along with a transient array of different co-factors such as DNAJ, HSPH, BAG-1, HIP, CHIP and HSPBP1 (2). The HSPH/HSPA and DNAJ families are protein families consisting of many members and as a whole, the HSPH/ HSPA/DNAJ gene family is the largest chaperone gene family found in humans.

It is thought that many of its members are specialized (3). For instance, members of the HSPA, DNAJ and HSPH family exist that are only expressed under stress conditions suggesting that these are specialized to function in the proteotoxic stress response (4). Constitutively expressed members are found as well and such members are found in several cellular compartments such as the cytosol, mitochondria and the ER suggesting that cellular compartmentalization has driven some of the HSPA/DNAJ gene expansion (5). In addition, some members have only been found at specific developmental stages or in specific cell types indicating the need for specialized members for specific substrates expressed only during specific developmental stages or in certain specialized cell types.

In contrast to the gene expansion as a result of compartmentalization, the gene expansion as a result of cellular specialization or organism development is poorly understood. It has been suggested that HSPA and DNAJ proteins bind small hydrophobic regions (6;7); yet there is great diversity and multiplicity within these families for which most members have not yet been studied in detail.

Although the various chaperone genes are now relatively well annotated, the molecular function for most of its members is currently unknown. For each of the families, only a single or restricted number of proteins have been studied in detail. Here, we used bioinformatics approaches to study the different HSPH, HSPA and DNAJ members (8). Thereafter, we describe the construction of a human HSPH/HSPA/DNAJ expression library.

Materials and methods

Bioinformatics

HSP gene retrieval

HSPH, HSPH and DNAJ genes were collected from NCBI Gene (9). Mouse orthologs were identified using NCBI Homologene (10). Protein molecular weights were calculated using the clone manager 7 suite (Sci-Ed Software).

Est count analysis

Expression data based on tissue specific and developmental stage specific EST numbers were collected from the NCBI UniGene database (10). EST numbers are displayed as counts per million.

Table 1: Overview of the human HSP70/HSP40 gene family

Affymetrix gene array

Investigation of genome-wide heat induced transcriptional activation was described previously (11). These experiments were performed in Hela cells using a 1.5 hour heat shock at 43 °C. Recovery times were 0.5, 2 and 4 hours at 37°C. Affymetrix gene array data were downloaded (11) and linear induction was calculated from the 2log fold change. Affymetrix uses different annotations for its probe sets. _at suffix designates a unique probe set, whereas the _s_at and _x_at suffixes designate probe sets that can cross hybridize with multiple genes. In the case of redundant probe sets, _at suffix were selected by default. In the case of no available _at suffix, the first probe set was selected routinely.

Subcellular localization analysis

Predictions on subcellular localizations were performed using pSort, pTarget, CELLO, Multiloc and Proteome analist (12-16). Sequences from complete gene families were uploaded as fasta files. In each case, only the first rank localization is displayed. For all predictors, the default settings for mammalian or animal proteins were used. The presence of prenelation motifs was determined using the PrePS web server (17).

Protein Alignments

Primary amino acid alignments were performed in ClustalX2 using the neighbour-joining algorithm and Blosum matrixes at the default settings (18). Bootstrap analysis was performed using 1000 random number generator seeds and 1000 bootstrap trials. Phylograms were made by importing the homology tree output of ClustalX in TreeView (19). The distance is depicted in the scale bar of Figure 1 as 0.1 amino acids substitutions per position.

Library cloning and validation

Gene Cloning

Detailed information about the plasmids used in this study can be found in Figure 2. Briefly, tetracycline-inducible HSP expression plasmids were constructed as follows. First, the GFP and the V5 tag, harbouring a Kozak consensus ATG initiation codon and lacking a stop codon, were cloned in the pcDNA5/FRT/TO vector (Invitrogen). Subsequently the coding sequence of the different chaperones was amplified using the primers listed in table 8. As a template source, cDNA was made from total RNA as previously described (20). As a source of total RNA, QPCR Human reference Total RNA (Stratagene) was used which is a mixed source of RNA from the following cell line derivations: Adenocarcinoma, mammary gland; Hepatoblastoma, liver; Adenocarcinoma, cervix; Embryonal carcinoma, testis; Glioblastoma, brain; Melanoma, skin; Liposarcoma, Histiocytic lymphoma, macrophage, histocyte; Lymphoblastic leukemia, T lymphoblast; Plasmacytoma, myeloma, B lymphocyte. DNAJB4, DNAJB5 and DNAJB8 were amplified from cloned full length cDNAs purchased from Open Biosystems (clone ID: DNAJB4: 4340658, DNAJB5: 4684829 and DNAJB8: 5296554). The fragments were cloned in pcDNA5/FRT/TO GFP lacking a stop codon resulting in a N-GFP-cDNA-C protein. The presence of the correct gene was sequenced verified. Protein expression was verified by Werstern blotting. Subsequently, fragments were subcloned to pcDNA5/FRT/TO V5 and pcDNA5/FRT/TO.

Luciferase refolding Assay

Cell lysis and luciferase activity measurements were done as previously described (21). Luciferase activity was plotted relative to the percentage of activity in an unheated control. Error bars on plots represent standard deviations.

Filter trap assay

To determine protein aggregates, the filter trap assay was performed as previously described (22). Briefly, 10, 2 and 0.4 µg of protein extracts were applied onto 0,2 µm pore Cellulose Acetate membrane pre-washed with FTA + 0.1% SDS. Mild suction was applied and the membrane was washed 3 times. Aggregated proteins trapped in the membrane were probed with a mouse anti-GFP antibody JL-8 (Clontech) at a 1:5000 dilution or a mouse anti-V5 antibody (Invitrogen) at a 1:5000 dilution followed by HRP-conjugated anti-mouse secondary antibody (Amersham) at 1:5000 dilution. Visualization was performed using enhanced chemiluminescence and Hyperfilm (ECL, Amersham).

Results

Bioinformatic analysis on the HSPH, HSPA and DNAJ gene family

Collecting the HSPH, HSPA and DNAJ gene family

In order to get a comprehensive overview of the gene family, we first extracted all human HSPH, HSPA and DNAJ family members from the NCBI gene database. It should be noted that beside these protein encoding genes, we found many pseudogenes scattered throughout the human genome. Typically, pseudogenes show types of decay such as frame-shifts, stop-codons or gaps. For the HSPA family alone, already 30 pseudogenes have been documented (5). For gene selection, we extracted the annotated non-pseudo genes from the NCBI gene bank (9). We found 4 HSPH chaperones, 13 HSPA chaperones and 49 DNAJ chaperones. The genes including the protein name, the old and alternative names, the NCBI human gene ID, the mouse orthologue gene ID, the human gene locus, the protein length and the calculated molecular mass are listed in Table 1. Classically, human chaperones were ranked according to molecular mass. However, as can be seen from table 1, many HSP genes deviate from this and contain only a HSP-like domain such as the HSP70 ATPase domain or the HSP40 DNAJ domain. For instance, while many HSP40/DNAJ proteins are around 40 kD, the sizes of proteins within this family range from 16 kD (DNAJC15) to 254 kD (DNAJC13). For this reason, a revised nomenclature was recently suggested (Table submitted to Cell Stress and Chaperones).
HSPA6 and HSPA7 were not found in mice. Although HSPA7 contains an internal frame shift and might be a pseudogene, bypassing the frame shift will result in a protein with a full length homology to HSPA1A. Thus, the HSPA7 protein with a full length homology to HSPA1A might be produced and this has recently been explained elsewhere (5).

Patterns of tissue specific HSPH, HSPA and DNAJ expression

Cellular specialization may require specialized chaperone proteins and therefore may be responsible for part of the chaperone gene expansion. The expression pattern of most chaperone genes is currently unknown. An estimation of the expression pattern can be made by

Table 2: Expression levels of HspH and HspA genes in various human tissues. Number of transcripts per million are indicated.

assessing the relative number of Expressed sequence tags (EST) per tissue using the Unigene database (23). However, some caution should be taken as the Unigene assignments of ESTs to individual genes is not necessarily accurate (i.e. poor sequence quality and related sequences lead to incorrect 'binning' of some ESTs).

The expression estimates are displayed in Table 2 (HSPH/HSPA), Table 3 (DNAJA/B) and Table 4 (DNAJC). The peak expression for each tissue is indicated in bold. As expected, HSPA8 shows a high expression in most tissues (Table 2). In contrast, HSPH3, HSPA1L, HSPA6, HSPA7, HSPA12A and HSPA12B show very low levels in most tissues. HSPH3 and HSPA1L show the highest expression in the testis which is in agreement with literature (24;25). HSPA6 is absent under non stress conditions and only expressed upon severe heat shock conditions (26). The expression of HSPA1A is extremely variable ranging from being absent in lymph

Table 3: Expression levels of DnaJA and DnaJB genes in various human tissues. Number of transcripts per million are indicated.

(node), parathyroid and umbilical cord to being expressed at very high levels in the spleen. As for the HSPH/HSPA family, the DNAJ family shows a highly variable expression profile (Table 3 and 4). The highest expressed members throughout tissues are DNAJA1, DNAJB1 and DNAJB6 indicative for being "housekeeping" DNAJ chaperones although they all are lacking in a few tissues. As for the HSPA/HSPH families, the DNAJ family shows testis specific members (DNAJB7, DNAJB8, DNAJC5B, DNAJC5G). In general, with the exception of the testis, most HSP genes do not show an expression restricted to only a single tissue. In addition, peak levels per tissue are highly variable from gene to gene, providing no direct correlative clue for any specific partnerships between the diverse family members.

Patterns of developmental expression

We also used the Unigene database to look for developmental specific expression patterns (Table 5). The results show that HSPs are differentially expressed at different developmental stages. HSPA1A shows a large variation throughout different developmental stages. Interest-

ingly, many DNAJC members are expressed during embryogenesis but are repressed in the neonate or infant (DNAC4-6 and DNAJC16-20). Only a minority of the genes were expressed the highest at adult stages.

Heat induced transcription

Although HSPs were originally identified as heat inducible proteins, most members are identified according to presence of typical domains such as the HSP70 ATPase domain or the HSP40 DNAJ domain. For most of these members, it is currently unknown whether they are induced by heat. To investigate this, we used Affymetrix gene array data (11) and performed a biased search on the heat inducibility for HSPH, HSPA and DNAJ members (Table 6). We used an arbitrary threshold of 2-fold induction to define heat inducibility. Using this threshold we found that HSPH1, HSPA1A, HSPA1B, HSPA1L, HSPA6, DNAJB1, DNAJB2, DNAJB4 and DNAJB6 are the major heat inducible genes in Hela cells. Thus, the majority of HSPs are not heat inducible. Of course, it must be noted that these patterns could be different for other cell lines and other heat conditions.

Subcellular localization

Determination of HSP localization is essential to understand its biochemical function. Unfortunately, high throughput analysis of HSP localization without the use of possible interfering tags is currently impossible due to the lack of specific antibodies. As subcellular localization signals share common characteristics, computational methods have been developed to predict the subcellular localization of proteins (27). We selected several publicly available localization prediction methods which accept large batches of protein sequences and which were able to predict all of the major subcellular localizations. The selected methods were Wolf PSORT (12), pTarget (13), CELLO (15), Multiloc (16) and Proteome Analyst (14). In addition, we searched the human protein database (28) for experimentally verified HSP localizations. As can be seen from Table 7, there are large variations in the prediction using the various programs. Therefore, we first searched for the prediction method that showed the highest accuracy for biochemical verified HSP members such as HSPA1A/HSP70 (cytosol/nucleus), HSPA1B/HSP72 (cytosol/nucleus), HSPA8/Hsc70 (cytosol/nucleus), HSPA5/Bip (ER), HSPA9/Grp75 (mitochondria), DNAJA3/Tid1 (Mitochondria), DNAJB1/HSP40 (cytosol/nucleus), DNAJB9/ERdj4 (ER) DNAJB11/Erdj3 (ER), DNAJC1/ERdJ1 (ER), DNAJC10/ERdj5 (ER) and DNAJC19/TIM14 (mitochondria). Out of these 12 known localized proteins the following number of correct predictions were found: Wolf PSORT: 7, pTarget: 10, CELLO: 8, Multiloc: 7 and Proteome Analyst: 10. Thus, Proteome Analyst and CELLO showed the highest correct prediction. However it should be noted that at this stage, all prediction are potentially unreliable and should be used carefully. The scoring of the most reliable prediction method does rely on a relatively low number of verified chaperone proteins and the most reliable prediction program could therefore change in the future once more proteins will be experimentally verified.

We used the PrePS web server to predict farnesylation of chaperones. As shown in Table 7, DNAJA1 and DNAJA4 are predicted to be prenylated by farnesyltransferase which is in agreement with literature (29). In addition, DNAJB2b was predicted to be prenylated by geranylgeranyltransferase I as shown in the literature (30).

Homology of HSPH, HSPA and DNAJ paralogs

Next, we computed protein similarity trees based on the alignments of the HSP protein sequences using the Neighboring-joining clustering method (31). Figure 1 shows the output of

these alignments depicted as phylograms. Three subfamilies can be derived from Figure 1A. As expected, the first contains all the HSPH/HSP110 members. The second subfamily contains the cytosolic predicted HSPA proteins HSPA1A, HSPA1B, HSPA1L, HSPA2, HSPA6, HSPA8 and is flanked by the ER localized HSPA5 and the mitochondrial localized HSPA9 protein. The third sub-family consists of the distantly related HSPA12A and HSPA12B proteins. Thus a high number of highly related HSPA proteins are localized in the cytosolic/nuclear compartment. To date, the reason for so many highly related cytosolic HSPA proteins is unknown.

DNAJ proteins can be divided in three sub families on the bases of the primary amino acid composition and are classified as type A, B and C proteins (32). Type A proteins are the closest human orthologues of the *E. coli* DNAJ and contain, besides an extreme N-terminal J-domain, a glycine/phenylalanine-rich region, a cysteine rich region, and a variable C-terminal domain. Type B proteins contain an N-terminal J-domain, a glycine/phenylalanine-rich region but lack the cysteine rich region. Type C DNAJ proteins contain only the J domain that is not necessarily restricted at the N-terminus but can be positioned at any place within the protein (32). DNAJA is a highly related family of proteins and DNAJA3 (the mitochondrial localized member) is the most distantly related member (Figure 1B). For the DNAJB family, three ma-

jor subfamilies are found (Figure 1C). The first consists of the members DNAJB2, DNAJB6 DNAJB7 and DNAJB8, the second of the members DNAJB1, DNAJB4, DNAJB5, DNAJB9, DNAJB11 and DNAJB13 and the third of the members DNAJB12 and DNAJB14. Although different C-termini could be defined based on the primary amino acid level within the DNAJB family, at present, no clear biochemical function can be assigned to one of these subfamilies. The DNAJC family (Figure 1D) shows the highest divergence of all families. Based on these results we decided to clone the HSPH, HSPA, DNAJA and DNAJB family. As the DNAJC family is highly diverse, we omitted this family for library construction.

Cloning the HSPH, HSPA and DNAJ gene families

Selection of an expression system

For cloning a human expression library to perform reverse genetic screens, we used a robust and versatile system with a high degree of flexibility; the Flp-In T-Rex tetracycline inducible expression system. The core promoter of this construct contains the full human cytomegalovi-

rus (CMV) promoter followed by two tetracycline repressor binding sites. Thus, in cell systems engineered to express the tetracycline repressor, tetracycline can be used for regulated expression of the gene of interest, whereas full CMV strength promoter activity will be achieved in cell systems which do not contain the tetracycline repressor (33). In addition to regulated expression, the vector contains an FRT recombination site for the Flp recombinase mediated stable integration of the vector at a specific site in an engineered FRT site harboring cell line (34). The eukaryotic selection marker lacks a start codon which selects for a site specific integration in the target genome. We selected the Flp-In T-Rex 293 cell line, a modified human embryonic kidney (Hek-293) cell line that expresses the tetracycline repressor and harbors a single copy of the FRT site at an active site in the genome. The Hek-293 cell line has been used extensively as a model for protein folding diseases and is widely known for its ease of manipulation (35). A summary of the Flp-In T-Rex system is depicted in Figure 2.

Construction of vector fusion tags

Specific antibodies against most of the recently identified human heat shock proteins are not available. To verify the expression of the different proteins, we used a subset of frequently used protein tags. In some cases, protein tags interfere with the native function of the protein (36). Therefore, caution must be taken with the interpretation of the results obtained. In general, experiments using this library can always be confirmed using the non-tagged version. Although the protein expression can not be confirmed with the untagged version, one can easily compare the biological effects detected in a particular assay.

As a first step towards a vector library for the expression of different heat shock proteins, we selected different protein tags harboring different biological properties. eGFP was selected for subcellular localization studies. As a second (smaller) tag, we used the V5 tag, consisting of only 14 amino acids for which high affinity anti-bodies are commercially available. In addition, we used a hexa-histidine tag for protein precipitation experiments (Figure 2).

To reduce cloning efforts, an N-terminal fusion tag was preferred. In this setting, we could maintain the natural stop codon in the gene of interest, which allows for simple shuttling from

tagged to non-tagged constructs. However, it should be mentioned that N-terminal fusion tags could inter-fere with the import in subcellular or-ganelles such as the ER or mitochon-dria and non-tagged versions are in such cases preferred.

An overview of the fusion tag clon-ing primers and procedure is shown in Figure 2. The PCR product of the eGFP gene lacking a stop-codon was cloned in pcDNA5/FRT/TO. For V5 and His tags, the corresponding oligos where annealed and cloned directly in the pcDNA5/FRT/TO vector.

Cloning the chaperone library

The focus of our gene library is on the cytosolic and nuclear expressed chaperones. Therefore, we selected the HSP70/HSPA proteins which are putatively expressed in the cytosol or the nucleus (Table 7). For the HSP40/ DNAJ family of proteins, we select-ed the major part of the DNAJA and DNAJB subfamily which are the clos-est orthologs to *E. coli* DNAJ. As a certain human cell type typically only expresses a subset of its genes, we used pooled RNA from 10 different human cell lines as a source for cDNA synthesis and gene amplification. No amplification products were obtained for DNAJB4, DNAJB5 and DNAJB8. Instead, these genes were amplified from commercially obtained cDNA

plasmids (Open Biosystems, Huntsville, AL). In addition, the HSPA6 gene was not amplified from the pooled cDNA. As this gene did not contain any introns, we amplified it directly from human chromosomal DNA. The yeast HSP70 gene SSA1, and the prokaryotic HSP70 gene DNAK were amplified from genomic *Saccharomyces cerevisiae* and *Escherichia coli* DNA respectively. An overview of the cloning procedure can be found in Figure 2 and the cloning details can be found in Table 8. We used a nested PCR approach for the HSPH gene family as the sequence start and end of these members is highly similar. The PCR products were puri-fied, digested and cloned in the pcDNA5/FRT/TO GFP vector. The constructs were sequence verified for the presence of the correct insert. Thereafter, expression was verified by Western blot analysis (data not shown) and the genes were subcloned in the pcDNA5/FRT/TO V5, pcDNA5/FRT/TO HIS and the pcDNA5/FRT/TO vector.

(C) Schematic representation of the FRT locus within the Flp-In T-REx HEK-293 cell line. (D) Primer sequences for the construction of the indicated fusion tags.

Validation of the library

To test the effect of the different protein tags, two different biochemical assays were used. First, the effect of the tag on the ability of HSPA1A to assist the refolding of heat-denatured luciferase was tested (37). Therefore, we used constructs containing the HSPA1A gene downstream and in frame with the GFP tag, the V5 tag and the pcDNA5/FRT/TO vector lacking a tag and compared the efficacy in the stimulation of luciferase refolding. The GFP tag significantly reduced the activity of the HSPA1A protein (Figure 3A), whereas the V5 tag showed little to no significant effect on HSPA1A activity. Yet, modulation of HSPA1A related refolding by the co-factor BAG-1 (38) could be achieved with all tagged versions (Figure 3B). Thus, HSPA1A N-terminally tagged with eGFP may be less active related to non-tagged versions but seems unaffected in its ability to cooperate with its cofactors.

To test the effect of tagging DNAJ like proteins, we used a filter trap assay to detect aggregation of polyglutamine proteins such as mutant Huntingtin. Aggregated Huntingtin is SDS insoluble and retains trapped in a non-protein binding cellulose acetate membrane and DNAJB1 is known to be able to inhibit this aggregation (22;39). We used constructs containing the DNAJB1 gene downstream and in frame with the GFP tag, the V5 tag and the pcDNA5/FRT/TO vector lacking a tag and compared the efficacy of DNAJB1 in the suppression of mutant huntingtin aggregation. As shown in Figure 3C, untagged DNAJB1 strongly suppresses mu-

tant Huntingtin aggregation containing a polyQ tract of 74 residues. Both the V5 and the GFP tagged showed an equal slight reduction on the aggregation suppression, but yet retained substantial activity. Thus, N-terminal tagging sometimes does influence the maximal activity of the chaperones tested. This implies that after performing experiments with our tagged HSPs, confirmation with untagged versions is required.
Discussion

The HSPH/HSPA and DNAJ families are large gene families with many poorly studied individual members. We used bioinformatics approaches to study the expression, the localization and the homology of these families. These approaches generated large datasets which will be useful for the systematic biochemical analysis of these family members. It was found that HSPs are expressed at highly variable levels in different tissues. So far, no clear patterns were seen for paired expression of certain members within e.g. the HSPA and DNAJ family in most tissues. Although it is valid to search for the highest expressing tissue for a particular transcript, it is difficult to compare the level of different transcripts for a particular tissue. This is believed to be partly caused by the fact that different messengers may have large differences in mRNA stability. Interestingly, we did find some pattern for the testis. A testis specific HSPA transcript was found (HSPA1L) as well as testis specific DNAJ members (DNAJB7, DNAJB8, DNAJC5B and DNAJC5G). This could indicate that HSPA1L cooperates with one of these DNAJ members.

We also studied the expression levels of HSPs during various developmental stages. The results of the peak expression per transcript show that there is a wide variation in HSP expression throughout different developmental stages but many DNAJC members peak at the blastocyst and fetal stages, indicating that there is a need for specialized DNAJ members early in development.

Figure 3: The effect of different fusion tags on HSPA1A (A) and (B) or DNAJB1 (C). (A) Luciferase refolding assay using GFP, V5 and untagged HSPA1A versions. Cells were transfected with different tagged versions of HSPA1A together with a plasmid encoding firefly luciferase. HSPA1A expression was induced using tetracycline. The day after transfection, the cells were heated at 37°C or 45°C for 30 minutes and reincubated for 1 hour at 37°C to allow luciferase refolding. Thereafter, cells were lysed and measured for luciferase activity. The percentage of luciferase activity is plotted relative to the activity in unheated control cells (100%). (B) Modulation of tagged HSPA1A versions by BAG-1. Cells were treated as in (A) but also co-transfected with a BAG-1 encoding plasmid as indicated. (C) Filter trap assay showing aggregation of expanded Huntingtin. GFP, V5 and untagged versions of DNAJB1 were used as indicated. Cells were transfected with different tagged versions of DNAJB1 together with a plasmid encoding GFP tagged Huntingtin containing either 23Q or 74Q. DNAJB1 was induced by tetracycline. Two days after transfection, cells were lysed and the lysates were loaded on a cellulose acetate membrane. After transblotting, blots were immunostained for GFP to detect aggregated Huntingtin. GFP-tagged DNAJB1 alone did not show any signal on the membrane (not shown).

Surprisingly, the heat inducibility of the different HSPs was only restricted to a limited number of members within each family (HSPH1, HSPA1A/B, HSPA6, DNAJB1, DNAJB2, DNAJB4 and DNAJB6). This could mean that HSPA1A or HSPA6 cooperate with HSPH1 and one of these DNAJ members following stress conditions. Interestingly, no heat inducible DNAJC member was found indicating that DNAJC members do not function in the stress response. It should be noted, however, that the array did not contain probes corresponding to all DNAJC members.

Analyzing the cellular distribution and homology of different HSP members showed that a very homologous subfamily of the HSPA family is predicted to be expressed in the cytosol (HSPA1A/B, HSPA1L, HSPA2, HSPA6 and HSPA8). This indicates that only a minority of the gene duplication occurred as a result of compartmentalization. It is unclear at this stage if this homologous subgroup of HSPA chaperones is regulated by the same subset of co-factors

and if they bind the same subset of client proteins. It will be highly interesting to answer these questions by using available biochemical approaches. For this purpose, we cloned a large collection of chaperone encoding genes in a tetracycline inducible vector system. Different tags with different properties were used in order to detect expression levels (V5), study subcellular localization in living or fixed cells (GFP/V5) or to enrich the expressed protein from crude cell lysates (His). In addition, non-tagged versions were made to verify obtained biological effects. This expression library will be useful to systematically study the biochemical and cell biological features of these poorly characterized HSPs and might help answer the intriguing question why we have so many HSPA and DNAJ chaperones.
