Abstract

Mutations in centrosome genes deplete neural progenitor cells (NPCs) during brain development, causing microcephaly. While NPC attrition is linked to TP53-mediated cell death in several microcephaly models, how TP53 is activated remains unclear. In cultured cells, mitotic delays resulting from centrosome loss prevent the growth of unfit daughter cells by activating a pathway involving 53BP1, USP28, and TP53, termed the mitotic surveillance pathway. Whether this pathway is active in the developing brain is unknown. Here, we show that the depletion of centrosome proteins in NPCs prolongs mitosis and increases TP53-mediated apoptosis. Cell death after a delayed mitosis was rescued by inactivation of the mitotic surveillance pathway. Moreover, 53BP1 or USP28 deletion restored NPC proliferation and brain size without correcting the upstream centrosome defects or extended mitosis. By contrast, microcephaly caused by the loss of the non-centrosomal protein SMC5 is also TP53-dependent but is not rescued by loss of 53BP1 or USP28. Thus, we propose that mutations in centrosome genes cause microcephaly by delaying mitosis and pathologically activating the mitotic surveillance pathway in the developing brain.

Introduction

Neocortical development relies on the extensive proliferation of neural progenitor cells (NPCs) during embryonic development (Noctor *et al*, 2001; Florio & Huttner, 2014). Radial glial cells (RGCs) are located in the ventricular zone (VZ) and constitute the major subtype of NPC within the developing neocortex (Malatesta *et al*, 2000; Noctor *et al*, 2001; Heins *et al*, 2002). During cortical development, RGCs undergo proliferative symmetric divisions to replenish themselves and asymmetric divisions to produce a second type of NPC termed intermediate progenitors (IPs) (Miyata *et al*, 2004; Noctor *et al*, 2004; Franco & Muller, 2013). IPs reside in the sub-ventricular zone (SVZ) and are thought to produce the majority of cortical neurons (Haubensak *et al*, 2004; Englund *et al*, 2005; Kowalczyk *et al*, 2009). Newborn neurons migrate outward toward the cortical plate giving rise to the inside-out formation of the lamina layers of the mature neocortex (Rakic, 1972; Noctor *et al*, 2001). Defects in NPC divisions result in the generation of incorrect numbers of progenitors, which in turn influences brain size and function (Feng & Walsh, 2004; Lizarraga *et al*, 2010; McIntyre *et al*, 2012; Chen *et al*, 2014; Insolera *et al*, 2014; Marjanovic *et al*, 2015; Ding *et al*, 2019; Shi *et al*, 2019; Sheehan *et al*, 2020).

Autosomal recessive primary microcephaly (MCPH) is an inherited disorder of fetal brain growth characterized by a dramatically reduced cerebral cortex that is architecturally normal (Jayaraman *et al*, 2018). MCPH is caused by a depletion of the NPC pool and death of neurons during embryonic development, both of which lead to the generation of fewer mature neurons in the developed cortex (Faheem *et al*, 2015). So far, MCPH has been linked to mutations in ~ 25 genes (Jayaraman *et al*, 2018; Degraasi *et al*, 2019). Remarkably, many of these genes encode proteins required for centrosome duplication, underscoring a critical role of these

organelles in the production of normal neuronal populations in the cortex (Marthiens & Basto, 2020).

Centrosomes are microtubule-nucleating organelles with important roles in interphase and in forming the mitotic spindle. Each centrosome comprises a pair of centrioles, which assemble a surrounding protein matrix known as the pericentriolar material (PCM) that harbors proteins required for microtubule nucleation (Woodruff *et al*, 2014). Forming the core of centrosomes, a mature centriole can dock at the plasma membrane and form a basal body, which templates the formation of cilia (Firat-Karalar & Stearns, 2014; Breslow & Holland, 2019). Multiple mouse models with mutations in centrosome proteins have been found to exhibit microcephaly (Lizarraga *et al*, 2010; Gruber *et al*, 2011; McIntyre *et al*, 2012; Chen *et al*, 2014; Insolera *et al*, 2014; Marjanovic *et al*, 2015; Jayaraman *et al*, 2016; Ding *et al*, 2019; Lin *et al*, 2020). Analysis of these animals revealed that NPCs are depleted by both apoptosis and the precocious onset of neurogenic divisions. Importantly, for several of these models, microcephaly can be rescued by deletion of *TP53*, highlighting a central role of this transcription factor in NPC attrition and microcephaly pathogenesis (Insolera *et al*, 2014; Marjanovic *et al*, 2015; Lin *et al*, 2020). Nevertheless, the pathway responsible for TP53 activation in NPCs with defective centrosomes remains unknown.

Recent work has established that *in vitro*, centrosome loss triggers activation of a USP28-53BP1-TP53 signaling axis hereafter referred to as the mitotic surveillance pathway (Fong *et al*, 2016; Lambrus *et al*, 2016; Meitinger *et al*, 2016). Cultured cells with defects in centrosome number or function take longer to assemble a bipolar spindle, resulting in an increased mitotic duration (Bazzi & Anderson, 2014; Lambrus *et al*, 2015; Wong *et al*, 2015). This, in turn, triggers a G1 arrest in daughter cells to prevent the expansion of potentially unfit progeny. The current evidence suggests that centrosome defects activate the mitotic surveillance pathway by prolonging mitosis (Uetake & Sluder, 2010; Fong *et al*, 2016; Lambrus *et al*, 2016; Meitinger *et al*, 2016). Nevertheless, it remains unclear in which context the mitotic surveillance pathway functions *in vivo*.

Consistent with work in cell culture, depletion of centrosome proteins in the developing mouse brain leads to an increased mitotic index in NPCs (Gruber *et al*, 2011; Insolera *et al*, 2014; Marjanovic *et al*, 2015; Pilaz *et al*, 2016; Ding *et al*, 2019; Shi *et al*, 2019). In addition, prolonging mitosis in NPCs with pharmacological agents or through depletion of the exon junction complex protein MAGOH, leads to increased death or premature differentiation of the progeny from these divisions (Pilaz *et al*, 2016; Mitchell-Dick *et al*, 2020). The intriguing link between extended mitotic duration and NPC cell fate motivated us to ask whether activation of the mitotic surveillance pathway is responsible for the depletion of NPC in microcephalic brains with centrosome defects.

Here, we show that NPCs with centrosome defects delay in mitosis but undergo normal chromosome segregation. The increase in mitotic duration in NPCs activates the mitotic surveillance pathway and suppresses the proliferation of the progeny from these divisions. Disabling the mitotic surveillance pathway prevents TP53 activation and restores the expansion of the NPC pool and brain size in two microcephaly mouse models with centrosome defects. Finally, we show that loss of the non-centrosome protein SMC5 leads to microcephaly that is not rescued by the inactivation of the mitotic surveillance pathway. Since mutations in centrosome and spindle proteins are the major cause of primary microcephaly, we propose that

activation of the mitotic surveillance pathway is a central mechanism underlying microcephaly pathogenesis in human patients.

Results

Neural progenitors with centrosome defects delay in mitosis

To investigate the impact of centrosome defects on NPC divisions, we analyzed two published microcephaly mouse models with decreased levels of the centrosome proteins CEP63 or SAS4 (Bazzi & Anderson, 2014; Insolera *et al*, 2014; Marjanovic *et al*, 2015). CEP63 localizes at the base of the parent centriole, and mutations in *Cep63* cause Seckel syndrome, which is characterized by both growth retardation and microcephaly (Sir *et al*, 2011). SAS4/CENPJ/CPAP is a centriole protein and mutations in *Sas4* cause microcephaly in humans (Bond *et al*, 2005).

Mice that are homozygous for a gene-trap insertion in the *Cep63* gene (*Cep63^{T/T}*) exhibit growth retardation and microcephaly (Marjanovic *et al*, 2015). Consistently, we observed that the telencephalic area of *Cep63^{T/T}* animals was reduced by 26% and cortical thickness was reduced by 19% at P60 (Figs 1A and B, and EV1A and B). Conditional deletion of *Sas4* from NPCs using *Nestin-Cre* (hereafter referred to as *Sas4^{CKO}*) produced a more severe microcephaly phenotype leading to a 30% reduction in telencephalic area and a 17% reduction in cortical thickness at P14 (Figs 1C and D, and EV1C and D) (Insolera *et al*, 2014). As previously reported, *Sas4^{CKO}* mice also lack cilia and develop severe hydrocephalus and cerebellar hypoplasia (Chizhikov *et al*, 2007; Insolera *et al*, 2014). As a consequence, 33% of *Sas4^{CKO}* mice failed to survive past P14 (Fig EV3D).

To examine how the loss of CEP63 and SAS4 disrupted centriole duplication and spindle organization *in vivo*, we analyzed dividing NPCs at the VZ in E14.5 cortices. Loss of CEP63 led to a decline in centriole and centrosome number and a concomitant increase in the percentage of monopolar spindles in dividing NPCs, phenotypes that were even more severe in *Sas4^{CKO}* embryos (Figs 1E and F, and EV1E–G). Surprisingly, centrosome defects in *Cep63^{T/T}* and *Sas4^{CKO}* mice did not grossly disrupt the orientation of NPC divisions relative to the ventricular surface (Fig EV1H). To determine if centrosome loss leads to an increased mitotic duration *in vivo*, we calculated the fraction of phosphorylated H3-Ser10-positive (PH3⁺) mitotic cells among the Ki67⁺ cycling progenitors. The mitotic index of *Cep63^{T/T}* and *Sas4^{CKO}* developing brains were increased by 2.1- to 2.7-fold compared to control brains, consistent with a delayed progression through mitosis due to spindle assembly defects (Fig 1G and H).

To establish if NPCs from *Cep63^{T/T}* and *Sas4^{CKO}* embryos successfully completed mitosis following a mitotic delay, we performed live imaging of dissociated *Nuclear-mCherry⁺* progenitors from control, *Cep63^{T/T}* and *Sas4^{CKO}* brains (Fig 1I). Cultures generated from embryonic brains consisted of TBR2⁺ intermediate progenitors (5–10%) and PAX6⁺ radial glial cells (55–61% in WT and *Cep63^{T/T}*, 34% in *Sas4^{CKO}*) (Fig EV1I and J). As expected, centrosome loss and monopolar spindle configurations were observed in cultured *Cep63^{T/T}* and *Sas4^{CKO}* NPCs (Fig EV1K). Nevertheless, time-lapse imaging showed that > 95% of these progenitors successfully completed mitosis and divided into two daughter cells (Fig EV1L). However, while control NPCs had an average mitotic duration of

22 min, *Cep63^{T/T}* and *Sas4^{cKO}* NPCs took an average of 10 and 35 min longer to divide, respectively (Fig 1J and K). This increase in mitotic duration did not significantly alter the total cell cycle length, indicating that the duration of other cell cycle phases is not affected by the loss of CEP63 or SAS4 (Fig EV1M and N). Collectively, these data show that *Cep63^{T/T}* and *Sas4^{cKO}* NPCs delay in mitosis and that the length of the mitotic delay scales with the severity of centrosome loss.

Delays in NPC mitosis lead to increased frequency of cell death in the progeny

We next evaluated if the mitotic delay observed in NPCs leads to an alteration in the fate of progeny cells. To assess this, we tracked the progeny of NPCs after mitotic exit and determined if they divided, arrested, or underwent cell death (Movies EV1 and EV2). While 60% of control progeny re-entered mitosis within the time frame of

- J Representative images from live-cell movies of *Nuclear-mCherry⁺* *WT*, *Cep63^{T/T}*, and *Sas4^{CKO}* NPCs. The timing of mitosis began at nuclear envelope breakdown (NEBD) and finished at nuclear envelope reformation. White arrows track the mitotic events of the mother cell from NEBD to the generation of daughter cells following cytokinesis.
- K Plot showing the duration of mitosis in *WT*, *Cep63^{T/T}*, and *Sas4^{CKO}* NPCs. Triangles represent individual cells; triangles of the same color represent cells derived from the same embryo. Circles represent the average mitotic duration of cells from each embryo. *WT* $n = 202$ cells, $N = 4$ embryos; *Cep63^{T/T}* $n = 141$ cells, $N = 3$ embryos; *Sas4^{CKO}* $n = 138$ cells, $N = 3$ embryos; two-tailed Welch's *t*-test.

Data information: All data represent the means \pm SEM. * $P < 0.05$; ** < 0.01 ; *** < 0.001 ; **** < 0.0001 and not significant indicates $P > 0.05$. See also Fig EV1.

our movies, only 38% of *Cep63^{T/T}* and 29% of *Sas4^{CKO}* daughter cells divided again (Figs 2A–C and EV2A). In the case of control cells, the majority of the non-proliferative progeny underwent a cell cycle arrest, while a small fraction of NPCs (9%) died in interphase (Fig 2A). By contrast, the progeny of *Cep63^{T/T}* and *Sas4^{CKO}* NPCs underwent much higher rates of cell death (25 and 37%, respectively) (Figs 2B and C, and EV2A).

We hypothesized that the NPCs with mitotic delays would preferentially undergo cell death. To test this, we evaluated the fate of progeny derived from NPCs that experienced a normal or delayed mitosis. Virtually all control (92%) NPCs completed mitosis within 30 mins, and thus, we classified delayed mitosis as lasting longer than 30 mins (Fig 2A and D). Control, *Cep63^{T/T}* and *Sas4^{CKO}* NPCs that progressed through mitosis in ≤ 30 mins produced primarily viable progeny (Fig 2A–F). By contrast, control, *Cep63^{T/T}* and *Sas4^{CKO}* NPCs that delayed in mitosis produced an increased frequency of non-viable progeny. Moreover, the frequency of cell death increased with the duration of the extended mitosis (Fig 2D–F). In the most extreme cases in which *Sas4^{CKO}* NPCs spent > 90 min in mitosis, 16% of the mother cells died during cell division, while 66% of the progeny underwent cell death in the following interphase (Fig 2F). These data argue that the probability of generating non-viable progeny increases with mitotic duration.

Since chromosome missegregation has been shown to occur following centrosome loss or delays in cell division (Lambrus *et al*, 2015; Wong *et al*, 2015), we assessed whether loss of CEP63 or SAS4 was associated with an increase in aneuploidy in the brain. We performed single-cell DNA sequencing of dissociated NPCs from two control, *Cep63^{T/T}* and *Sas4^{CKO}* E14.5 cortices. While all of the control and *Cep63^{T/T}* cells analyzed were diploid, 5% (2/42) of the cells from *Sas4^{CKO}* brains showed gains of a large region of chromosome 14, and in one case, an accompanying loss of a large part of chromosome 9 (Figs 2G and H, and EV2B). We conclude that the mitotic delay observed in *Sas4^{CKO}* NPCs is associated with only a modest increase in the level of aneuploidy.

Our findings suggest that centrosome defects prolong mitosis in NPCs, leading to an increased frequency of cell death in the progeny. Therefore, we analyzed whether TP53 was induced following

centrosome loss in *Sas4^{CKO}* and *Cep63^{T/T}* dissociated progenitors. We observed a > 5 -fold increase in the fraction of TP53⁺ progenitors in dissociated cultures from *Cep63^{T/T}* and *Sas4^{CKO}* cortices (Fig EV2C–E). Moreover, $> 70\%$ of the TP53⁺ *Cep63^{T/T}* and *Sas4^{CKO}* NPCs had a reduction in centrosome number (Fig EV2E). Since aneuploidy is rare in the *Cep63^{T/T}* and *Sas4^{CKO}* brains, the upregulation of TP53 in NPCs with centrosome defects is unlikely to be a result of chromosome missegregation.

Centrosome defects activate the mitotic surveillance pathway to reduce cortical expansion

Centrosome defects have been shown to activate the mitotic surveillance pathway by delaying mitosis (Uetake & Sluder, 2010; Bazzi & Anderson, 2014; Fong *et al*, 2016; Lambrus *et al*, 2016; Meitinger *et al*, 2016). Thus, we set out to test whether pathological activation of the mitotic surveillance pathway causes the reduced cortical expansion in *Cep63^{T/T}* and *Sas4^{CKO}* animals. While knockout of *Trp53*, *Usp28*, or *Trp53bp1* alone did not alter brain size (Fig EV3A and B), genetic ablation of *Usp28* or *Trp53bp1* largely restored the telencephalic area and cortical thickness of *Cep63^{T/T}* mice at P60 and of *Sas4^{CKO}* animals at P14 (hereafter referred to as double knockout animals) (Fig 3A–F). Intriguingly, knockout of *Usp28* or *Trp53bp1* did not rescue the reduced body weight of young *Cep63^{T/T}* mice, suggesting that centrosome defects cause whole-body growth retardation and microcephaly via distinct mechanisms (Fig 3G). As expected, the severe hydrocephalus and cerebellar hypoplasia caused by the loss of cilia in *Sas4^{CKO}* brains were also not rescued by knockout of *Usp28* or *Trp53bp1* (Figs 3A and EV3C). Nevertheless, *Sas4^{CKO};Usp28^{CKO}* and *Sas4^{CKO};Trp53bp1^{-/-}* mice had improved overall survival compared to *Sas4^{CKO}* animals, showing that alleviating microcephaly extended the lifespan of these animals (Fig EV3D).

To assess the organization of the cortical layers in the adult brain, we compared the number of CUX1⁺ cells in the superficial layers (layer II–IV) and CTIP2⁺ cells in the deep layers (layer V–VI) of the cortex between control, *Cep63^{T/T}*, *Sas4^{CKO}*, and double knockout animals. *Cep63^{T/T}* cortices showed a loss of CUX1⁺ upper layer and CTIP2⁺ deep layer neurons, while *Sas4^{CKO}* brains had a preferential reduction of CUX1⁺ neurons (Figs 3H–K and EV3E–H). By

contrast, the overall cell density and the total number of CUX1⁺ and CTIP2⁺ neuronal subtypes in double knockout animals were similar to that of control mice (Figs 3H–K and EV3E–H). Collectively, these data demonstrate that genetic ablation of the mitotic surveillance pathway can restore brain size and the abundance of neurons in two microcephaly mouse models with centrosome defects.

Inactivation of the mitotic surveillance pathway prevents the attrition of NPCs in mice with centrosome defects

To determine if the rescue of cortical size and neuronal production in double knockout animals was associated with a restoration of the NPC pool, we analyzed the abundance of PAX6⁺ RGCs and TBR2⁺

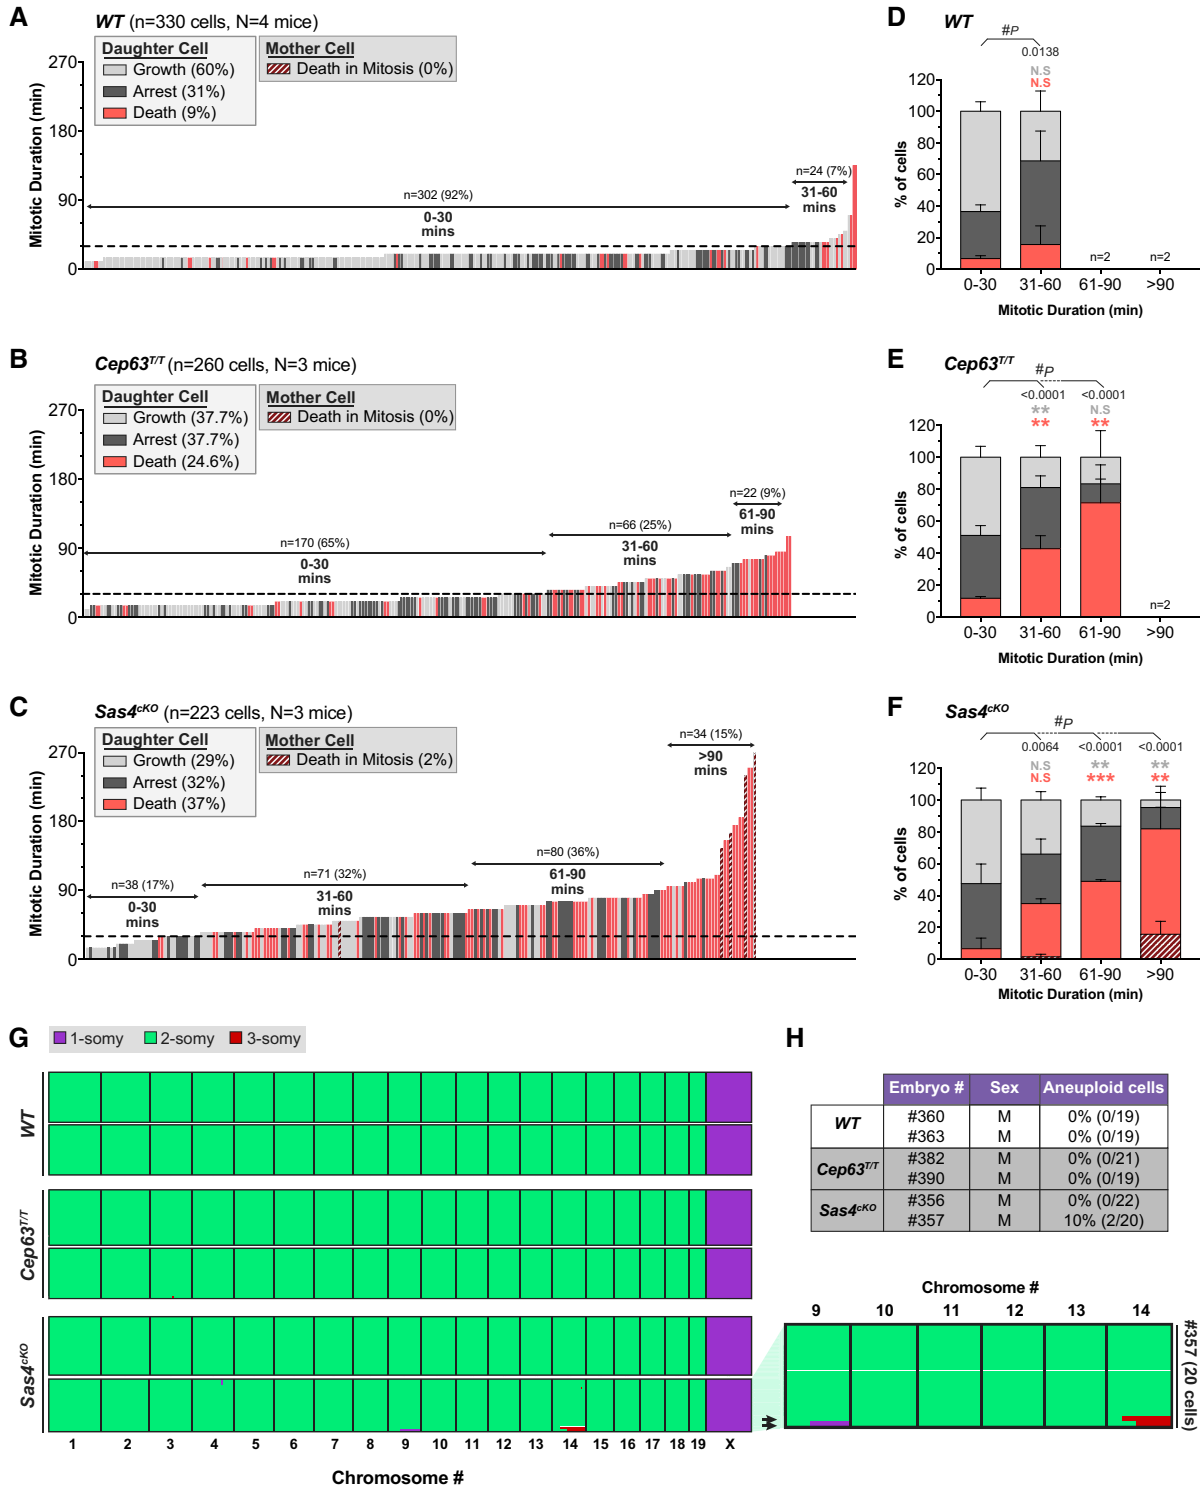

Figure 2.

Figure 2. Prolonged mitosis leads to an increased frequency of cell death in the progeny of NPCs.

- A–C Graph showing the mitotic duration of NPCs and the fate of their progeny in primary cultures generated from E14.5 embryos. Each bar represents one cell; its height represents the amount of time the mother cell spent in mitosis; bar color represents the fate of the progeny. Dashed line is set at 30 mins. *WT* $n = 330$ cells, $N = 4$ embryos; *Cep63^{T/T}* $n = 260$ cells, $N = 3$ embryos; *Sas4^{CKO}* $n = 223$ cells, $N = 3$ embryos.
- D–F Percentage of proliferating, arrested and apoptotic progeny within each group of the indicated mitotic duration, calculated from data shown in (A–C); groups with $n < 20$ cells were excluded from this quantification; #, chi-square test with *, *post hoc* analysis, within each genotype, comparisons are made to the 0–30 min group.

IPs in E14.5 brains from control, *Sas4^{CKO}*, *Cep63^{T/T}*, and double knockout animals. Consistent with previous reports, the number of RGCs was reduced in both *Cep63^{T/T}* and *Sas4^{CKO}* cortices (Insolera et al, 2014; Marjanovic et al, 2015; Fig 4A and B). In addition, a portion of these progenitors were displaced from their normal position in the VZ and mislocalized to regions further away from the ventricle (Fig 4A). TBR2⁺ IPs were also significantly reduced in *Sas4^{CKO}* but not in *Cep63^{T/T}* cortices (Fig 4A and C).

While the deletion of the mitotic surveillance pathway genes alone did not alter the number of PAX6⁺ or TBR2⁺ NPCs in the developing cortex (Fig EV4A and B), knockout of *Usp28* restored both populations of progenitors in *Sas4^{CKO}* and *Cep63^{T/T}* cortices to levels similar to that in controls (Fig 4A–C). Although the total number of progenitors in the double knockout cortices was comparable to control mice, we observed a large population of ectopic PAX6⁺ RGCs in the SVZ and intermediate zone (IZ) of the developing neocortex (Fig 4A). A similar phenotype has been reported in *Sas4^{CKO};Trp53^{-/-}*, and *Cep63^{T/T};Trp53^{-/-}* mice and arises due to the suppression of cell death in the misplaced RGCs (Insolera et al, 2014; Marjanovic et al, 2015). We also observed ectopic IPs in both *Sas4^{CKO};Usp28^{CKO}* and *Cep63^{T/T};Usp28^{-/-}* embryonic brains that were displaced from the SVZ (Fig 4A). Altogether, these data show that inactivation of the mitotic surveillance pathway rescues the attrition of the NPC pool in mice with centrosome defects but does not prevent the NPC delamination.

To establish whether suppression of apoptosis contributed to the restoration of NPC pools, we analyzed the levels of TP53 and cleaved-caspase 3 (CC3) at E14.5. Only rare instances of TP53 and CC3 labeling were observed in the cortex of control mice (Fig 4D–F). However, TP53⁺ and CC3⁺ cells were widespread in the cortex of *Cep63^{T/T}* and *Sas4^{CKO}* animals, with cell death occurring in both NPCs and TBR1⁺ neurons (Figs 4D–F, and EV4C and D). Strikingly, deletion of *Usp28* reduced the number of TP53 and CC3-expressing cells in the *Sas4^{CKO}* and *Cep63^{T/T}* cortices to levels similar to that observed in control brains (Fig 4D–F). This shows that activation of the mitotic surveillance pathway is responsible for TP53 upregulation and cell death in NPCs and neurons.

To determine whether the loss of SAS4 or CEP63 leads to DNA damage that can activate TP53, we stained cortices with the DNA double-strand break marker γ -H2AX. Although there was a minor increase in γ -H2AX⁺ cells in both *Cep63^{T/T}* and *Sas4^{CKO}* animals, the staining occurred in apoptotic cells with either a condensed DNA morphology or no DNA staining (Fig EV4E and F). DNA damage occurs in dying cells as a result of caspase-activated DNase activity

(Enari et al, 1998). In accordance with this, suppression of cell death by knockout of *Usp28* dramatically reduced the number of γ -H2AX⁺ cells in *Cep63^{T/T}* and *Sas4^{CKO}* cortices (Fig EV4E and F). We conclude that centrosome defects induced by loss of SAS4 or CEP63 do not lead to an increase in DNA damage outside of apoptotic cells.

Inactivation of mitotic surveillance does not rescue centrosome function or alleviate mitotic delays in *Sas4^{CKO}* and *Cep63^{T/T}* NPCs

To determine if the primary deficits persist following inactivation of the mitotic surveillance pathway, we analyzed centrosome number and mitotic duration in *Sas4^{CKO}* and *Cep63^{T/T}* NPCs that lacked *Usp28*. Similar to what we observed in the cortex of *Cep63^{T/T}* and *Sas4^{CKO}* mice, mitotic progenitors in *Cep63^{T/T};Usp28^{-/-}* and *Sas4^{CKO};Usp28^{CKO}* animals had reduced numbers of centrioles and an increased frequency of monopolar spindles (Figs 5A and B, and EV5A and B). To examine if mitotic delays persisted in *Sas4^{CKO}* and *Cep63^{T/T}* NPC after inactivation of the mitotic surveillance pathway, we stained E14.5 brains with PH3 and Ki67. As expected, the deletion of *Trp53*, *Usp28*, or *Trp53bp1* alone did not significantly change the mitotic index in the developing cortex (Fig EV5C). By contrast, the mitotic index in *Cep63^{T/T};Usp28^{-/-}* and *Sas4^{CKO};Usp28^{CKO}* cortices was increased to a level similar to that observed in the *Sas4^{CKO}* and *Cep63^{T/T}* mice (Fig 5C). To directly measure the mitotic duration in these NPCs, we performed live imaging of dissociated *Sas4^{CKO};Usp28^{CKO}* NPCs. This confirmed that the inactivation of the mitotic surveillance pathway did not alter the extended mitotic duration in *Sas4^{CKO}* progenitors (Fig 5D and E).

We next proceeded to track the fate of *Sas4^{CKO};Usp28^{CKO}* progeny after mitotic exit. While only 29% of *Sas4^{CKO}* progeny re-entered mitosis within the time frame of our movies, 64% of *Sas4^{CKO};Usp28^{CKO}* daughter cells divided again, which is similar to what was observed in control NPCs (Figs 5F and G, and EV5D). In the case of *Sas4^{CKO}* cells, 37% of progeny underwent cell death in interphase, and this was reduced by > 3.5-fold in *Sas4^{CKO};Usp28^{CKO}* progenitors to a level similar to that of control NPCs (Figs 5F–I, and EV5D). Importantly, knockout of *Usp28* dramatically reduced the frequency of apoptosis in the progeny that resulted from an extended mitosis (Fig 5G and I). Finally, single-cell DNA sequencing of dissociated progenitors showed that similar to *Sas4^{CKO}* mice, cells from *Sas4^{CKO};Usp28^{CKO}* brains had only modest levels of aneuploidy (2.4%, 1/41) (Fig EV5E and F). Note that this level of aneuploidy is similar to that of *Sas4^{CKO}* (5%) (Fig 2G and H). Thus, the continued proliferation of NPCs with centrosome defects does not lead to a clear

increase in chromosome segregation errors. We conclude that inactivation of the mitotic surveillance pathway rescues the proliferation of NPCs downstream of the centrosome defects and extended mitoses.

To directly test if the mitotic surveillance pathway is responsible for triggering apoptosis in NPCs with extended mitotic duration, we adopted an approach to reversibly delay NPCs in mitosis using the spindle poison nocodazole (Uetake & Sluder, 2010; Pilaz et al, 2016). Dissociated control and *Usp28^{CKO}* NPCs were treated with

nocodazole for 4 h to delay cells in mitosis and subsequently released into drug-free media for an additional 48 h (Fig EV5G). This approach allowed us to track the fate of progeny from cells with different mitotic durations. Control and *Usp28^{CKO}* NPCs that entered mitosis following nocodazole washout divided with a normal mitotic duration, showing that the drug treatment was fully reversible (Fig EV5H, K and L). 47% of control cells that were delayed in mitosis (> 30 min) produced non-viable progeny (Fig EV5H and I). By contrast, cell death was reduced by 2.6-fold in

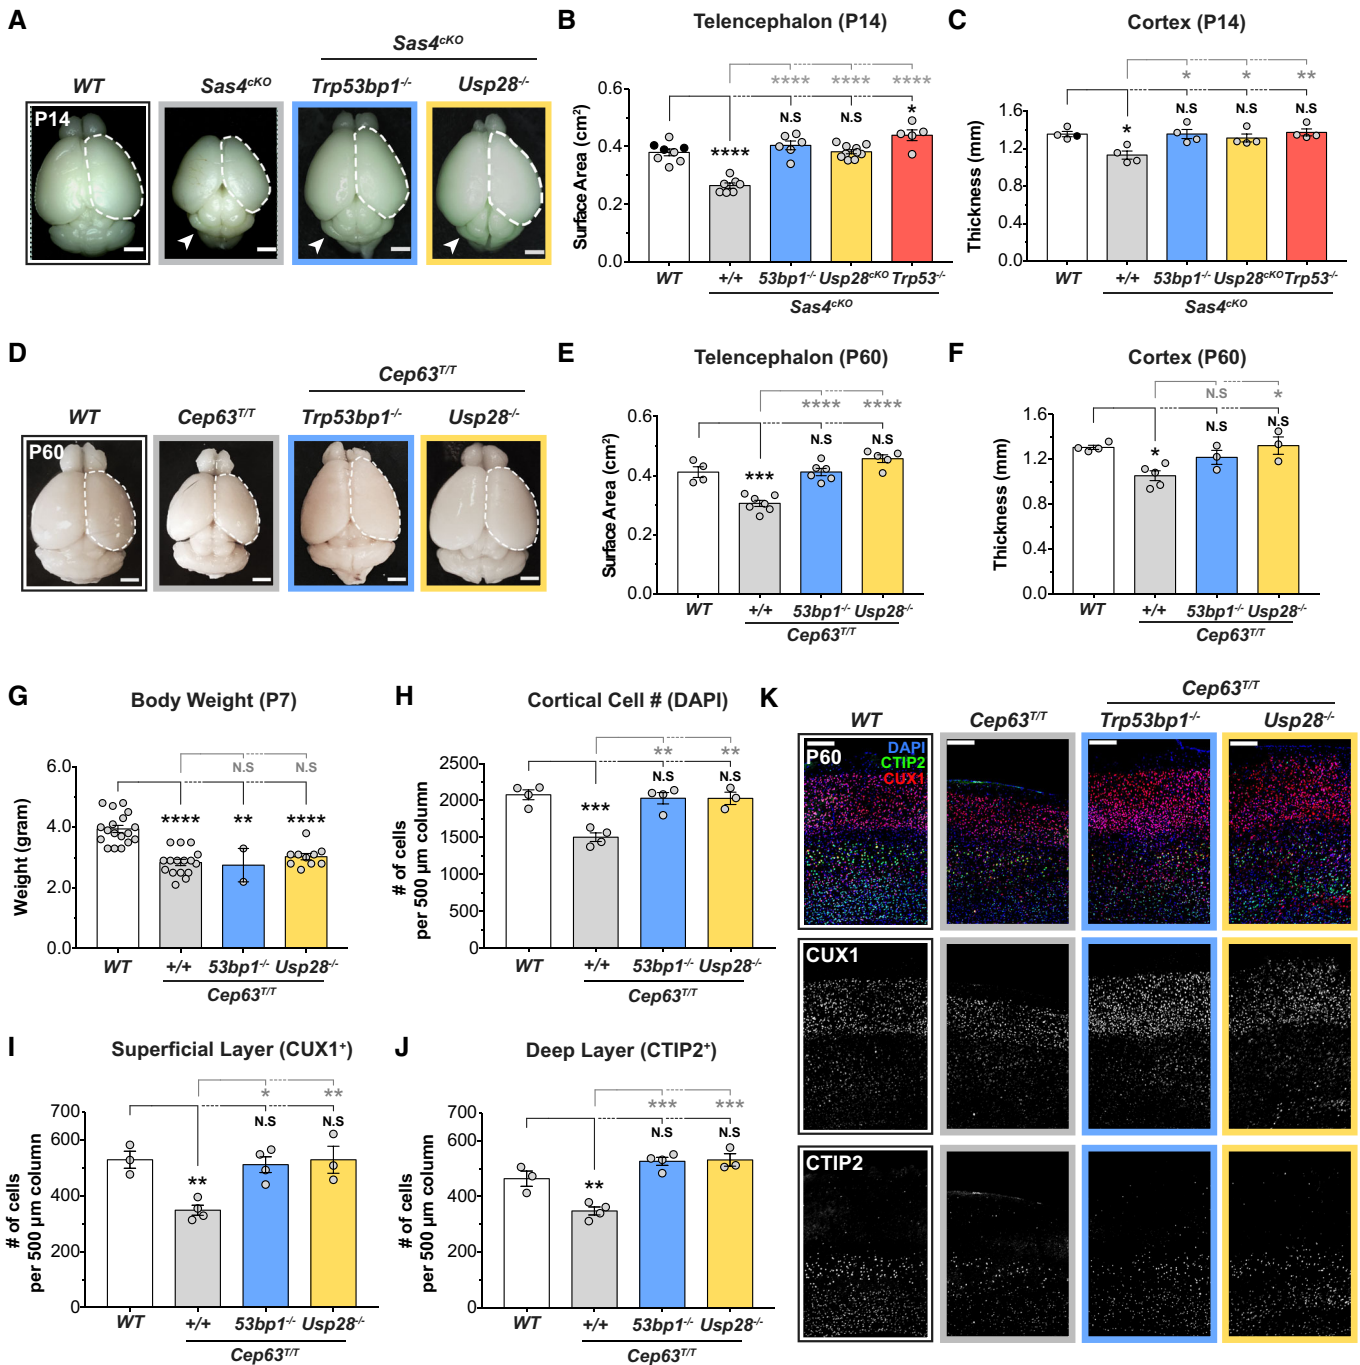

Figure 3.

Usp28^{cko} NPCs that experienced similarly prolonged mitoses (Fig EV5H and J). Altogether, these data confirm that USP28 is required to initiate cell death in the progeny of cells that delay in mitosis.

Distinct pathways lead to TP53 activation in microcephaly

Our data suggest that activation of the mitotic surveillance pathway is a central cause of microcephaly in multiple mouse models with centrosome dysfunction. To examine whether defects in non-centrosomal genes also cause microcephaly via activation of the mitotic surveillance pathway, we examined a microcephaly mouse model caused by loss of the structural maintenance of chromosome (SMC) complex protein SMC5. The SMC5/6 complex is best characterized for its function in DNA repair and maintenance of genome stability (Fousteri & Lehmann, 2000; Sergeant *et al*, 2005; Zhao & Blobel, 2005), and mutations in the SMC5/6 complex component *NSMCE2* cause primordial dwarfism and microcephaly in humans (Payne *et al*, 2014). Conditional deletion of *Smc5* using *Nestin-Cre* (hereafter referred to as *Smc5^{cko}*) did not alter centriole or centrosome number in dividing NPCs (Fig 6A–C) or increase the mitotic index in the developing neocortex (Fig 6D and E). However, loss of *Smc5^{cko}* resulted in increased numbers of TP53⁺ and CC3⁺ cells in the cortex at E14.5 (Figs 6F and G, and EV6A), leading to a 24% reduction in telencephalic area at P21 (Fig 6H and I).

Prior work has shown that knockout of TP53 partially rescues progenitor numbers and the microcephaly phenotype in *Smc5^{cko}* animals (Atkins *et al*, 2020). We, therefore, tested if the knockout of the mitotic surveillance pathway component *Usp28* can also rescue brain size in *Smc5^{cko}* mice. Genetic ablation of *Usp28* failed to provide any rescue of brain size in *Smc5^{cko}* mice (Figs 6H and I, and EV6B). Thus, these data show that genetic deletion of *Usp28/Trp53bp1* and *Trp53* are not functionally equivalent *in vivo*, and that deficiency in the SMC5/6 complex leads to activation of TP53 independently of the mitotic surveillance pathway.

Discussion

Previous work in cultured cells showed that centrosome loss activates the mitotic surveillance pathway by prolonging mitosis (Fong *et al*, 2016; Lambrus *et al*, 2016; Meitinger *et al*, 2016). However, the consequence of activating this pathway *in vivo* remain unexplored. In this manuscript, we provide several lines of evidence to support the proposal that pathological activation of the mitotic surveillance pathway leads to NPC depletion and reduced brain growth in microcephaly mouse models with centrosome defects. First, NPCs with centrosome defects delay in mitosis, and the probability of producing non-viable cells increased with mitotic duration. Second, inactivation of the mitotic surveillance pathway suppresses apoptosis and restores NPC pools and brain size in two microcephaly models. Third, this restoration of the NPC number occurs without correction of the upstream defect in centrosome function or the increase in mitotic duration. Altogether, these data argue that activation of the mitotic surveillance pathway is a central cause of microcephaly in mice, and potentially human patients, with centrosome dysfunction.

Our findings are consistent with previous work showing that extending mitosis in NPCs leads to increased apoptotic progeny and premature differentiation (Pilaz *et al*, 2016; Mitchell-Dick *et al*, 2020). We show that depletion of centrosome proteins that are mutated in human patients with microcephaly delays bipolar spindle assembly and prolongs mitosis in NPCs. Delayed NPCs complete mitosis with minimal chromosome segregation errors, but the extended mitotic duration increases the frequency of death in the resulting progeny. This apoptotic phenotype was suppressed by the deletion of USP28, leading to a full rescue of telencephalon size and cell number in the adult brains of *Sas4^{cko}* and *Cep63^{TT}* animals. Although *Cep63^{TT};Usp28^{-/-}* and *Sas4^{cko};Usp28^{cko}* embryonic brains have restored NPC pools, some progenitors are located outside of the VZ and SVZ. This is consistent with prior work showing that centrosome loss leads to the delamination of RGCs from the VZ (Insolera *et al*, 2014; Marjanovic *et al*, 2015). Knockout of

Data information: All data represent the means \pm SEM. **P* < 0.05; **< 0.01; ***< 0.001; ****< 0.0001 and not significant indicates *P* > 0.05. See also Fig EV4.

USP28 suppresses apoptosis in these ectopic RGCs, allowing them to continue to proliferate and produce the correct number of IPs and neurons. Thus, while our analysis of cortical layer markers showed that the gross organization of adult *Cep63^{T/T};Usp28^{-/-}* and *Sas4^{CKO};Usp28^{CKO}* cortices are normal, we do not rule out specific defects in lamina organization or brain function. Nevertheless, our data clearly demonstrate that genetic ablation of the mitotic surveillance pathway is sufficient to restore the proliferation of NPCs with centrosome defects and rescue neuronal loss and microcephaly in adult animals.

Although multiple microcephaly genes have established functions at the centrosome, several of these genes have reported roles in DNA damage signaling and defects in many DNA repair and DNA damage signaling factors also result in microcephaly (Jayaraman *et al*, 2018). Several lines of evidence argue that the depletion of NPCs in *Sas4^{CKO}* and *Cep63^{T/T}* animals is a result of activating the mitotic surveillance pathway and not a consequence of DNA damage signaling. First, while long mitotic delays of > 8 h can lead to the initiation of apoptosis and subsequent DNA damage (Orth *et al*, 2012), the mitotic delay caused by loss of CEP63 or SAS4 in NPCs was well below this threshold, with the majority of *Cep63^{T/T}* and *Sas4^{CKO}* progenitors completing mitosis in less than 90 min. Second, we, and others, did not observe an increase in DNA breaks outside of the apoptotic cells in the cortices of *Cep63^{T/T}* and *Sas4^{CKO}* animals (Insolera *et al*, 2014;

Marjanovic *et al*, 2015). Third, despite not being critical for the DNA damage response *in vitro* and *in vivo* (Knobel *et al*, 2014), USP28 removal can dramatically rescue NPC abundance and suppress cell death in both *Cep63^{T/T}* and *Sas4^{CKO}* embryonic brains. Finally, prior work showed that unlike removing TP53, loss of ATM or CHK2 does not rescue the microcephaly phenotype in *Cep63^{T/T}* mice (Marjanovic *et al*, 2015). Taken together with previous data in cultured cells demonstrating that the mitotic surveillance pathway is mechanistically distinct from the DNA damage response (Fong *et al*, 2016; Lambrus *et al*, 2016; Meitinger *et al*, 2016), our data strongly indicate that activation of the mitotic surveillance pathway is the major mechanism leading to NPC depletion in the developing neocortex with centrosome defects.

Nevertheless, our work highlights that multiple mechanisms can promote TP53 activation and the attrition of NPCs in the neocortex. Defects in DNA double-strand break (DSB) repair factors, including LIG4, NBS1 and RAD50, have been shown to result in apoptosis in the developing brain and underlie multiple human syndromes characterized by microcephaly (McKinnon, 2017). Loss of ATM, CHK2, or TP53 rescued viability and suppressed neuronal apoptosis in LIG4-deficient mice and *Trp53* deletion suppressed cell death in mice lacking NBS1 (Carney *et al*, 1998; Varon *et al*, 1998; Frank *et al*, 2000; Lee *et al*, 2000; O'Driscoll *et al*, 2001; Frappart *et al*, 2005; Waltes *et al*, 2009;

- J Model for two TP53-dependent pathways underlying primary microcephaly. In the first model, NPCs with mutations in centrosome genes take longer to assemble their spindle in mitosis. This delay triggers the activation of the mitotic surveillance pathway, which activates TP53 through 53BP1 and USP28. By contrast, in microcephaly caused by mutations in genes required for DNA repair or genome stability, centrosome function and mitotic duration are unaffected. Instead, accumulated DNA lesions trigger DNA damage signaling in NPCs to activate TP53. In both models, increased TP53 activity leads to apoptosis, thus depleting the NPC pool and decreasing the final number of neurons.

Data information: All data represent the means \pm SEM. * $P < 0.05$; *** < 0.001 ; **** < 0.0001 and not significant indicates $P > 0.05$. See also Fig EV6.

Foster et al, 2012), indicating that DSBs potentially activate TP53 through the ATM-CHK2 pathway during neurodevelopment. Consistent with these previous findings, our data show that while knockout of TP53 largely rescued brain size in *Smc5^{CKO}* animals, the loss of USP28 had no effect. In addition, loss of SMC5 in cultured cells activates CHK2 (Venegas et al, 2020) and knockout of *Chk2* also rescues microcephaly in *Smc5^{CKO}* animals (Atkins et al, 2020), further establishing that the role of USP28 in rescuing NPCs is uncoupled from DSB signaling. Thus, we propose that centrosome defects activate TP53 via the USP28-dependent mitotic surveillance pathway, while DNA damage signaling in response to DSBs can independently upregulate TP53 through ATM and CHK2 (Fig 6J). The pathways that feed into TP53 activation in NPCs are therefore likely to vary depending on the particular function of the microcephaly gene that is mutated. In this regard, it is also worth noting that microcephaly caused by hypomorphic mutations in ATR, an ATM-related kinase that responds to replication stress and is mutated in Seckel Syndrome, is exacerbated by *Trp53* deletion (O'Driscoll et al, 2003; Murga et al, 2009). This indicates that while TP53 activation is a prominent cause of microcephaly, there are also TP53-independent pathways relevant to microcephaly that are caused by non-centrosomal defects.

While mutations in some centrosome proteins cause both primary microcephaly and dwarfism (Chavali et al, 2014), several microcephaly genes only affect brain size (Mahmood et al, 2011). This leads to an outstanding conundrum of why mutations in ubiquitously expressed centrosome proteins selectively impact brain development. One explanation could be that NPCs have a lower threshold for activating the mitotic surveillance pathway compared to other cell types. Our data from dissociated cultures suggest that this threshold is set at around 30 min for NPCs, with cell death steadily increasing with additional time spent in mitosis. Whether this threshold is indeed higher for other proliferating cells in the body remains to be tested. Another possible explanation is that activation of the mitotic surveillance pathway promotes different cellular responses between NPCs and other cell types. In retinal pigment epithelial (RPE1) cells, TP53 targets CDKN1A (P21) and triggers a G1 arrest instead of cell death following an extended mitosis (Fong

et al, 2016; Lambrus et al, 2016; Meitinger et al, 2016). This suggests that TP53 signaling occurs through different downstream factors to induce apoptosis in NPCs. Last but not least, our data reveal that although inactivation of the mitotic surveillance pathway restores brain size in *Cep63^{T/T}* mice, these double knockout animals still display body growth retardation. This argues that mutations in centrosome genes can cause brain and body size reduction through distinct pathological mechanisms.

In conclusion, our data provide evidence to support the pathological role of the mitotic surveillance pathway in neurodevelopmental disorders. Inhibitors of USP28 are under development and may have therapeutic utility in disorders of brain growth (Wrigley et al, 2017). Understanding the biochemical “timing” mechanism that allows cells to measure mitotic duration and what sets the sensitivity of this response are important questions for the future.

Materials and Methods

Animals

Cep63^{T/T} mice were obtained from the laboratory of T. Stracker (Institute for Research in Biomedicine, Spain; Marjanovic et al, 2015). The following primers were used for genotyping: *Cep63-5P2*, 5'-GTAGGACCAGCCTTAGCGTTAG-3'; *Cep63-3P1a*, 5'-TAAGTGT AAAAGCCGGGCGTGGT-3' and MutR (B32), 5'-Caagcggaatgtgggta acg-3'.

Sas4^{CKO} mice were obtained from the laboratory of K. Anderson (Memorial Sloan Kettering Cancer Center, USA; Bazzi & Anderson, 2014). The following primers were used for genotyping: *Cenpj LoxP2 F*, 5'-TGCTTGCTTCTCTCTCTCTGA-3'; *Cenpj LoxP2 R* 5'-GCTGACACCAAGTGGGAAAT-3'; *Cenpj FRT1F* 5'-GGGAGCAG ACTTCAACT-3'.

Smc5^{CKO} mice were generated in the laboratory of P. Jordan (Johns Hopkins Bloomberg School of Public Health, USA; Atkins et al, 2020). The following primers were used for genotyping: *Smc5F (WT/Flox) Primer1 Fwd* 5'-ACTCAGTCTCACACGGCAAG-3'; *Smc5F (WT/Flox) Primer2 Rev* 5'-ATCCTTCCCACCTTGAAAC-3'.

Nestin-Cre mice were obtained from The Jackson Laboratory (stock #003771). The following primers were used for genotyping: Nestin-Cre Fwd 5'-ATTGCTGTCACCTGGTCGTGGC-3'; Nestin-Cre Rev 5'-GGAAAATGCTTCTGTCCGTTTGC-3'.

Trp53bp1^{-/-} mice were obtained from the laboratory of S. Franco at (Johns Hopkins University School of Medicine, USA; Rybanska-Spaeder *et al*, 2013). The following primers were used for genotyping: 53bp1 Common 10694 5'-GAACTTGGCTCACACCCATT-3'; 53bp1 WT 10693 5'-CTCCAGAGAGAACCAGCAG-3'; 53bp1 Mut oIMR5316 5'-CTAAAGCGCATGCTCCAGAC-3'.

Usp28^{F/-} mice were obtained from the laboratory M. Eilers (University of Wuerzburg, Germany; Diefenbacher *et al*, 2014). The following primers were used for genotyping: Usp28 Common Fwd 1718 27 5'-GAGGCTTGAGTTATGACTGG-3'; Usp28 WT Rev 1718 m28 5'-AGAACACCTGCTGCTTAAGC-3'; Usp28 Del Rev 5'-TCCCCAAGAGTGTTTTTCAC-3'.

Trp53^{-/-} mice were obtained from The Jackson Laboratory (stock #02101). The following primers were used for genotyping: TP53 COMMON 01 MR 0336 5'-ATAGGTCGGCGGTTTCAT-3'; TP53 WT 01MR 0337 5'-CCCGAGTATCTGGAAGACAG-3'; TP53 MUT 01MR 0013 5'-CTTGGGTGGAGAGGCTATTC-3'.

Nuclear-mCherry^{F/FI} mice were obtained from The Jackson Laboratory (stock #023139). The following primers were used for genotyping: Nuclear-mCherry COM Fwd oIMR8545 5'-AAAGTCGCTCTGAGTTGTAT-3'; Nuclear-mCherry WT Rev oIMR8546 5'-GGAGCGGGAGAAATGGATATG-3'; Nuclear-mCherry Flox Rev 10507 5'-TTATGTAACCGGAACTCCA-3'.

Analysis of *Smc5*^{CKO} and *Cep63*^{T/T} mice and associated genotypes was performed on a congenic C57BL6 background, while analysis of *Sas4*^{CKO} mice and associated genotypes was performed on a mixed FVB/NJ and C57BL6 background. Genotyping was carried out using standard PCR protocols. Embryos and adults from both genders were included in our analysis. Mice were housed and cared for in an AAALAC-accredited facility, and all animal experiments were conducted in accordance with Institute Animal Care and Use Committee approved protocols.

Post-natal brain dissection, whole-brain imaging, and histology

Post-natal day 14 (P14), P21 and P60 animals were anesthetized with Avertin before being perfused with PBS and 1% paraformaldehyde. The brains were removed from the skull and post-fixed in 4% paraformaldehyde overnight at 4°C. The next day, the brains were rinsed three times with PBS before being weighed and imaged using a MU1003 digital camera attached to a dissecting microscope (Amscope). The two hemispheres were separated down the midline; one hemisphere was processed for cryosectioning (details below), while the other hemisphere was sent for histological analysis. The Johns Hopkins University, School of Medicine, phenotyping core performed the tissue processing, paraffin embedding and hematoxylin & eosin staining.

Brain section, immunohistochemistry, and confocal imaging

For analysis of embryonic brain sections, timed pregnant females carrying the respective transgenes were anesthetized with isoflurane before cervical dislocation. The heads of the embryos were removed and rinsed with ice-cold PBS, followed by incubation in 4%

paraformaldehyde for 4 h (for TBR1 and Mouse-Pax6 antibody specifically) or overnight (for all other antibodies) at 4°C. The next day, the brains were dissected out of the skulls, rinsed three times in PBS before being incubated in 30% sucrose at 4°C for 24 h. Brains were embedded in O.C.T medium and frozen for cryosectioning. 20 µm brain sections were cut using a Leica CM1950 or CM3050 cryostat and collected on Superfrost microscope slides (Thermo Fisher Scientific). For immunohistochemistry staining, the brain sections were rehydrated with PBS, blocked and permeabilized with blocking solution (10% donkey serum (Sigma Aldrich), 0.1-0.5% Triton X-100 in PBS), and incubated with the respective primary antibodies diluted in blocking solution for 12 h at 4°C or 1.5 h at RT (Table EV3). The following primary antibodies were used: Rabbit-PAX6 (Covance, PRB-278P, 1:500), Chicken-TBR2 (EMD Millipore, AB15894, 1:250), Rat-α-tubulin (Pierce Antibodies, MA1-80017, 1:500), Goat-γ-tubulin (homemade, polyclonal, raised against the peptide CDEYHAATRPDIYSWGTQEQ, 1:500), Rabbit-Ki67 (D3B5) (Cell Signaling, 9129, 1:500), Mouse-PH3 (Cell Signaling, 9701, 1:100), Rabbit-CC3 (Asp175) (Cell Signaling, 9661, 1:500), Rabbit-centrin (in house, raised against human centrin2 (a.a. 1-172); 1:500), Rabbit-γ-H2AX (p-Ser139) (Cell Signaling, 2577, 1:250), Mouse-TP53 (1C12) (Cell Signaling, 2524S, 1:250), Mouse-TBR1 (ProteinTech, 66564-1-Ig, 1:250) and Mouse-PAX6 (Thermo Fisher Scientific, MA1-109, 1:250). Following primary antibody staining, the tissue slides were washed 3 times with PBST (0.1-0.5% Triton X-100) and incubated with secondary antibodies and DAPI diluted in blocking solution for 1 h at room temperature. Following secondary antibody staining, the tissue slides were washed three times with PBST before mounting. Secondary antibodies were conjugated to Alexa Fluor 488, 555, or 647 (Thermo Fisher Scientific, 1:500).

For analysis of P14, P21 and P60 brain sections, the brains were dissected and post-fixed in 4% paraformaldehyde at 4°C overnight as described above. The next day, brains were rinsed with PBS, incubated in 30% sucrose for at least 48 h and embedded in O.C.T medium. 20 µm brain sections were collected onto Superfrost microscope slides. For antigen retrieval, slides containing the brain sections were rehydrated with PBS and boiled in citrate buffer (10 mM citric acid, 0.1% Triton X-100, pH 6.0) at 95°C for 15 min. Slides were then rinsed three times in PBS before being incubated with blocking solution and stained with respective primary and secondary antibodies, as described above. The following primary antibodies were used: Rat-CTIP2 (Abcam, ab18465, 1:1,000) and Rabbit-CUX1 (ProteinTech, 11733-1-AP, 1:1,000). Secondary antibodies were conjugated to Alexa Fluor 488, 555, or 647 (Thermo Fisher Scientific, 1:500).

Stained tissue sections were mounted in ProLong Gold Antifade Mountant (Invitrogen). Images of stained sections were obtained using an LSM700 (Zeiss) or SP8 (Leica Microsystems) confocal microscope. For centrosome and centriole staining, images were collected using a Leica 63× 1.40 NA oil objective at 0.25 µm z-sections. For all other staining, images were collected using a Zeiss 20× 0.8 NA air objective at 1 µm z-sections.

Neural progenitor primary cultures

Embryos at embryonic day 14.5 (E14.5) were removed from pregnant females following cervical dislocation. The brain was removed

from the skull and the dorsolateral telencephalon isolated as previously described (Landeira *et al*, 2017). Following dissection, the dorsolateral telencephalon tissues were incubated with Trypsin-EDTA (0.05%) for 10 min at 37°C. Proliferation medium (10% FBS, 0.4% glucose, 1% penicillin/streptomycin in DMEM) was added to stop Trypsin activity, and the cells were mechanically dissociated by gentle pipetting. Cells were then washed twice with proliferation medium to remove residual Trypsin before being counted. For time-lapse imaging, 500,000 cells were seeded into each well of a 48-well glass-bottom plate (MatTek Corporation) or 8-chamber glass-bottom dish (ibidi) coated with Poly-D-Lysine. For immunofluorescence staining, 1,000,000 cells were seeded onto 12-mm glass coverslips (Thermo Fisher Scientific) coated with Poly-D-Lysine. Seeded cells were maintained at 37°C, 5% CO₂ for 2–5 h before being used for fixed or live-cell imaging.

Time-lapse Imaging of neural progenitor culture

Cells were maintained in proliferation media at 37°C, 5% CO₂ with an environmental control station throughout the entire imaging session. 24 to 52-h time-lapse movies were captured using a SP8 microscope (Leica microsystems) controlling a Leica DFC9000 GTC sCMOS camera. Images were acquired with a 40× 0.8 NA air objective. Every 5 min, 6 × 3-μm z-sections were acquired in the Texas-Red channel to observe the Nuclear-mCherry signal. Note that Nuclear-mCherry corresponds to a transgenic H2B-mCherry mouse obtained from Jax (stock #023139). While the H2B-mCherry fusion protein fails to localize to the chromosomes, it provides a nuclear signal that disperses at the beginning of mitosis and reappears in late anaphase when nuclear envelope reformation occurs. Thus, we were able to make use of the H2B-mCherry protein to monitor mitotic duration by determining the time taken from NEBD to nuclear envelope reformation.

Prolonged mitosis assay

500,000 cells were seeded into each well of a 48-well glass-bottom plate as described above. After 2 h of incubation at 37°C, media with nocodazole (0.08 μM final concentration) was added, and fields of cells were continuously followed by video time-lapse microscopy at 37°C for 4 h. After 4 h, media with nocodazole was removed and cells washed with fresh medium several times. The same fields of view were continuously followed for an additional 48 h.

Immunofluorescence staining of neural progenitor culture

Cells were grown on glass coverslips and fixed for 10 mins in 4% paraformaldehyde at room temperature. Cells were blocked in blocking solution (2.5% FBS, 200 mM glycine, and 0.1% Triton X-100 in PBS) for 1 h at room temperature or overnight at 4°C. Cells were then incubated in primary antibody diluted in the blocking solution for 1 h, rinsed with PBST (0.1% Triton X-100 in PBS), followed by secondary antibody staining prepared in the same blocking solution. DNA was stained with DAPI, and cells were mounted in ProLong Gold Antifade Mountant (Invitrogen). The following primary antibodies were used: Rabbit-PAX6 (Covance, PRB-278P, 1:1,000), Chicken-TBR2 (EMD Millipore, AB15894, 1:1,000), Mouse-TUJ1 (Covance, MMS-435P, 1:1,000), Goat-γ-

tubulin (homemade, polyclonal, raised against the peptide CDEY-HAATRPDYISWGTQEQ, 1:1,000) and Mouse-TP53 (1C12) (Cell Signaling, 2524S, 1:1,000). Secondary antibodies were conjugated to Alexa Fluor 488, 555, or 647 (Thermo Fisher Scientific, 1:1,000).

Single-cell sequencing

Single cells were isolated from embryonic brains at E14.5, as described above, and immediately stored in proliferation medium with 10% DMSO at –80°C until sorted. Single-cell karyotype analysis was performed and analyzed as previously described (Bakker *et al*, 2016; Levine *et al*, 2017).

Quantification and statistical analysis

Image and movie analysis

Imaris software version 9.2.1 (Bitplane) was used to quantify the total number of nuclei per field of view in the tissues stained with Ki67, PH3, PAX6, TBR2, CC3, TP53, CTIP2, CUX1, γ-H2AX, and DAPI. ImageJ software (US National Institutes of Health) was used to quantify the telencephalon area from whole-brain images and cortical thickness from stained brain sections. The same software was also used to quantify the fraction of dissociated neural progenitor cells stained with PAX6, TBR2, and TP53.

LAX software (Leica) was used to measure mitotic duration (from NEBD to nuclear envelope reformation), cell cycle length (from NEBD of the mother cell to the NEBD of one of the two daughter cells), and track cell fate following cell division in Nuclear-mCherry⁺ dissociated neural progenitor cultures. For cell cycle length and cell fate analysis, dissociated NPC were filmed for 48 h and only cells that enter mitosis within the first 24 h period were selected for fate tracing. The same software was also used to quantify spindle angle or the number of centrioles and centrosomes per NPC in embryonic sections.

Statistical analysis

Statistical analysis was performed using GraphPad Prism software. Differences between samples were analyzed using a two-tailed unpaired Student *t*-tests (Mann–Whitney *t*-test or Welch's *t*-test), chi-square test with *post hoc* analysis, one-way ANOVA with *post hoc* analysis, or a log-rank test for survival analysis as indicated in the figure legends. Error bars represent SEM unless otherwise indicated. Figure legends state the number of cells or animals used per experiment (Tables EV1 and EV2).

Data availability

This study includes no data deposited in external repositories.

Acknowledgements

The research grant supporting this project was terminated by March of Dimes one year after the project began (FY17-698, <https://www.nature.com/articles/d41586-018-05875-7>). We are grateful to Jeremy Nathans, Antony Rosen, and the Johns Hopkins Institute for Basic Biomedical Sciences for providing bridge support to allow the completion of this work. We also thank the members of

the Nathans and Mueller laboratory for their valuable insights and technical support. This work also was supported by the National Institutes of Health grants R01GM114119 and R01GM133897, an American Cancer Society Scholar grant RSG-16-156-01-CCG, and an American Cancer Society Mission Boost Grant MBG-19-173-01-MBG (to A.J.H.). T.P. was funded by the National Institutes of Health training grant (T32GM007445).

Author contributions

TPP performed and analyzed the majority of the experiments and prepared the figures. ALM assisted with experiments using dissociated NPCs and characterization of the adult *Smc5^{CKO}* mice. CAB and JL assisted with animal husbandry and brain dissections. AA performed the initial characterization of the *Smc5^{CKO}* mice and associated double knockout animals. AT, DCJS, and FF performed the single-cell sequencing experiments. THS provided the *Cep63^{TT}* mice, HB provided the *Sas4^{FF}* mice, and PWJ provided the *Smc5^{FF}* mice. AJH and TPP wrote the manuscript. All authors edited the manuscript. AJH conceived and supervised the study.

Conflict of interest

The authors declare that they have no conflict of interest.
