Abstract

60

Local anaesthetics are administered as a diffuse superficial slow injection in blepharoplasty. Current transcutaneous local anaesthetic formulations are not licensed for use on the face due to safety concerns. Here we report for the first time the permeation of local anaesthetics (lidocaine, bupivacaine loaded SNEDDS and their hydrogels) across human eyelid and mouse skin as a novel and ocular safe formulation for eyelid surgery. SNEDDS were loaded with high levels of anaesthetics and incorporated within carbomer hydrogels to yield nano-enabled gels. Lidocaine hydrogels have a significantly reduced lag time compared to EMLA, while they enhance lidocaine flux across human eyelid skin by 5.2 fold. *Ex vivo* tape stripping experiments indicated localisation of anaesthetics within the stratum corneum and dermis. Initial histopathological studies have shown no apparent signs of skin irritation. These results highlight the potential clinical capability of nano-enabled anaesthetic hydrogels as a non-invasive anaesthetic procedure for eyelid surgery.

1. Introduction

Blepharoplasty, a surgical procedure for removal of excess skin and adipose tissue from the upper or lower eyelids, can be functional to correct for “droopy” upper eyelids but also cosmetic and is the second most popular surgical procedure in men and women [1]. Local anaesthesia and intravenous sedation are frequently used for patients undergoing upper eyelid surgery, even though general anaesthesia might be desirable for some patients e.g. patients with needle phobias [2]. Local anaesthesia is usually administered as a diffuse superficial slowly subcutaneous injection along the lid skin crease [3]. Local anaesthesia in eyelid and intraocular surgery carries inherent risks such as haemorrhage, swelling, tissue distortion and obscuration of surgical landmarks, collateral damage [2]. Thus, there is a clear need for ideally needless alternatives for anaesthetic delivery to match this increasingly unmet clinical need.

Transcutaneous delivery of anaesthetics have been used as successful alternatives to invasive anaesthetic procedures to minimise anxiety, pain and discomfort during dermatological surgical procedures [4]. The clinical efficacy of topically administered anaesthetics depends on the pharmacological and physicochemical properties of the molecule and its ability to transverse the superficial layers of the skin [5]. Most local anaesthetics (LAs), as relatively hydrophobic ionisable amines, undergo partitioning into lipids in order to reversibly inhibit the generation and propagation of the action potential by blocking the neuronal voltage-gated sodium channel while changing the lipid membrane fluidity at the surrounding area [4]. Their physicochemical properties (pKa and hydrophobicity) and their varied efficacy depending on the thickness and hydration of the stratum corneum (SC), necessitates that LAs are administered in some cases using a needle to provide effective dermal anaesthesia.

EMLA cream is commonly used for local anaesthesia prior dermatological procedures. EMLA is an 1:1 oil/water emulsion with the oily phase comprised by an eutectic mixture of lidocaine 2.5% w/w and prilocaine 2.5% w/w cream, while the aqueous phase consists of synthetic high molecular weight polymers of acrylic acid that are cross-linked with either allyl sucrose or allyl ethers of pentaerythritol that are gelled with sodium hydroxide by screening the carboxylic acid charges which results in the cream's alkaline pH. This alkaline pH of EMLA contra-indicates its use for administration to eyelid skin. The eutectic mixture of the anaesthetics lowers their melting point, hence solubilising the crystalline anaesthetics for incorporation within the topical preparation in high concentrations [5-7]. However, administration of EMLA cream on intact skin is needed for at least one hour prior achieving a depth of anaesthesia of 3 mm, while a two hour application is needed to reach a depth of 5 mm [8]. Other topical anaesthetic gels such as AMETOP gel (tetracaine 4% w/w xanthan gum gel) still requires 30-45 minutes application prior operation with the anaesthesia lasting for 4-6 hours, but there have been reports of eyelid oedema, itching and blistering associated with its use [7].

Eyelid skin offers advantages for topical delivery due to the reduced thickness compared to other parts of the body (0.05 cm compared to that of the palm and sole of 0.4 cm) [9]. The eyelid skin surface is highly hydrated similarly to adjacent facial skin, but possesses extremely low amounts of surface lipids, unlike neighbouring skin regions [9]. Corneocytes of the eyelid skin display a significantly large surface size, while the SC turnover remains slow allowing for sufficient maturation of corneocytes that enables them to exert efficient water binding capacity [9]. Eyelid pH tends to be higher (pH 6.0 ± 0.05) than that of facial skin [9]. Thus, an ideal non-invasive anaesthetic formulation for eyelid surgery should aim to promote the permeation of

anaesthetics via the thin, hydrated eyelid skin with a rapid onset of action, adequate duration of action and low toxicity.

Lipidic nanoparticles (e.g. solid lipid nanoparticles), polymeric micelles and microemulsions such as self-nanoemulsifying drug delivery systems (SNEDDs) have shown promise in the topical delivery of LAs [10]. In our previous work, we compared permeation of these three types of promising nanomedicines prepared using safe (GRAS) excipients with high loading of lidocaine for the topical delivery of anaesthetics. Lidocaine SNEDDS illustrated high drug loading, high colloidal stability compared to other nanomedicines with a short lag time achieving high concentrations within the first hour [5]. Here we report for the first time the permeation of LAs loaded SNEDDS and their respective hydrogels across human eyelid and mouse excised skin tissue as a novel and ocular safe formulation for eyelid surgery.

2. Material and methods

155

2.1 Materials

Lidocaine (99+%) and all other chemicals and solvents were purchased from Sigma Aldrich (Dorset, UK). Bupivacaine (98+%) was purchased from Alfa Aesar (Heysham, UK). Labrasol (Caprylocaproyl macrogol-8 glycerides), Transcutol P (diethylene glycol monoethyl ether) and Capryol 90 (Propylene glycol monocaprylate) were obtained from Gatefosse (Alpha Chemicals, Berkshire, UK). Carbopol 940 was purchased from Fisher Scientific UK (Loughborough, UK). The artificial skin (cellulose acetate membranes, Visking dialysis tubing, cut-off: 12-14KDa, thickness: 2 mm) were purchased from Medicell Membranes Ltd (London, UK). Franz cells were specially made by Soham Scientific Ltd (Fordham, UK).

165

2.2 Excised human skin samples

Excised human eyelid samples were collected (Dr GM Saleh and Dr K Emeriewen– Moorfields Eye Hospital) from patients undergoing eyelid surgery for clinical or cosmetic reasons after full institutional review board and ethical committee approval was obtained (NHS Health Research Authority North Wales REC (Central and East) 13/WA/0066 for IRAS project ID 117286: “ Nanoparticle behaviour in human and artificial skin tissue”). The human skin (0.4–0.7 mm) was frozen on the day of excision and stored in water-impermeable plastic bags at –80°C (SANYO, Buckinghamshire, UK) until required. Skin samples were used within 10 months of excision (specimens are certified to be viable for a period of 5 years [11]). Skin samples were thawed in acetate buffer (20 mM, pH 6.00 ± 0.1, 37°C) and hair, muscle or fat tissue, if any, were removed prior to sample mounting on Franz cells.

2.3 Excised mouse skin samples

NMRI male mice (8 weeks old, 25-28g) purchased from Harlan Iberica (Barcelona, Spain) were euthanised and the skin was removed and frozen on the day of excision and stored in water-impermeable plastic bags at –80°C until required. Skin samples were used within 2 months of excision. Skin was thawed and shaved using a scapel and the skin was placed in 60°C de-ionised water for 30 seconds prior to removal of the epidermis from the dermis and hypodermis. The epidermis was then placed in acetate buffer (20 mM, pH 6.00 ±0.1, 37°C) prior being mounted on the Franz cells for diffusion assays.

2.4 Preparation of Lidocaine and Bupivacaine SNEDDS

Lidocaine SNEDDS (10 or 20 % w/w) (LID-SNEDDS) and Bupivacaine SNEDDS (2 or 5% w/w) (BUP-SNEDDS) were prepared by dispersing lidocaine (1 or 2 g) or Bupivacaine (0.2 or 0.5g) within an isotropic mixture of Labrasol (3g), Capryol 90 (1g)

and Transcutol P (6g) respectively [5]. The ratio of oil:surfactant and solvent was optimised in terms of particle size using tertiary diagrams and choice of surfactants and solvents was based on solubility studies [5, 12]. The LID-SNEDDS and BUP-SNEDDS were magnetically stirred for 15 minutes and left in an agitated water bath (50 rpm, Kotterman D1365, Hanigsen, Germany) at 37°C overnight for 16 hours [13]. Mixtures of the two drugs can be prepared by adding both of the drugs together in the required concentrations or by mixing finally prepared SNEDDS in required ratio.

2.5 Preparation of LID-SNEDDS Gels (10% w/w) and BUP-SNEDDS Gels (2% w/w)

Carbopol 940 (1 g) was added in de-ionised water (25 mL) and left to swell overnight. LID SNEDDS (20% w/w, 10g) were added dropwise to the Carbopol gel (4% w/w, 10g) and mixed in a mortar and pestle. The pH was adjusted to pH 6.0 ± 0.1 (Accumet AB200 pH meter, Fisher Scientific, Loughborough, UK) using neat glacial acetic acid (~200-250 μL) to prepare the final LID-SNEDDS gels (10% w/w). Sodium hydroxide (1M, 0.14g) was added to swollen Carbopol gel (4% w/w, 4 g) and mixed prior the addition of BPQ-SNEDDS (5% w/w, 2.86 g) to yield final BUP-SNEDDS gels (2% w/w) with a final pH of 6.0 ± 0.1 .

2.6 Measurement of particle size and zeta potential of prepared SNEDDS and SNEDDS loaded gels.

All formulations were diluted (1 in 1000 v/v) with de-ionised water (pH 6.5 ± 0.1). SNEDDS samples were vortexed and left to stand for 15 minutes prior analysis. Gels were diluted and centrifuged (5,000 rpm, 5 minutes, SciSpin Micro Centrifuge, Shropshire, UK) to remove carbomer, which is insoluble in water, and the supernatant was left to stand for 15 minutes prior to analysis. Particle size and zeta-potential was measured as previously described using a Nano-ZS Zetasizer (Malvern Instruments, Worcestershire, UK) [5, 14, 15].

2.7 Morphology of SNEDDS and SNEDDS enabled gels (TEM, AFM).

A drop of the aqueous diluted formulations for particle size measurements was placed on a Formvar/Carbon coated grid (F196/100 3.05 mm, mesh 300, TAAB Labs Ltd, Berks, UK) prior staining with 2% uranyl acetate and transmission electron microscopy (TEM) imaging as previously described [5, 14, 15].

Similarly, the aqueous diluted formulations (5 μL) were placed on the surface of muscovite mica (1 cm^2 , Agar Scientific, Essex, UK) and left to dry for 2 minutes, and dried under nitrogen gas prior to being attached to a nickel disk (1 cm^2) using double-side adhesive tape and placed on the AFM scanner (Multi-Mode/Nanoscope IV scanning probe microscope, Bruker, Santa Barbara, CA, USA). Measurements were performed in air under ambient conditions ($T = 23\text{ }^\circ\text{C}$, $\text{RH} = 21\%$) using the J-scanner (max $xy = 200\text{ }\mu\text{m}$). Scanning was performed in tapping mode using Si cantilevers with integrated tips ($t = 3.6 - 5.6\text{ }\mu\text{m}$, $l = 140-180\text{ }\mu\text{m}$, $w = 48-52\text{ }\mu\text{m}$, $V_0 = 288-338\text{ kHz}$, $k = 12-103\text{ N m}^{-1}$, $R < 7\text{ nm}$; OTESPA, Bruker, France) and an RMS amplitude of 0.8 V. The images were processed and dimensions measured using Nanoscope Analysis software (V1.4, Bruker).

2.8 Rheology studies of EMLA and LID-SNEDDS gel

The viscosity of LID-SNEDDS gel (10% w/w) or EMLA was measured by placing ~2g of the formulation on the Peltier temperature controlled platform of an AR 2000 rheometer (TA Instruments, Elstree, UK) and using a Carri-Med cone 4 cm flat plate. Continuous ramp conditions were used at 37°C with a 2-minute equilibration time. The shear rate was set at 0.1-100 $1/\text{s}$ with a total duration time of 20 minutes. A log mode was used and measurements were taken at 10 points per decade.

2.9 *In vitro* Franz cells diffusion studies

240 Modified Franz diffusion cells displayed an approximate diffusional area of 0.07 cm^2
[5]. After the compartments were rinsed with an acetate buffer (20 mM, pH 6.0 ± 0.1)
and a 3 x 2 mm stirrer bar was added to the receiver compartment, the compartment
was filled up with 2 mL of acetate buffer [5]. The washed cellulose acetate membranes
were cut into square pieces (0.2 cm^2) or human eyelid skin with the SC facing upwards
245 were mounted to adequately cover the receptor chambers. The donor compartment
and the receptor compartment were tightly sealed using Parafilm™ and clamped
together. The donor chamber was filled with acetate buffer (1 mL) and placed in a
waterbath at 37°C (RCT basic, IKA® England Ltd, Oxford, UK). After 1 hour, the
acetate buffer was removed from the receptor chamber and collected for analysis. The
250 receptor chamber was refilled with fresh acetate buffer pre-warmed to 37°C . The
acetate buffer in the donor chamber was removed and the formulation (EMLA; 1g, LID-
SNEDDS 10% w/w, LID-SNEDDS gel 10% w/w; 0.8 g) was added to the donor
chamber ensuring it was in contact with the artificial or human skin. Syringes were
activated five times prior to sampling (0.2 mL) at predetermined times from the
255 receptor chamber using a 1 mL syringe with a 21g needle (38 mm in length) and
samples were analysed by HPLC as described below. The receptor chamber was
immediately replenished with pre-warmed acetate buffer (0.2 mL).

After 9 hours of exposure, the human skin samples were wiped with an ethanol
impregnated cotton bud, and the samples were fixed using formalin (10%, neutral) for
260 a minimum of 48 hours in the fridge till processed for histopathology studies as
described below.

Solubility studies were conducted for bupivacaine in six different receptor chamber
media to allow for the selection of receptor media that will ensure sink conditions
during diffusion studies. The tested media included acetate buffer (20 mM, pH $6.0 \pm$

265 0.1), ethanol: acetate buffer (6:4 v/v), 2-hydroxypropyl- β -cyclodextrin (1%, pH 6.0 \pm 0.1), Soluplus (1% w/v, pH 6.0 \pm 0.1), phosphate-buffered saline (50 mM, pH 7.4 \pm 0.1) and sodium chloride (0.9 %). Bupivacaine (10mg) was dispersed in the media (1 mL) and allowed to stir for 24 hours at 37 °C prior centrifugation (5,000 rpm for 5 minutes) and analysis of the supernatant after dilution using HPLC. Ethanol: acetate
270 buffer demonstrated high solubility and was thus selected. Cellulose acetate and NMRI male mouse skin was used for diffusion studies of BUP-SNEDDS (5% w/w) and BUP-SNEDDS gel (2 % w/w) were performed using specially manufactured Franz diffusion cells (receptor chamber: 3 mL, donor chamber: 1 mL, diffusion area: 1.19 cm²) as described above. However, the receptor chamber of the Franz cells were filled
275 with ethanol: acetate buffer and a PTFE stirrer bar (6 x 2 mm) were used instead. The formulations, BUP in DMSO (2%, 1 mL), BUP-SNEDDS (0.4g), and BUP-SNEDDS gel (1 g) were added to the donor chamber and samples (0.3 mL) were taken at predetermined time points prior to HPLC analysis.

After 24 hours of exposure, the mouse skin samples were wiped with an ethanol
280 impregnated cotton bud. Skin was cut in half and one half was homogenised with 25 mL/g of ethanol: acetate buffer, centrifuged at 5,000 rpm for 10 minutes and the supernatant was analysed by HPLC for drug content, while the other was fixed as above for histopathology studies.

2.10 Ex vivo tape stripping experiments

285 Permeability of BUP in DMSO, BUP-SNEDDS and BUP-SNEDDS gels was carried out using custom made Franz diffusion cells (receptor chamber: 3 mL, donor chamber: 1 mL, diffusion area: 1.13 cm²). After the receptor compartment was rinsed with an ethanol: acetate buffer (20 mM, pH 6.0 \pm 0.1) (6:4 v/v), a 6 x 2 mm stirrer bar was added to the receiver compartment and filled with the same buffer. The donor

290 compartment was placed over NMRI male mouse excised skin and loaded with BUP
in DMSO (1mL, 2% w/v), BUP-SNEDDS (1g, 5% w/w) and BUP-SNEDDS gels (1g,
2% w/w). Skin was exposed to formulations for 30 or 60 minutes (n=3). Skin was then
collected and cleaned three times with cotton tips and three times with tips dipped in
ethanol: acetate buffer. The skin was weighted and placed on a flat surface with the
295 SC facing up. Skin stripping was carried out using tapes (13mm, round self-adhesive
stickers, Party Decor™, UK) that were pressed for 30 seconds under slight manual
pressure using a custom made weight (13 mm, 61.235g). Tape strips collected before
and after tape stripping were weighted and 40 sequential tapes were collected in tubes
containing 0.25mL of ethanol: acetate buffer, shaken for 15 minutes (Microscopic
300 mixer, SciQuip, Shropshire, UK), bath sonicated for 15 minutes (Grant ultrasonic bath,
XUB13, Cambridge, UK) and finally centrifuged (5,000 rpm, 10 minutes). The
supernatant was analysed by HPLC as shown below. The remaining mouse skin was
homogenised with 25 mL of ethanol: acetate buffer / g of skin, filtered through 0.2 µm
nylon filters and analysed by HPLC.

305 **2.11 Quantification of Lidocaine and Bupivacaine levels using HPLC**

Lidocaine was quantified as previously described [5]. A stock solution of bupivacaine
(1mg mL⁻¹ in DMSO) was diluted with ethanol: acetate buffer (6:4 v/v) to prepare
standards (1-100 µg mL⁻¹). A Phenomenex Hypersil BDS C18 column (150 x 4.6 mm,
5 µm) was maintained at 25°C for analysis at 220 nm using an Agilent 1100 series
310 HPLC attached to a PDA detector [5]. Samples (40 µL) were eluted at 1.2mL min⁻¹
using an acetate buffer (50mM, pH 6.0± 0.1): acetonitrile mobile phase (64:36 v/v) with
bupivacaine having a retention time of 7.3 min.

2.12 Histopathological analysis of human and mouse treated skin.

Fixed treated human skin (9h) with lidocaine formulations and mouse skin (24h) with
315 bupivacaine formulations were prepared and imaged and previously described [16].

3. Results

Prepared LAs-SNEDDS and LAs-SNEDDS gels illustrated sizes consistently below
300 nm (Table 1), good colloidal stability and quasispherical morphology (Figure 1).
320 The amount of LAs loaded was chosen based on the concentration of clinically
approved formulations for both LAs in order to avoid toxicity of formulations, however,
these can be tailored accordingly if combination products are needed (to ensure a
longer and deeper anaesthesia). To ensure gels possessed appropriate viscosity for
application to the skin by patients, we compared their rheological properties with
325 EMLA. Both EMLA and LID-SNEDDS gel demonstrated a shear thinning
(pseudoplastic) behaviour and have demonstrated comparative viscosity to EMLA
cream ($p > 0.05$, 2-tailed Student T-test) (Figure 2A).

Linear permeation profiles were observed for both EMLA, LID-SNEDDS and LID-
SNEDDS gels (Figure 2B,C). Across artificial skin, LID-SNEDDS gels enhanced
330 permeation by 14.7 fold (EMLA J_{ss} : $30 \pm 4.2 \mu\text{g cm}^{-2} \text{h}^{-1}$, LID-SNEDDS gel J_{ss} : 155.4
 $\pm 37.2 \mu\text{g cm}^{-2} \text{h}^{-1}$) with no determinable lag time and reaching the plateau after 2.5
hours while EMLA demonstrated a lag time of 23.8 ± 35.2 minutes and reached
plateau levels after 4 hours (Figure 2B). Across human excised eyelid skin, LID-
SNEDDS gel demonstrated a significant reduced lag time compared to EMLA ($9.1 \pm$
335 19.1 vs 49.8 ± 12.7 minutes), while they enhanced flux at steady state by 5.2 fold and
the permeability co-efficient by 1.6 fold (Table 2). We attempted to analyse the steady
state flux in skin samples of male and female patients as we observed higher fluxes in
female patient skin, however results were not significant possibly due to small size of

available male patient samples. An increased lag time was observed in male patients,
340 which could be attributed to the slightly higher skin thickness of male patient samples
compared to female (0.098 ± 0.01 cm vs 0.088 ± 0.06). Comparing the correlation co-
efficients for various release mathematical models, the Korsmeyer-Peppas model was
found to best fit lidocaine release from each formulation tested across human eyelid
skin (Table 3).

345 Amongst media tested to ensure sink conditions for permeability studies, ethanol:
acetate demonstrated by far the highest solubility (Figure 2A). Across artificial skin,
BUP-SNEDDS and BUP-SNEDDS gels demonstrated a linear permeation profile
(BUP-SNEDDS Jss: 95.52 ± 17.31 $\mu\text{g cm}^{-2} \text{h}^{-1}$, BUP-SNEDDS gel Jss: 41.31 ± 6.85
 $\mu\text{g cm}^{-2} \text{h}^{-1}$) with almost no determinable lag time (BUP-SNEDDS: 3.66 ± 4.32 minutes,
350 BUP-SNEDDS gels: 0 minutes) (Figure 2B, Table 4). Across mouse skin with similar
thickness to eyelid skin, flux for all formulations tested were not statistically significant
(Repeated measures One-Way Anova, $p > 0.05$). BUP-SNEDDS gels enhanced the
permeability co-efficient by 1.4 compared to Bupivacaine in DMSO. As with lidocaine
formulations, the Korsmeyer-Peppas model was able to fit better the bupivacaine
355 release from nano-enabled formulations, while a zero-order release was observed for
bupivacaine in DMSO solutions (Table 3).

Ex vivo tape stripping were undertaken to access BUP levels within the SC and dermis
after 30 and 60 minutes of exposure to the formulations. The cumulative weight per
unit area of SC removed by sequential tape-stripping (mean \pm SD; $n = 9$) is linear and
360 analysis of variance followed by Scheffe's F-test shows that the weight of the SC
removed per strip is independent of the tape-strip number per formulation ($p > 0.05$).
Both time points selected for tape stripping experiments based on previously
calculated lag times (Table 4) were collected after steady state was established

($t_{exp} > 1.7t_{lag}$) [17]. Thus, equation 1 was used to calculate the partition co-efficient of
 365 BUP between the SC and the vehicle ($K_{sc/v}$):

$$K_{sc/v} = \frac{2}{L_{sc} A C_v^0} + \sum_{i=1}^{NTS} m_i \quad (\text{Equation 1})$$

where L_{sc} is the effective thickness of the SC, A the surface area of exposure i.e. being
 tape stripped and C_v^0 the initial concentration of BUP in the vehicle [17]. Values are
 summarised in Table 5. Considering that the thickness of the SC from the back of
 370 NMRI mice is approximately 15 μm [18], the concentration in the SC (15 μm), dermis
 (~15 μm) and remaining homogenised skin is summarised in Table 5 and cumulative
 bupivacaine levels and cumulative mass of skin stripped per tape number are shown
 in Figure 4. At 30 minutes, levels of bupivacaine DMSO in the dermis are 5 fold lower
 than levels achieved by both the BUP-SNEDDS and BUP-SNEDDS gels ($p > 0.05$),
 375 although levels obtained from homogenising the remaining of the skin are significantly
 higher than levels of the nano-enabled formulations ($p > 0.05$, One-way ANOVA).
 Thus, DMSO as a penetration enhancer can result in levels that can reach the blood
 but without localising the formulation in the dermis (where nerve endings are present)
 after a short pre-operative exposure time. After one hour, there is no significant
 380 difference in levels of bupivacaine in the dermis amongst the 3 formulation (applied at
 the same bupivacaine dose). However, the levels of bupivacaine in the homogenised
 skin are 38% lower than those of bupivacaine DMSO ($p > 0.05$, One-way ANOVA),
 indicative of dermis localisation of the formulation. Tape stripping can vary depending
 of type of formulation used and has been particularly difficult for oily formulations [19].
 385 This is something that we observed in our study as well as a higher number of tapes
 were needed for SNEDDS compared to DMSO and nano-enabled hydrogels to ensure
 we remove an effective thickness of 15 μm . Histopathology studies of remaining skin

after removal of 40 tapes have also confirmed the absence of the complete removal of the SC (data not shown).

390 There are no apparent signs of skin irritation (e.g. oedema or erythema) on visual examination of the skin samples following treatment with blank SNEDDS, LID-SNEDDS, LID-SNEDDS gel or mouse skin samples following treatment with BUP-SNEDDS and BUP-SNEDDS gel. Skin treated with SNEDDS or SNEDDS gels were devoid of inflammatory cells and no disruption of the epidermal and dermal layers was
395 evident (Figure 5), with no signs of acanthosis or hyperkeratosis.

4. Discussion

The increasing number of blepharoplasty and associated eyelid procedures
400 undertaken annually necessitates the development of a non-invasive anaesthetic procedure that is efficacious and safe without the need for subcutaneous injection of anaesthetics. Here we present an ocular safe nano-enabled gel from GRAS excipients for the delivery of anaesthetics or anaesthetic mixtures based on nano-emulsifying drug delivery systems incorporated into a cross-linked polyacrylate polymers
405 (carbomers). Preference of patients to hydrogel formulations and preparation of anaesthetic gels with GRAS excipients minimises barriers for use of the developed nano-enabled hydrogel in a clinical setting considering the ease of scalability of our described formulation. SNEDDS were optimised by ternary phase diagrams to identify optimal ratios for type IV SNEDDS with a good solvent capacity [5].
410 Previous studies have reported a clear correlation of enhanced LA solubility with medium chain triglycerides (MCT) consisting of caprylic/capric acid triglycerides [20]. Thus, apart from Transcutol, a high Labrasol content can aid in improving the drug

loading, LA permeability and efficacy of LA. MCT enhance LA efficacy against cold sensation (reaching cold receptors in the epidermis) possibly due to their ability to interact with similar properties lipids present in the SC [5, 20]. SNEDDS are able to load extremely high levels of anaesthetics [$>749.955 \pm 9.567 \text{ mg g}^{-1}$ mg Lidocaine and $>50 \text{ mg}$ Bupivacaine per 1g of SNEDDS [5]] and combinations within currently used clinically doses is possible by simply mixing SNEDDS at needed proportions and then loading within hydrogels as shown above. Lidocaine is the most commonly used LA in eyelid surgery, due to its potency, rapid onset (<2 minutes) and moderate duration of action (30-45 minutes) [5]. Bupivacaine, on the other hand, has a slightly slower onset of action (typically 2-10 minutes) but results to a longer duration of action and elicits effective nerve block [21, 22]. Typically, both are used with adrenaline in eyelid surgery to limit haemorrhage and elicit vasoconstriction to reduce systemic uptake and clearance of the anaesthetics [2, 23]. Adrenaline can be added to our gels just prior administration. This platform technology can yield combination anaesthetics with a quick onset of action and able to maintain depth of anaesthesia by tailoring the amount and type of anaesthetics used. This has been achieved by eutectic mixtures (e.g. EMLA), but careful titration of anaesthetic levels are needed to ensure stability of these formulations, while they are not designed or are safe for ocular use.

Particle size of our nano-enabled LA formulations was consistently below 300 nm with a low polydispersity (<0.4) and adequate colloidal stability ($<-30\text{mMV}$) (Table 1). Near spherical morphology with an electron dense core was observed (Figure 1) for nano-enabled formulations with LID-SNEDDS particles demonstrating a core-shell morphology indicative of a dense packing within the core of the particle due to high drug loading. Differences in the size from TEM as compared with their hydrodynamic

diameter from DLS data is likely attributed to sample drying for AFM and TEM sample preparation and imaging respectively [24].

Dilution of SNEDDS loaded gels in aqueous media, results in nanoparticulate suspensions of similar size and morphology ($p > 0.05$). When LID-SNEDDS are incorporated in the swollen carbomer hydrogel (acidic pH), a rapid increase in pH is observed (>8) resulting from the interaction between the amine of lidocaine and the free carboxylic groups of carbomer 940 resulting in an opaque gel. The carbomer gel behaves as a reservoir of lidocaine in which a high proportion of the drug is available as the ion pair form ($R-COO^- \text{Lidocaine } H^+$) [25, 26]. When the pH is titrated using dilute hydrochloric acid to a pH of 6.0 ± 0.1 , lidocaine is present in the ionised state ($\text{Lidocaine } H^+$) and gradual entrapment of lidocaine within the particle core of SNEDDS is possible yielding a clear shiny gel. This step is only needed for lidocaine hydrochloride. When unloaded or when the free base of bupivacaine is used, this pH change is not observed and pH is raised to a pH of 6.0 with dilute sodium hydroxide to yield the final gel [26]. The clarity of the latter gels also indicates that the high water content ($>40\%$) of our loaded hydrogels is not responsible for translucency, as previously reported for lidocaine hydrogels [26]. Shear thinning observed for LID-SNEDDS gels is typical for carbomer 940 gels [27]. Variability in viscosity with our gels is explained by the particle size and polydispersity of the four batches tested as there is an inversely proportional relationship between gel viscosity and size of nanoparticulate dispersions.

Transport from the gels was best described by the Korsmeyer-Peppas model ($n < 1$) (Table 3). As release was from a slab and n was below 1, lidocaine or bupivacaine release was non-Fickian (anomalous). The anomalous diffusion mechanism demonstrates both diffusion controlled and swelling controlled drug release [27]. Transport from bupivacaine DMSO solutions is likely to be zero-order (time dependent

and concentration independent), as high DMSO concentrations are known to lead to fluidisation of the SC lipids. The low lag time indicates that SNEDDS release from hydrogels is not hindered, possibly due to regions of low microviscosity of the carbomer gels as only 50% of the polymer chains are ionised at pH 6.0 [28, 29].
465 Surface moisture can also influence release from cross-linked polymeric matrixes. Considering that the SC of human eyelid skin has a high water content compared to other parts of the body [9], this high water content can hydrate and swell the polymer resulting in relaxation of the polymer chains and rapid SNEDD release.

470 LID-SNEDDS gels demonstrated high flux, which is 10-fold higher than recent reported values for other lipid-based nanoparticulate systems such as nanostructured lipid carriers [30] and 5-fold higher than EMLA cream (Table 2). LID-SNEDDS gels possessed a 10 fold higher flux compared to lidocaine NLCs (1%) and 23-fold higher flux than free lidocaine (1%) aqueous solutions previously reported [30]. These NLCs
475 were able to elicit near maximal anaesthesia in the tail flick test for 60 minutes and had a duration of action for at least 2 hours [30]. Although, further studies are needed to elucidate appropriate lidocaine concentration for adequate anaesthesia, the observed levels suggest that the gels (likely even with as low as 1% lidocaine loading) would be clinically relevant to elicit effective anaesthesia. Our nanoemulsions and
480 nano-enabled gels demonstrate linear flux with a short if any lag time (~9 minutes) compared to EMLA (~50 minutes) (Table 2). The shortened lag time suggest that LID-SNEDDS gels will have a rapid onset of action compared to clinically used preparations such as EMLA, which require 45 minutes to 1 hour to achieve an adequate anaesthetic effect [7]. The higher flux of the nano-enabled hydrogels
485 compared to SNEDDS is linked to their supersaturated state (>1 for hydrogels and

0.013 for lidocaine as the maximum solubility of lidocaine within the SNEDDS isotropic mixture is $\sim 750 \text{ mg g}^{-1}$).

Lidocaine flux across male eyelid skin was lower compared to skin from female subjects but results were not significant. The low number of male ($n=3$) versus female
490 ($n=15$) samples in our study might contribute to this. More samples are needed to draw definite conclusions, but male samples are difficult to obtain, as blepharoplasties are more common in women. Skin thickness might be a factor as studies have shown that male skin is 10-20% thicker than female skin ($n=88$, 18-61 years) [31]. However, other studies did not confirm this [32], and our male subjects are older than the reported
495 range in this study (age of male patients: 64, 87, 92) and skin thickness is known to decrease with ageing [32].

A linear flux was observed for bupivacaine gels and with minimal lag time. (Figure 3, Table 4). Mouse skin used in this study possessed similar thickness to eyelid skin. Drug transport from these gels was best described by the Korsmeyer-Peppas model
500 and release was also non-Fickian (anomalous). *Ex vivo* tape stripping was used a surrogate for *in vivo* tape stripping experiments [33]. Complete removal of the SC was possible under our experimental conditions. However, the number of tapes needed to do so varied between formulations [19], with SNEDDS being the hardest to strip. BUP-SNEDDS gels were able to provide localisation in the SC and dermis and resulted in
505 38% lower levels in remaining homogenised skin.

Histopathology studies showed no apparent sign of skin irritation (e.g. oedema or erythema) on visual examination of skin eyelid samples with blank SNEDDS, LID-SNEDDS, and LID-SNEDDS gels with no sign of acanthosis or hyperkeratosis even after 9 hours of exposure. Analysis of mouse skin exposed to BUP SNEDDS gels for
510 24 hours versus BUP DMSO showed no evident signs of irritation either. Transcutol

P, although used within approved FDA levels for skin products, can cause swelling of the lipid bilayer structures resulting in an intracutaneous drug depot effect, which improves drug retention within the skin and allows drugs to be released in a sustained manner.

515

5. Funding

These results highlight the potential clinical capability of nano-enabled anaesthetic hydrogels as a non-invasive anaesthetic procedure for eyelid surgery. Further *in vivo* studies are needed to elucidate the dose-efficacy and safety profile of our nano-enabled hydrogels.
