ARTICLE INFO

ABSTRACT

During directed energy deposition (DED) additive manufacturing, powder agglomeration and sintering can occur outside of the melt pool when using titanium alloy powders. Using *in situ* synchrotron radiography we investigate the mechanisms by which sintering of Ti6242 powder occurs around the pool, performing a parametric study to determine the influence of laser power and stage traverse speed on sinter build-up. The results reveal that detrimental sinter can be reduced using a high laser power or increased stage traverse speed, although the latter also reduces deposition layer thickness. The mechanism of sinter formation during DED was determined to be in-flight heating of the powder particles in the laser beam. Calculations of particle heating under the processing conditions explored in this study confirm that powder particles can reasonably exceed 700 °C, the threshold for Ti surface oxide dissolution, and thus the powder is prone to sintering if not incorporated into the melt pool. The build-up of sinter powder layer on deposit surfaces led to lack of fusion pores. To mitigate sinter formation and its detrimental effects on DED component quality, it is essential that the powder delivery spot area is smaller than the melt pool, ensuring most powder lands in the melt pool.

1. Introduction

Laser Directed Energy Deposition (DED) is an additive manufacture (AM) is a fabrication technique for the rapid production of complex components by progressively adding layers of material via simultaneous delivery of laser energy with either wire or powder as feedstock [1]. It is particularly useful for producing large free-form parts, adding surface coatings [2], joining dissimilar materials [3], building functionally graded components [4], or for use in repair applications [5,6]. The elimination of porosity in DED builds presents one of the greatest challenges: porosity can be a result of entrapped gas in the feedstock powder [7], entrained shield [8] or carrier gas [9], or lack of fusion pores caused by insufficient melting between deposition layers [1].

Many DED studies have concentrated on exploring the relationships between DED nozzle geometries and the powder deposition characteristics, including interactions between the powder jet and the laser beam or the nozzle working distance [10]. Laser attenuation increases is affected by processing conditions and powder focus, increasing powder feed rate [11], and the work by Pinkerton et al. [12] has shown that in-flight powder heating varies across the width a laser beam. Tan et al. [13] reported the divergence of powder jets over prolonged powder feeding times, which decreased deposit height due to reduced powder capture.

Wolff et al. [14] conducted *in situ* synchrotron X-ray imaging of powder DED using a process replicator with a piezo-driven system to deliver powder to a laser spot, in which high speed radiography

---

provided important new insights into melt pool formation, gravitational powder flow, and the powder capture into a melt pool. *In situ* work on melt pool geometry [15,16] and porosity formation mechanisms in DED has also been carried out [17]. However, the conditions used in these studies involved a much smaller spot size and lower powder feed rate compared to industrial DED processes, as it was optimised for high resolution and high-speed imaging of powder. Chen et al. performed *in situ* synchrotron X-ray radiographic characterisation studies using a blown powder process replicator (BAMPR) that more closely emulates the characteristics of an industrial system. Varying laser power, speed, and powder feedrate in DED of austenitic grade 316 L stainless steel (SS316L) revealed changes to melt pool geometries and surface roughness [18]. Furthermore, examination of the nickel-based superalloy IN718 [19] and the industrially important titanium alloy Ti6242 (Ti–6Al–2Sn–4Zr–2Mo in wt%) [20] has revealed mechanisms of track development and porosity formation during DED, highlighting substantial differences in the melt pool shapes of these alloys under the conditions investigated.

Fig. 1 summarises these differences, observed using *in situ* synchrotron X-ray imaging of 3 different materials: **(a)** SS316L; **(b)** IN718; and **(c)** Ti6242, *after* [18,19]. SS316L and IN718 exhibit a uniform track with some partially-melted powder particles visible on the solidified track surface as shown by the blue arrows. In the case of Ti6242 (Fig. 1c), a large amount of powder is visible, which appears to have accumulated on the track surface in a layer *ca.* 300 μm thick. Chen et al. [20] proposed that powder sintering was responsible for this powder build up. Nickel and steel alloys both form stable Cr-based oxides [21, 22], which inhibit sintering, whereas titanium oxide films can diffuse into the bulk as interstitial oxygen at temperatures well below the melting point [23]. In our previous DED studies on SS316L [18] and IN718 [19], powder agglomeration around the melt pool was not visible for the conditions tested, across a range of laser powers, traverse speeds, or powder feedrates. A range of other processing conditions for SS316L and IN718 are shown in Supplementary Figs. 1, 2 respectively.

Henceforth in this work, *powder agglomeration* and *sinter* refer to the accumulation of unmelted powder particles, which are bonded together via necking, reminiscent of early stage sintering. Unmelted powder particles adhering to the track has been reported for SS316L and attributed to misalignment of the laser beam or the powder spot [24]. Syed et al. [25] indicated three explanations for powder adhering to track surfaces: particles heated in the laser loosely adhering to the solidified track; solid particles impacting the end of the melt pool, with insufficient heat to fully melt and incorporate them; or particles which impact the melt pool and become semi-molten. However, the number or semi-melted particles is significantly less than that seen with Ti alloys. Gharbi et al. [26] observed excessive powder agglomeration on the surface of Ti–6Al–4V tracks during DED.

The agglomerated Ti powder layer has a profound effect on the advancing melt pool. It significantly alters the pool shape (forming a concave rather than convex surface), appears to alter the wetting angle at the front of the melt pool, and will thus lead to markedly different multilayer build characteristics between the three materials. Supplementary Table 1 and Supplementary Fig. 3 show a comparison of typical DED processing conditions for titanium alloys.

The aim of the work is to use *in situ* synchrotron X-ray imaging to further explore the influence of the DED process conditions on titanium and titanium alloy powder deposition during multi-layer builds. Specifically, this paper will investigate the hypothesis that sintering is the mechanism causing powder accumulation on the surface and explore how this can be mitigated, reducing a potential cause of defects such as lack of fusion porosity.
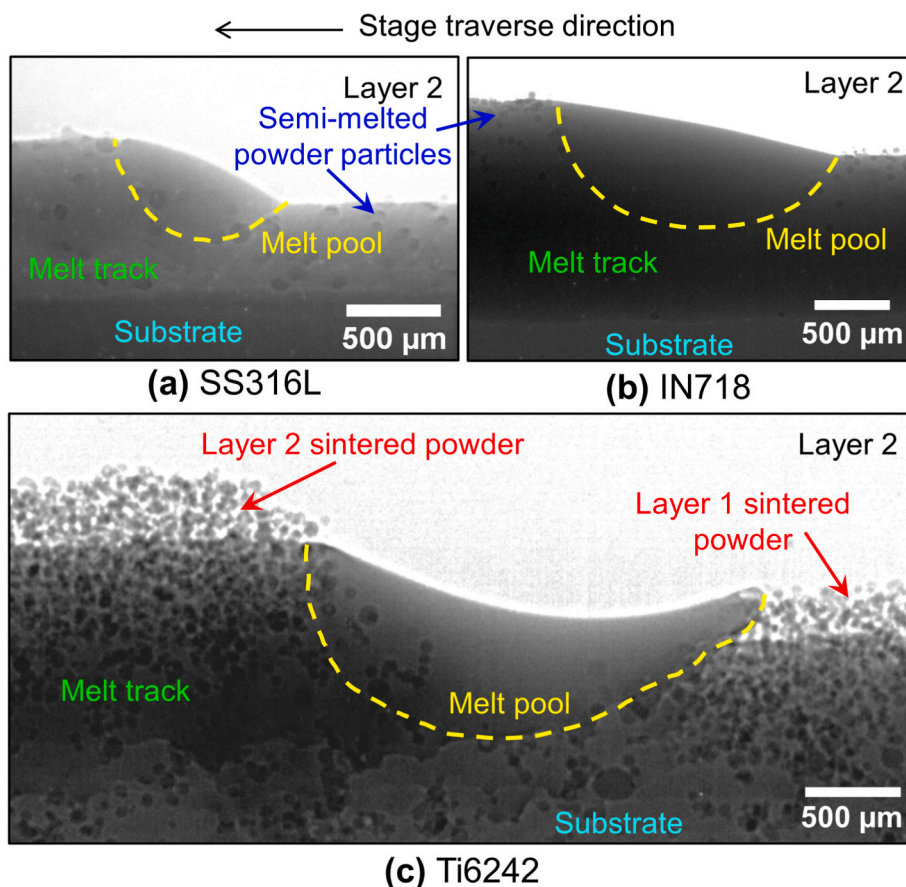

Fig. 1. *In situ* synchrotron X-ray images of (a) SS316L, (b) IN718 and (c) Ti6242 DED multilayer builds using BAMPR at laser power 200 W, stage traverse speed 1 mm s^{-1}. The melt pool shape boundary is shown by the dashed yellow line. The blue arrows indicate semi-melted powder particles adhered to the track surface, and red arrows indicate additional sintered powder not incorporated into the melt pool. Significant differences are seen in both the melt pool shape and the deposition of powder on the track surface, after [18,19]. 2. Experimental methods

2.1. Materials

Two gas atomised powders were used in this study: Ti6242 (Ti–6Al–2Sn–4Zr–2Mo in wt%), and Commercially Pure (CP) Ti (both from *Carpenter Additive, UK*). The Ti6242 powder had a nominal size range of 45–106 μm with $D_{10} = 50$ μm, $D_{50} = 74$ μm, and $D_{90} = 90$ μm. The substrates were made from Ti6246 (Ti–6Al–2Sn–4Zr–6Mo in wt%) and CP Ti for the alloy and CP Ti powders, respectively. Substrates were 1 mm thick to allow for adequate X-ray transmission during imaging and to emulate thin wall builds by aiming to keep conductive heat losses approximately the same in all layers.

The primary investigation used Ti6242 powder, and a limited number of additional experiments were conducted using CP Ti powder and substrates. This was to determine whether the observed sintering effect is a specific feature of Ti6242 or is a more general phenomenon that occurs during DED of titanium-based powders.

2.2. In situ blown powder DED process replicator

A laser blown powder DED additive manufacturing process replicator (BAMPR) was designed to replicate a commercial laser blown powder DED system, with the ability to be employed onto a synchrotron beamline. The system is described in detail in previous works [19]. Briefly, the system is composed of an industrial DED nozzle and a 200 W continuous wave 1070 nm Yb-doped fibre laser (SPI Lasers Ltd, UK). The laser was focussed to a 400 μm ($4\sigma_{xy}$) diameter spot using tuneable optics (Optogama, Lithuania) and was aligned along the nozzle axis. The laser beam had a Gaussian distribution [27]. Powder delivery was via four jets arranged concentrically with the nozzle axis. An industrial powder feeder (Oerlikon Metco TWIN-10-C, Germany) was used to deliver powder to the nozzle via argon gas flow, at a constant flowrate. An additional argon shield gas flowed axially through the nozzle to create an inert atmosphere around the laser melting area and prevent oxidation. The substrates onto which powder was deposited were mounted onto a 3-axis *XYZ* motion stage (Aerotech Inc, USA) with travel of 25 × 50 × 50 mm (length × width × height). The entire deposition system was enclosed in an environmental chamber with X-ray transparent Kapton film windows. The chamber was evacuated and backfilled with argon (99.998% purity) prior to powder deposition.

2.3. Experimental build conditions

A range of processing parameters were investigated to observe the effect of laser power and sample traverse speed during DED, as shown in Table 1. Each build was a single track, 8 mm long in the *x*-direction. The stage was lowered in the *z*-direction for each deposition layer to maintain a consistent working distance between the nozzle and the sample. Samples built at 200 W were 5 layers high (*z*-direction), and samples at 150 W and 100 W were built 4 layers high. The final layer was not deposited for the latter conditions, as the emerging sinter layer approached the nozzle and posed a powder blockage risk. Layers were added in a bi-directional scanning strategy, alternating each layer. This choice of processing parameters was a compromise between replicating

industrial conditions as accurately as possible whilst maintaining optimum imaging requirements.

2.4. In situ synchrotron radiography

In situ X-ray radiography experiments were carried out at the I12 Joint Engineering, Environmental and Processing (JEEP) beamline at Diamond Light Source (UK) [28]. A monochromatic X-ray beam was used with a mean energy of 53 keV. The imaging system consisted of a LuAg:Ce scintillator and a 2x magnification long working distance objective lens (0.21 numerical aperture). The radiograph images were captured using a PCO. edge high-resolution imaging camera (PCO, Germany) at 200 frames per second, with an exposure time of 4 ms and an effective pixel size of *ca.* 3.24 μm. The framerate of 200 fps was selected as the optimal compromise for beamline I12 between sufficient temporal resolution and X-ray transmission for image signal to noise ratio, and high spatial resolution. This combination of frame rate and spatial resolution was appropriate to capture the powder agglomeration and its interaction with the melt pool as well as the formation of lack of fusion pores.

2.5. Characterisation and micro-computed tomography (μCT)

The samples were examined by scanning electron microscopy (SEM) in secondary electron imaging mode at 10 kV (JEOL JSM-6610 LV, Tokyo). Images were taken of the top surface of the track after the final deposition layer.

Multilayer samples were also examined *ex situ* by micro-computed tomography (μCT) using a Phoenix Nanotom (General Electric, USA) to image and quantify microstructural features such as porosity. 1000 projections were collected over 360°, with an exposure time of 1 s. The data were reconstructed using filtered back projection [29], resulting in a voxel edge size of 8 μm [30]. The image analysis was performed using Avizo 9.3 (ThermoFisher Scientific) [31].
2.6. Image analysis of synchrotron radiographs

The open-source software Fiji version 1.52i [32] was used to analyse radiographs. Flat-field correction removed artefacts and noise variation inherited during the acquisition process; 100 flat-field and 100 dark-field X-ray images were collected to do so. The acquired radiographs were normalised using the standard flat-field correction (FFC) equation [27].

After FFC, measurements were taken from the radiograph images. The deposition height was measured as the thickness of the added material onto the previous layer build height; not including any remelt depth in the measurement. The sinter height was measured as the thickness of the powder particles visible above the solid material for each layer. The measurements are shown graphically in Supplementary Fig. 4.

3. Results

The results show a large amount of Ti6242 powder on the track surface following a 5-layer build for a range of laser powers and speeds. Left to right in Fig. 2a-e, the track widths (*y*-direction) were 2.2 mm, 2.1 mm, 2.8 mm, 1.0 mm, and 1.2 mm respectively. The amount of sintered powder visible on the surface decreases with an increase in traverse speed. Fig. 2f highlights the sintering in Fig. 2a, with sintered powder denoted by pink dashed arrows, and semi-fused powder by yellow arrows. Fig. 2g shows a high magnification image of powder particles, displaying sinter necking. The necks between particles in Fig. 2f and g are 19 ± 3 μm in length. Although Fig. 2 illustrates the presence of both semi-melted and sintered powder particles on the track surface, the amount of semi-melted particles is low compared to sintered particles, and hereafter the large accumulation of powder will be referred to as a

Table 1
Processing parameters selected for Ti6242 builds.

Experimental condition	Laser power, P (W)	Traverse speed, v (mm s^{-1})	Powder feedrate, f (g min^{-1})
1	100	1	1
2	150	1	1
3	200	1	1
4	200	2.5	1
5	200	5	1

sintered powder layer. Images of powder sintering for the conditions in Fig. 2b–e are shown in Supplementary Fig. 5a–d.

Reconstructed μCT images of the tracks are shown in Fig. 3. There is a large decrease in interlayer porosity between deposition layers as the laser power increases from 100 W to 200 W. At the 1 mm s^{-1} and 100 W deposition condition, a considerable amount of sintered powder is visible, with a thick layer on the top surface. Layers were not fused together, and there is unmelted powder visible between layers, forming interlayer pores. The cross section shows no layer cohesion. The track detached from the substrate during μCT sample preparation due to insufficient fusion of the melt track to the substrate during layer 1 deposition. The 150 W condition reveals large, interconnected interlayer pores between layers. Sintered powder can be seen between melt layers on the sides and top surface of the track. The 200 W condition induced sintered powder on the outside of the track, and the cross section shows an inverted 'saddle' shaped melt pool [20], increasing in width as the layer number increased. Some smaller pores were visible at layer boundaries, as well as small spherical pores at the end of the track. As traverse speed increased to 2.5 mm s^{-1}, the layer thickness decreased, but the width of the track similarly increased with each deposited layer. Much less sinter is present on the track surface; however, some particles can be seen along the sides of the track. At $v = 5$ mm s^{-1}, the layer thickness is smaller, and some lack of fusion pores can be seen between the substrate and layer 1. Since sintered powder on the track surfaces can be seen in Fig. 2, it is possible that sintered particles were inadvertently removed from the samples during preparation for μCT, as the sintered particles were not strongly bonded to the track surface. The percentage volume of lack of fusion porosity between build layers caused by the sintered powder particles, if the whole sample were to be considered as a solid track, is listed in Table 2.

In situ synchrotron X-ray images obtained during the building process are shown in Fig. 4 and Supplementary Videos 1–4, where the effects of laser power on the formation of accumulated powder layers are revealed. Fig. 4a shows layer 1 melting at 100 W. The melt track shows insufficient wetting to the substrate, and a layer of sintered powder on the track surface *ca.* 650 μm thick; roughly twice as thick as the melt track itself. The powder delivery gave a focussed powder footprint from all four incoming jets of 4.9 ± 0.1 mm diameter. Therefore, despite the centre of the powder jet impinging on the laser spot, a large fraction of the powder jet is not striking the melt pool due to its relatively small size. The deposition of layer 3 at the same condition is in Fig. 4b, in which the thick powder layer has created a barrier between the solidified layer 2 melt track, and the melt pool, resulting in lack of fusion defects between layers. The melt pool is considerably longer than for layer 1. Fig. 4c shows layer 1 melting at a laser power of 200 W. A deep hemispherical melt pool remelting the substrate, and a layer of sintered powder on top of the melt track, *ca.* 300 μm thick, are both evident. A cluster of sintered powder ahead of the melt pool is also visible, which was later incorporated into the melt pool as seen in Supplementary Video 3. In this case, the larger melt pool would increase the powder capture efficiency compared to the 100 W condition. Fig. 4d shows layer 3 of the same 200 W laser power condition, showing an elongated melt pool, and a change in wetting at the front of the melt pool, caused by the layer of sintered powder pre-existing track. In this case, the melt pool was large enough to ensure sufficient fusion between layers.

Fig. 5 and Supplementary Videos 5–8 demonstrate the effect of transverse speed on the formation of sintered powder layers. For comparison, the 1 mm s^{-1} processing condition is in Fig. 4c, d. Fig. 5a shows layer 1 melting at 2.5 mm s^{-1} showing a smaller melt pool, and reduced sinter layer compared to the 1 mms^{-1} traverse speed. However, the melt pool still remelts the substrate sufficiently to achieve bonding. The deposited layer height in this case is 260 ± 11 μm. Fig. 5b is layer 3 melting for the same condition, showing an elongated melt pool and reduced melt pool depth. The change in wetting at the front of the melt
Fig. 3. µCT rendered images of tracks with a quarter section removed, and cross sections, showing track widening and lack of fusion between layers. The 100 W condition detached from the substrate during sample preparation due to insufficient melting in layer 1 deposition (shown in Fig. 4), and so the approximate substrate size is drawn in dotted lines.

pool caused by the sinter layer is also observed here. Fig. 5c shows layer 1 melting for a traverse speed of 5 mm s^{-1}. The melt pool is smaller with a deposited track height of 145 $\pm$ 9 µm. Fig. 5d is layer 3 melting, similarly showing an elongated and shallower melt pool than layer 1.

Table 2 includes the average deposited layer thickness measurements for all conditions: the 100 W and 150 W conditions show a high deposited layer thickness because the sinter layer prevents complete fusion to take place and the deposited track is built upon the sintered layer.

The measurements of the sintered layer height for each processing
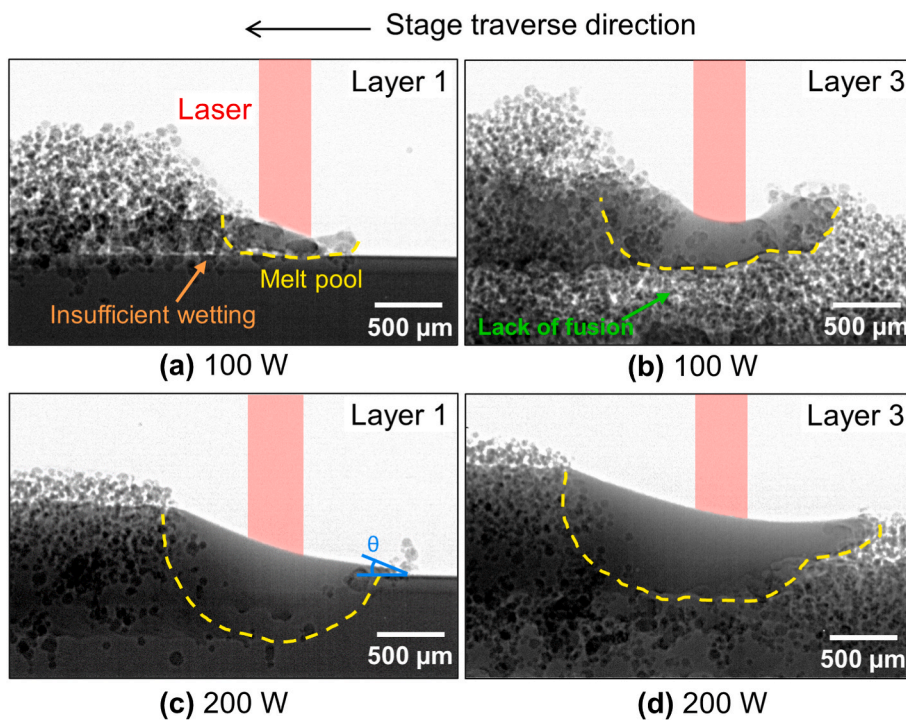

condition are summarised in Fig. 6, as described in Supplementary Fig. 4, averaged over all deposition layers. The 200 W, 1 mm s^{-1} condition is plotted on both graphs. Inset radiograph images show a visual representation of the changing sinter height for each process condition. Fig. 6a shows that changing laser power has a significant effect on the height of the sintered layer, as decreasing from 200 W to 100 W increased the sinter height by *ca.* 400 µm. Fig. 6b shows that increasing the stage traverse speed decreases the sintered layer height: increasing from 1 to 5 mm s^{-1} decreased the sinter layer by *ca.* 130 µm. This is likely due to less powder being deposited during the total build time, as it takes 1/5 of the time to deposit each layer, and thus there is 80% less powder delivered per track length at a constant powder feedrate.

A limited number of experiments were conducted using CP Ti powder and substrates. Radiographic results are shown in Fig. 7, built at 200 W, 2.5 mm s^{-1}, and powder feedrate of 1 g min^{-1}. Supplementary Video 9 shows the deposition at 5 mm s^{-1}, similarly showing a reduced sinter layer height, demonstrating that the relationship between the formation of sinter layer and the processing parameters is probably common across Ti-based materials. Fig. 7b shows sintered CP Ti powder particles on the track surface. The CP Ti behaves similarly to the Ti6242 (Fig. 2); most of the powder particles are sintered together rather than semi-melted and fused to the track. This data shows that the powder sintering phenomenon is not unique to Ti6242 powder and may affect other Ti alloys as well.

4. Discussion

In this study, we observed that Ti alloy powder accumulates on the track surface behind the pool during deposition. The SEM images show only a small fraction of powder particles appear partially-melted and fused together and the majority of the powder particles appear to be sintered. The evidence for this is shown in Fig. 2f, as some particles are most likely partially-melted and fused together, as they have changed in shape, whereas the majority of particles resemble that of Fig. 2g, having developed a neck feature between particles. This feature does not distort the particles and they retain a spherical shape, indicating early stage sintering [33]. Powder build-up via other means such as high velocity impacts, analogous to the cold-spray technique, was ruled out as a mechanism for sinter formation, as the powder particles shown in Fig. 2 have no obvious signs of impact deformation. Schmidt et al. have performed extensive work on determining the critical impact velocity for the cold spray process, which for titanium was predicted and measured to be in excess of 700 m s^{-1} [34]. In DED it could be argued that the highly elevated temperature of some particles would cause the critical impact velocity to be much lower, due to higher ductility. Goldbaum et al. show that even in the cases of gas heated to 1000 °C, the critical velocity remains in excess of 400 m s^{-1} [35], approximately 15 times the maximum velocity of particles exiting our DED nozzle.

The sinter layer formed during deposition is a feature of the experimental setup, and the thermal properties of the powder. Due to the rapid processing times, high heat input in DED, and accelerated diffusion at these high temperatures [36], it is speculated that solid state sintering or even liquid phase sintering is responsible for powder agglomeration [20]. For Ti, furnace sintering generally occurs in the

range $700 < T < 1350$ °C [23]. Liquid phase sintering occurs if a powder particle experiences enough heating to partially melt the surface and grain boundaries where segregated alloy elements lower the melting temperature, but the particle core remains solid [33,37]. The partially-molten particles wet to the surface of one another, forming a layer of sintered powder [38]. This binding mechanism is the most prevalent in the selective laser sintering process (SLS) [39,40], which typically uses a similar laser setup. Furthermore, the work undertaken has shown that the phenomenon of sintering is not confined to the alloy Ti6242 but also occurs during DED deposition of CP Ti powder, Fig. 7b.

Our hypothesis for the formation of a sintered powder layer is related to the dimensions of the powder delivery area and the melt pool surface area. If the powder focal spot is larger than the melt pool, some powder will land outside the pool and will not be incorporated (unless landing ahead of the melt pool). The powder may pass through the laser beam, and undergo heating during flight, or land on the substrate close to the melt pool, heated by the deposited track. It is known that oxides on powder surfaces can inhibit sintering [23,41], and also that titanium

dissolves its own oxide above temperatures of approximately 600 °C–700 °C [23,42]. The oxide dissolution leaves a 'clean' surface on the powder, enhancing sintering. Heated particles which land outside of the melt pool will then sinter to the track and/or other particles. Impact with the heated track could raise particle temperatures enough to induce oxide dissolution and subsequent sintering. The generation of vapour plumes from the melt pool [43] may also induce further particle heating. Heated particles can impact each other in flight, and some may sinter to one another. A recent study by Wolff et al. [14] using high-speed radiography observed two Ti–6Al–4V powder particles colliding in flight, and sintering together, perhaps as a result of surface oxide dissolution. When compared to SS316L and IN718, for example in Fig. 1, both materials form Cr-based oxides on the powder surface [21,22] which are thermodynamically stable, even at high temperatures, and hence these powders will not sinter as readily.

The physical phenomena which lead to the formation of sintered powder is discussed below, and the extent to which the present observations are relevant to a wider range of DED processing conditions is examined.

4.1. The sintered powder layer formation mechanism

For this experiment, the nozzle and approximate powder flow paths are shown schematically in Fig. 8. The powder spot diameter was measured to be 4.9 ± 0.1 mm at the working distance of 6 mm. Fig. 8 shows that the total powder footprint at the consolidation plane is significantly larger than the laser spot size, and the substrate width (400 μm, and 1 mm respectively). The percentage of deposited powder landing in the melt pool in the final deposition layer has been calculated
Fig. 8. 2D schematic of the DED nozzle, with approximate powder jet profiles, creating a powder spot with 4.9 ± 0.1 mm diameter at the consolidation plane. The thin wall substrate is 1 mm, and the laser spot is 400 μm. Shown by a dark purple dotted line is one possible powder particle trajectory, which passes through the centre of the laser beam but lands outside of the melt area. The solid section of line denotes the time during which the particle undergoes laser heating.

in Table 2 with details of pool measurements in Supplementary

Information. The ratio of pool area to powder spot area shows that for these experimental conditions, a maximum of *ca.* 27% of powder is landing within the melt pool. At 1 mm s^{-1}, the area ratio at 100 W is roughly half that at 200 W, meanwhile, at 100 W the sinter layer height is just over double the height at 200 W. This indicates that a critical factor in reducing sintered powder is ensuring a high powder capture efficiency. In commercial DED machines, a larger spot size is typically used alongside a higher laser power (Supplementary Table 1). The mismatch in spot size/melt pool size and the powder delivery spot size in the present work is the key criteria for the excessive sinter observed, however this work highlights the issues which may arise if processing conditions are not correct. Previous work has reported a divergence of powder delivery streams after prolonged powder feeding under a high powder feed rates, caused by erosion of the nozzle inner walls [13]. The larger powder delivery spot led to a reduction in deposit height due to a lower powder capture efficiency. This shows that DED machines can deviate from the calibrated settings with time, and unexpected process phenomena such as sinter build-up could occur. To build fine features using Ti alloys, a very focussed and accurate DED powder delivery jet would be necessary and optimising the melt pool and powder area would be key.

Previous DED models [44] assume that powder particles are either captured by the melt pool or ricochet off and are not melted, whereas this study demonstrates that an additional mechanism is present for Ti alloys in which heated particles may adhere to the track surface but do not melt. As expected from the low ratio of melt pool to powder spot, the powder capture efficiency in Table 2 is also low. However, capture efficiencies can extend across a broad range in DED depending on processing conditions. The values in Table 2 lie within the range reported in previous work using commercial DED machines, of 3–33% [45] and 5% [46]. Larger values of between 54 and 74% [47] and 38–60% have also been seen, the latter in laser cladding [2]. Powder capture efficiencies are a function of the powder focus and nozzle working distance, and previous work has shown that the track temperature affects the capture efficiency, as retained heat in the material lessens the amount of heat input required to reach melting temperature, forming a larger melt pool [48]. The formation of a sintered layer will decrease this however, as the thermal conductivity through sinter is less than bulk material.

An analysis of powder heating during deposition has been carried out, to calculate temperature increases caused by interactions with the laser beam during flight. The heating is primarily caused by the absorption of laser energy as it passes through the beam. Wen et al. [49] and Yan [50] modelled the particle heating process in DED. A calculation of the increase in temperature of individual powder particles in the carrier gas stream was carried out for the processing conditions of the present study, using Equations 4-8 in the Supplementary Information [49]. The heating was calculated for D$_{10}$, D$_{50}$ and D$_{90}$ particle sizes. Powder particles were delivered from the nozzle via four jets, at an angle of *ca.* 14°, focussed to a spot 6 mm below the outlets. The laser power was 200 W. The absorption coefficient of Ti and Ti alloys ranges from 0.3 to 0.77 [50–53], hence this range was used for this calculation. Values used are specified Supplementary Table 2.

The following assumptions have been made in this calculation:

- Powder particles travel at the same velocity as the carrier gas for the duration of their flight [12]; which is *ca.* 26 m s^{-1} for each of the four nozzle jets. Particle velocity was calculated using the volumetric flowrate, shown in Supplementary Information Equation 11. Gravity and drag forces have been considered negligible. Although previous work [44] demonstrated that the particle velocity decreases after exiting the nozzle, this effect was not calculated here. The effect of shielding gas flow on the velocity of incoming powder particles was also not accounted for.
- The carrier gas and initial particle temperature were room temperature (20 °C).

- Powder particles were considered spherical, which is appropriate for gas atomised powders [12].
- Although the powder delivery spot and laser spot are Gaussian, both were represented as a constant intensity.
- Shadowing effects of other powder particles in the stream have been considered to be negligible (*after* [12,54,55]), and particles were assumed to heat uniformly.
- Any heat gained by a powder particle would remain for their full trajectory.

Fig. 9 shows calculated temperatures of one particle travelling through the laser beam and landing outside of the melt pool on the hypothetical path labelled in Fig. 8. The plot shows that for a number of conditions the particle temperature can exceed the threshold for titanium oxide dissolution (plotted here as 700 °C [23,42]), reaching over 1300 °C for the D$_{10}$ particle size of 50 μm, thus we hypothesise that this is causing the sintered layer. As a range of temperatures can be seen, not all particles would undergo oxide dissolution and may ricochet off the surface if not consolidated into the pool. From the SEM images of sintered powder, the particle diameter was measured for any particle exhibiting clear sintering. Across all processing conditions, the average sintered particle diameter was between 46 and 60 μm, indicating that the majority of the sinter layer was formed of particles on the low end of the particle size distribution, which supports the hypothesis of heating and oxide dissolution causing sintering. Since it has been previously reported that particle speeds decrease after exiting the nozzle [44], slower particles would remain in the laser for longer, thus reaching higher temperatures than the predicted values, and increasing the likelihood of sintering. Previous work on SS316L has shown powder particles melting and partially melting while passing through the laser beam, supporting this hypothesis that in-flight heating can be substantial [56]. Supplementary Fig. 6 shows the calculated temperatures if the particle speed was slowed to 75% of the carrier gas jet speed. It demonstrates that even for an absorption coefficient of 0.3, a 50 μm powder particle reaches *ca.* 700 °C, indicating that oxide dissolution and resultant sintering is plausible. The highest calculated temperature is *ca.* 1600 °C, which is nearing the melting temperature of titanium alloys, and may be why some particles in Fig. 2 were partially melted and fused

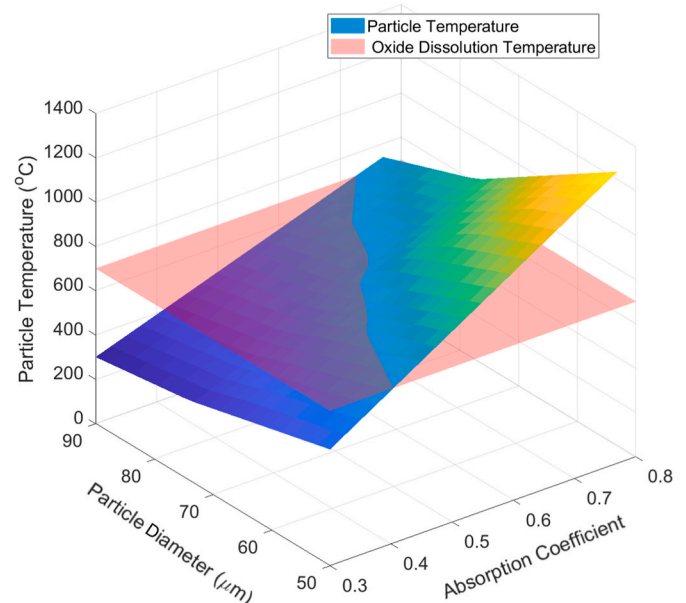

Fig. 9. Calculated temperatures of a powder particle following the path labelled in Fig. 8, for varying particle diameter (D$_{10}$, D$_{50}$, and D$_{90}$) and measured absorption coefficients from previous literature [51,52]. The oxide dissolution temperature is plotted as 700 °C [23,42].

together.

Substrate or track heating also takes place during deposition, and so a modified Rosenthal solution [57,58] has been used to calculate track temperatures around the melt pool. Supplementary Fig. 7a – j shows temperature contour plots with the predicted melt pool for all processing conditions, at the initial and final deposition layer. A fitting parameter has been included, which used the known melt pool length measured from the radiograph images, and fit the calculated pool geometry to this length, to predict pool depth and temperatures. The contour plots show that the temperature of the tracks behind the melt pool exceed 700 °C for all processing conditions, indicating that particles which impact the solidified track could heat and sinter upon impact. However, since the thermal conductivity through sinter is lower than solid track, any powder heating would be a secondary cause of sintering and not the predominant mechanism for the sinter layer formation.

The Rosenthal solution predicted deeper melt pools than measured from radiograph images; an average of 45% deeper for layer 1 and 121% deeper for the final deposition layer across all conditions. The large mismatch between measured and predicted depths in the final layer may be a result of the sinter layer: as can be seen in Figs. 4 and 5, the sinter causes melt pools to become elongated and shallower. It is thought that this is due to a change in pool wetting, onto powder as opposed to previously deposited track. The sintered powder almost acts like a pre-deposited powder layer in LPBF, and the melt pool must percolate through and melt the layer of powder in addition to incoming powder to ensure sufficient layer cohesion. Previous work on melt pool and powder interactions has shown low wettability of powder particles, related to oxides on powder surfaces [59]; this effect may further alter the wetting of the pool. The elongation of melt pools could increase powder capture; however, the subsequent shallowing of the pools decreases the inter-layer cohesion and can lead to lack of fusion porosity. The thermal gradients in the melt pool are also likely to be affected by the sinter layer, as heat transfer through sintered powder will be different than solid track. This could contribute to the melt pool shape change compared to other alloys, as seen in Fig. 1.

The differing melt pool shapes have been referenced in previous works [20], describing it as 'saddle-shaped' as a result of sintered powder. The μCT cross sections in Fig. 3 show the inverted melt pool shape, and an increase in track width as layer number increases for all conditions. Previous studies have also revealed a similar 'saddle' shape of deposited Ti–6Al–4V [60,61] and Ti6242 [5], and the agglomeration of powder Ti–6Al–4V particles on track surfaces [26]. The saddle shaped melt pool was attributed to Marangoni flow in the melt pool, in which material flows downwards at pool edges and is pushed upwards in the centre [26]. It is speculated that sinter layer could contribute to this saddle shaped pool if the melt pool spreads over the surface of the sinter. This could be exacerbated each time a new layer is deposited, as the melt pool could penetrate through the sinter layer, but also flow through the sinter down the sides of the track, rather than creating a deep hemispherical melt pool as expected. This effect would likely be reduced in a hatched melting strategy, as sinter on the sides of a track could be remelted and incorporated into the pool. The saddle effect which causes the melt pool width to increase with each layer could potentially be advantageous, if a need for such geometries arose.

Fig. 10 and Supplementary Video 15 show a Ti6242 sample in which the track was built under atmospheric conditions, instead of an argon purged chamber. The shield and carrier gas remained at the same flowrates; identical conditions were used for both builds, with the exception of the atmosphere. Although there is internal porosity being carried in the melt pool and significant cracking at the ends of the track during solidification due to increased oxygen content, one key observation is that there is no powder sintering on the track surface or during melting. A hypothesis for this is that in an atmosphere containing oxygen, the powder will still be heated if passing through the laser, and the oxide dissolution will take place, however, surrounding oxygen is present to continually replenish the oxide layer, meaning that powder

Fig. 10. Oxidised Ti6242 sample at $P = 200$ W, $v = 1$ mm s^{-1}. The oxygenated atmosphere introduces pores into the melt pool, but most importantly reveals that no sintered powder is present on previous layers or surrounding the melt pool. The melt pool shape resembles the SS316L sample more closely with a convex melt pool surface. See Supplementary Video 15.

particles cannot sinter, as oxides inhibit sintering in metal powders [23, 41]. All incoming powder is either incorporated into the pool and melted or ricochets off the track surface, matching our hypothesis. The melt pool shape in this condition is convex (similar to SS316L and IN718), rather than concave as observed in all other Ti conditions. Any resultant changes to the formation of a vapour plume or subsequent effect on powder sintering are considered negligible. A computational model of vapour plumes by Chen and Yan considered a convection mode situation [62], in which the velocity of the induced gas was *ca.* 0.4 m s^{-1}, which is over an order of magnitude smaller than 26 m s^{-1} gas flow exiting the nozzle in this study.

4.2. Relationship to processing conditions

The difference between titanium alloys and other materials is evident from Fig. 1. The concave as opposed to the convex-shaped melt pool and change in wetting at the leading edge of the pool is a direct result of powder sintering during deposition. The sintered particles in Fig. 2 suggest varying degrees of powder heating in flight between the nozzle and melt pool area, as although some particles had partially melted, the majority of powder particles were sintered as demonstrated in Fig. 2c.

The difference in the height of the sinter layer on the track surface was most noticeable when varying laser power. From the radiograph images in Figs. 4 and 5 and measurements in Fig. 6, it is clear that laser power has the largest influence on the melt pool size, and thus strongly impacts the sinter layer height. Fig. 4 shows that the melt pool created at 200 W is significantly larger than the laser spot size, and the melt pool covers more of the powder spot (*ca.* 27% overlap). For the 100 W condition, the pool is significantly smaller, and so the same amount of powder is flowing into the melt area, but a larger amount will land outside of the melt pool.

Increased traverse speed reduced the energy density and melt pool size, however, the reduced sinter layer height with increasing speed seen in Fig. 6 is a result of less powder being delivered to the laser spot during melting. The effect of increasing traverse speed is essentially analogous to decreasing powder feed rate for a constant speed. Thinner deposition layers were also caused by this reduction in available material, as well as smaller melt pools due to lower overall energy density.

To consider possible conditions which could reduce the sinter layer, the trendlines in Fig. 6 were extrapolated to the point at which sinter height was zero. Assuming a continuous linear relationship, this revealed that a laser power of *ca.* 280 W or higher could sufficiently decrease the sintered layer, likely by causing a larger melt pool and increasing the powder capture efficiency. For traverse speed, the extrapolation indicated that at 200 W, a speed of *ca.* 10.5 mm s^{-1} or higher would be necessary to reduce the sinter height to zero. However, such speeds would substantially reduce the deposition height, as only

half as much powder as the 5 mm s^{-1} condition would be fed into the system and available for melting, thus, increasing traverse speed would not be a suitable method of reducing powder sintering. Furthermore, the relationship between processing parameters and sinter height is likely not strictly linear, and increasing laser power or traverse speed could make the sinter negligible but not eliminate it entirely.

5. Conclusions

This work has provided a parametric study of a previously observed Ti alloy powder sintering phenomenon in DED, and has utilised *in situ* radiography to quantify the effects of different processing conditions on sinter build-up.

Sintering was present under all processing conditions investigated, but the thickness of the sinter layer varied. Increasing laser power, thereby creating a larger melt pool, decreased the sinter layer thickness on the surface of deposits. Increasing traverse speed (akin to reducing powder feed rate) also reduced the sinter, but was at a compromise of reduced deposition height.

A high powder capture efficiency by minimising any mismatch between the pool area and the powder delivery area is necessary to mitigate sinter formation in Ti alloys. Unoptimised processing conditions such as a very high powder feed rate could induce sintering if the incoming powder exceeds the melt pool capture ability.

Sinter is caused by powder heating, primarily via laser beam attenuation during flight. Particle heating calculations confirmed that Ti6242 powder particles can reasonably exceed 700 °C, resulting in surface oxide dissolution and subsequent sintering, under the processing conditions explored in this work.

The build-up of sintered powder layers can cause lack of fusion defects between layers, which were most prevalent in low laser power conditions, and is a feature to be aware of in commercial processing.
