ABSTRACT: Animal studies have revealed gut microbial and metabolic pathways of blood pressure (BP) regulation, yet few epidemiological studies have collected microbiota and metabolomics data in the same individuals. In a population-based, Chinese cohort who did not report antihypertension medication use (30-69 years, 54% women), thus minimizing BP treatment effects, we examined multivariable-adjusted (eg, diet, physical activity, smoking, kidney function), cross-sectional associations between measures of gut microbiota (16S rRNA [ribosomal ribonucleic acid], N=1003), and plasma metabolome (liquid chromatography-mass spectrometry, N=434) with systolic (SBP, mean [SD]=126.0 [17.4] mm Hg) and diastolic BP (DBP [80.7 (10.7) mm Hg]). We found that the overall microbial community assessed by principal coordinate analysis varied by SBP and DBP (permutational multivariate ANOVA P<0.05). To account for strong correlations across metabolites, we first examined metabolite patterns derived from principal component analysis and found that a lipid pattern was positively associated with SBP (linear regression coefficient [95% CI] per 1 SD pattern score: 2.23 [0.72-3.74] mmHg) and DBP (1.72 [0.81-2.63] mm Hg). Among 1104 individual metabolites, 34 and 39 metabolites were positively associated with SBP and DBP (false discovery rate-adjusted linear model P<0.05), respectively, including linoleate, palmitate, dihomolinolenate, 8 sphingomyelins, 4 acyl-carnitines, and 2 phosphatidylinositols. Subsequent pathway analysis showed that metabolic pathways of long-chain saturated acylcarnitine, phosphatidylinositol, and sphingomyelins were associated with SBP and DBP (false discovery rate-adjusted Fisher exact test P<0.05). Our results suggest potential roles of microbiota and metabolites in BP regulation to be followed up in prospective and clinical studies. (Hypertension. 2021;77:706-717. DOI: 10.1161/ HYPERTENSIONAHA.120.16154.) • Data Supplement

Key Words: blood pressure I lipids microbiota metabolome sphingomyelins

ypertension is a leading modifiable risk factor for cardiovascular disease and mortality.¹ Despite numerous clinical and public health efforts to curb the epidemic, the worldwide prevalence of hypertension has continued to increase over the past decade² and the prevalence of controlled hypertension has remained low.³

The blood pressure (BP) regulatory system is multifactorial, involving interactions among host genetics,⁴ sociodemographic factors, and diet.⁵ The gut microbiota and host metabolome, which may reflect these complex interactions,^{6,7} have been demonstrated to play fundamental roles in BP regulation in animal models⁸⁻¹¹ and humans.¹²⁻¹⁴ In particular, the metabolome reflects a thorough snapshot of various metabolic processes, allowing the identification of novel biomarkers and pathogenic pathways of elevated BP.¹⁵ For example, the microbiotamediated serum 4-hydroxyhippurate is positively associated with incident hypertension in blacks.¹⁶ Additionally, reductions in the overall gut microbial diversity and relative abundance of specific microbial groups, including

Novelty and Significance

What Is New?

- Our study fills the gap in population-based studies investigating both gut microbiota and circulating metabolomics in association with blood pressure (BP).
- Our sample is unique in that many participants with hypertension were untreated, allowing us to minimize the medication effects.

What Is Relevant?

• Our findings support a difference in the overall gut microbiota by BP.

Nonstandard Abbreviations and Acronyms

ARIC	Atherosclerosis Risk in Communities
BMI	body mass index
BDL	below detection limit
BP	blood pressure
CARDIA	Coronary Artery Risk Development in Young Adults
CHNS	China Health and Nutrition Survey
DBP	diastolic BP
FDR	false discovery rate
INTERMAP	International Population Study on Macronutrients and Blood Pressure
LDL-C	low-density lipoprotein cholesterol
ΡϹοΑ	principal coordinate analysis
SBP	systolic BP

Prevotella and *Coprococcus*, are associated with hypertension in animal models^{11,17} and humans,^{13,14,18} albeit with small sample sizes. However, there is a lack of populationbased studies that include microbial and metabolomic data along with phenotypic data, which is necessary to infer how microbiota influence host physiology through bioactive metabolites. Moreover, there is a need for studies conducted in populations with large burdens of hypertension but low rates of diagnosis and treatment for hypertension for the assessment of natural history of BP.

To this end, we used a well-characterized adult cohort from the 2015 China Health and Nutrition Survey (CHNS) to conduct 2 primary analyses: the association between (1) gut microbiota and (2) plasma metabolome with BP. We selected the CHNS because China has the greatest absolute burden of hypertension around the world¹⁹ coupled with a high rates of undiagnosed and untreated hypertension,²⁰ making China an ideal context for studying BP while minimizing the medication effects. • We identified a novel lipid pattern and several lipid metabolites (eg, sphingomyelins, acyl-carnitines) positively associated with BP.

Summary

In a well-characterized Chinese adult cohort, we showed associations between gut microbiota and plasma metabolites with BP, indicating potential roles of microbial and metabolites groups, like lipids, in BP regulation.

METHODS

The data and code that support the findings of this study are available to researchers upon request. All phenotypic data can be accessed at the CHNS website (https://www.cpc.unc.edu/projects/china).

Study Sample

We used data from the 2015 CHNS. The CHNS is a prospective, household-based study across 12 provinces and 3 megacities, which vary substantially in geography, customs, economic development, and health indicators.²¹ Informed consent was obtained for all participants. The study met the standards for the ethical treatment of participants and was approved by the Institutional Review Boards of the University of North Carolina at Chapel Hill and the National Institute for Nutrition and Health, Chinese Center for Disease Control and Prevention. Participants of the 2015 survey aged 30 to 69 years from four southern provinces (Henan, Hunan, Guizhou, Guangxi) with BP data and gut microbiome or plasma metabolome data were eligible for analysis (N=1285, Figure S1 in the Data Supplement). We excluded participants who were pregnant (n=1), selfreported use of antihypertension medication (n=99), or had missing covariates (n=86). For microbiota analysis, we additionally excluded 35 participants who currently used antibiotics, had diarrhea, inflammatory bowel disease, irritable bowel syndrome, or bowel removal. For metabolites analysis, we additionally excluded 16 participants who had detectable levels of four cardiovascular disease drug metabolites in plasma: metoprolol acid metabolite, alpha-hydroxymetoprolol, nifedipine, and valsartan. The total analysis sample had 1082 adults, with 1003 and 434 adults included in the microbiota and metabolomics analysis samples, respectively.

Blood Pressure

Resting BP was measured by experienced physicians, who had completed a 7-day training session and passed a comprehensive reliability test. After a 5-minute seated rest, systolic (SBP) and diastolic BP (DBP) were measured in triplicate (30-second interval between cuff inflation) using a standard mercury sphygmomanometer (measuring range, 0–300 mmHg) on the right arm (heart level in sitting position) rested on table with palm face up. The cuff size was selected according to standardized protocol.²² We used the average of the 3 readings as our measure of SBP and DBP. Hypertension was defined as SBP \geq 140 mm Hg, DBP \geq 90 mm Hg, or self-reported diagnosis.²³

Gut Microbiota

Participants collected stool samples at home using the QIAGEN collection kit (QIAGEN, Hilden, Germany) following standardized protocol. Samples were temporarily stored at foam boxes with frozen cold packs and brought to local community or village clinics immediately, where the samples were stored at -20°C. Then, samples were transported in cold-chain to laboratory and frozen at -80°C until processing. Samples were randomized for sequencing at Novogene Bioinformatics Technology, Co, Ltd, Tianjin, China, so that batches were not related to specific collection centers. Bacterial DNA was extracted using TIANGEN DNA extraction kits (TIANGEN Biotech, Beijing, China). Sequencing for 16S rRNA (ribosomal ribonucleic acid) targeting the V4 hypervariable region was performed using primers 515F/806R on the Illumina MiSeg PE250 platform. The raw sequencing reads were processed using the QIIME pipeline,²⁴ with forward and reverse reads merged with fastq-join and filtered using a minimum quality score of 20. No sample was filtered out due to low quality. Operational Taxonomic Units were identified using open-reference method based on a threshold of 0.97, with chimeric Operational Taxonomic Units detected by ChimeraSlayer being removed.25 Taxonomy was assigned based on the SILVA databases (Release 128). We rarefied the resulting taxonomic abundances of 1008 genera to 21 600 sequences/sample to correct for different sequencing depth (21648-89427 sequences/sample) before log₁₀ transformation.

Plasma Metabolomics

Fasting blood samples were collected within 3-days of fecal sample collection by clinicians following the same protocol for the collection, processing, and storage. Ethylenediamine tetraacetic acid was used as an anticoagulant and plasma was immediately separated through centrifugation and stored at -80°C. Detection and quantification of metabolites was performed by the partner campus of Metabolon Inc. in China using a nontargeted platform consisting of a Waters ACQUITY ultrahigh performance liquid chromatographer (Milford, MA) and a Thermo Scientific Q-Exactive high-resolution mass spectrometer (Waltham, MA).7 Methanol solvent was used to extract plasma samples, which were analyzed with several types of controls, including pooled experiment samples as technical replicate and extracted water samples as process blanks. Signals were extracted, peak identified, and processed using Metabolon's software and hardware. Metabolites were identified by comparing to the mass-to-charge ratio, rendition time/index, and chromatographic data in the Metabolon reference library of purified standards and labeled according to Metabolomics Standards Initiative defined identification levels.²⁶ Of the 1104 detected and quantified metabolites, we categorized 131 metabolites that were below detection limits (BDL) in 25% to 50% samples to 3 groups (BDL, <median, ≥median) and 99 metabolites with >50% of BDL to binary variables (BDL, ≥detection limit). For 874 metabolites with ≤25% of BDL, we rescaled the raw area count of each metabolite to a median of one and imputed values BDL by the minimum value before \log_2 transformation.

Covariates

Sociodemographic and behavioral information were collected using standard questionnaires administered by interviewers, including age, sex, education (yes/no completed high school), per-capita household income (household income/number of household member), ever smoking (yes/no), alcohol intake in the past year (yes/no), and total physical activity (metabolic equivalents/wk). We assessed community-level urbanization using a validated urbanization index that encompasses 12 dimensions of urbanization,27 including population density, health infrastructure, sanitation, and transportation. We included 2 validated measures of diet, total energy intake (kcal/day),²⁸ and sodium intake (mg/day),²⁹ collected using 3-consecutive 24-hour diet recalls and household food inventories. We also included 3 clinically measured health markers: (1) for kidney function, we used fasting serum creatinine concentration measured by picric acid method on Hitachi 7600 (Tokyo, Japan) to calculate estimated glomerular filtration rate (mL/min per 1.73m²) based on the Chronic Kidney Disease Epidemiology Collaboration equation³⁰; (2) LDL-C (low-density lipoprotein cholesterol, mg/dL) was measured by the polyethylene glycolmodified enzyme method on Hitachi 7600; (3) we calculated body mass index (BMI) from weight over squared height (kg/ m²) measured using calibrated beam scales and portable stadiometers, respectively.

Statistical Analysis

Primary outcomes were SBP and DBP. In the microbiota analysis sample, we first analyzed the overall gut microbiota by examining the associations of genus-level within-person microbial diversity (a-diversity), measured by Shannon index and richness, $^{\scriptscriptstyle 31,32}$ and between-person diversity (β-diversity), assessed by principal coordinate analysis (PCoA) based on Bray-Curtis dissimilarity matrix,33 with SBP and DBP using linear regression and permutational multivariate ANOVA with 999 permutations,³⁴ respectively. PCoA axis score is a weighted sum of genera scores (Table S1). Then, we quantified the association between each of the first four PCoA axes, explaining 8.61%, 5.58%, 3.54%, and 3.16% of microbial variability, respectively, as well as 1008 specific genera with SBP and DBP using linear regression. We treated 110 genera detected in ≥25% of the sample as continuous variables and dichotomized the rest 898 rare genera to presence/absence. We adjusted all analyses for the following potential confounders in Model 1 based on a priori knowledge: age, sex, provinces, urbanization index (tertiles),³⁵ education, per-capita household income (tertiles), total energy intake, animal-source food consumption,³⁶ sodium consumption,37 total physical activity (tertiles), tobacco use, alcohol consumption, and estimated glomerular filtration rate.³⁸ As BMI is a potential mediator for microbiota-BP relationship, we additionally adjusted for BMI in Model 2 as a sensitivity analysis to test whether the association was independent of BMI. Additionally, as lipid profile is correlated with BP and microbiota, we conducted a post hoc analysis that additionally adjusted for the atherogenic LDL-C.

In the metabolomics analysis sample, we first analyzed the overall metabolome by separately grouping 874 metabolites (continuous variables, ≤25% BDL) into uncorrelated patterns to account for complex correlations across metabolites, using principal component analysis followed by a varimax rotation to improve interpretation.³⁹ Based on 3 criteria: eigenvalues >1, the point of inflection in scree plot, and interpretability,40 we selected 3 metabolite patterns (Table S2). Pattern score is a weighted sum of rotated and inverse factor loadings. Then, we assessed the association between each metabolite pattern, as well as 1104 individual metabolites with SBP and DBP, using the above-mentioned multivariable-adjusted linear models adjusting for batch. We used a Wald test to assess the statistical significance of 131 metabolites with 3 categories (BDL, <median, ≥median). Based on model 1 results for individual metabolites, we calculated pathway enrichment score $\left[\frac{k}{m}/(\frac{n-k}{N-m})\right]$ reflecting the degree to which a given pathway was associated with SBP or DBP, where k and n are numbers of BP-associated metabolites in the given pathway and all

pathways, respectively, and m and N are numbers of tested metabolites in the given pathway and all pathways, respectively. We performed a Fisher exact test⁴¹ to evaluate whether the presence of BP-associated metabolites among identified compounds from a particular metabolic pathway was greater than expected by chance.

In a subsample of participants with microbiota and metabolite data (n=355), we examined the association between BP-associated microbiota features and BP-associated metabolites using linear models to understand the intercorrelation between microbiota and metabolites. Next, we conducted random forest regression (100 trees) which allows interaction across microbiota and metabolites,⁴² followed by 5 iterations of 2-fold cross-validation modified paired *t* test of root mean squared errors, a powerful test to compare the performance of learning algorithms with acceptable type I error,⁴³ to provide insight into which of the following data as a whole had the strongest association with BP: host factors (14 model 1 covariates), microbiota (1008 genera), metabolites (1104 metabolites), microbiota+host factors, microbiota+metabolites+host factors.

We adjusted *P* values for multiple comparisons using Benjamini-Hochberg method (false discovery rate, FDR)⁴⁴ in comparisons across taxa, metabolites, and metabolic pathways for SBP and DBP separately. All statistical tests were 2-sided with a significance level of 0.05. We used R 3.6.0 (http:// www.r-project.org) and Python 3.5.1 (https://www.python.org) for data analysis.

RESULTS

Our sample had large variation in SBP (mean [SD]: 126.0 [17.4] mm Hg) and DBP (80.7 [10.7] mm Hg), with 27.6% prevalence of hypertension (Table S3).

We first assessed the overall gut microbial measures. Within-person microbial diversity (Shannon index and richness) was not associated with SBP or DBP (Table S4, *P*=0.45–0.97). Between-person microbial diversity assessed by PCoA varied by SBP (Figure; permutational multivariate ANOVA R^2 =0.20%, P=0.002) and DBP (Figure S2; permutational multivariate ANOVA R^2 =0.14%, P<0.05). Only the fourth PCoA axis showed a clear separation of SBP (Figure), with higher axis

Figure. Microbial between-person diversity (β -diversity) assessed using principal coordinate analysis by systolic blood pressure (SBP).

Centroids illustrate the 95% CI for the mean location of each SBP (mm Hg) quartile. Vectors for 10 taxa with the greatest contributions to MDS (multidivisional scaling) 4 indicate the directions and strengths of their correlations with MDS4 (Table S1). In permutational multivariate ANOVA (N=1003), SBP had R^2 of 0.20% and *P* value of 0.002, after adjusting for age, sex, provinces, urbanization index, per-capita household income, education, total energy intake, animal-source food, sodium, physical activity, smoking, alcohol, and estimated glomerular filtration rate. Results remained the same after additional adjustment of body mass index.

score associated with higher SBP (Table S5). This axis was positively correlated with *Rothia, Serratia, Enterobacteriaceae, Leuconostocaceae*, and *Fusobacterium* and negatively correlated with *Coprococcus, Adlercreutzia, Eggerthella*, and *Raistonia.* However, after correction for multiple hypothesis testing, none of the 1008 specific genera were associated with SBP or DBP at FDR-adjusted P<0.05 (Table S6). We observed similar results after additionally adjusted for LDL-C (Table S7 through S9).

In plasma metabolite analysis, we identified 3 biologically possible patterns using principal component analysis that each explained 9.63%, 4.79%, and 4.69% of variance (Table 1). The second pattern characterized by lipids, like linoleate, palmitate, and oleate/vaccinate was positively associated with SBP (linear model coefficient [95% CI] per 1 SD pattern score: 2.23 [0.72– 3.74] mm Hg) and DBP (1.72 [0.81–2.63] mm Hg). The results were slightly attenuated by adjustment of BMI (SBP: 1.88 [0.38–3.38] mm Hg; DBP: 1.45 [0.55– 2.35] mm Hg).

To identify whether specific metabolites contributing to this lipid pattern drove the associations with SBP and DBP, we examined 1104 metabolites (Table S10 through S12) and found that 34 and 39 metabolites were associated with SBP (Table 2) and DBP (Table 3) at Model 1 FDR-adjusted P<0.05, respectively, including 8 sphingomyelins, 4 acyl-carnitines, and cholesterol. Among these SBP- and DBP-associated metabolites, 8 (23.5%) and 19 (48.7%) metabolites, respectively, had high loadings (>0.4) for the lipid pattern, including acyl-carnitines (C16, C26, C14, and C12), 1-palmitoleoylglycerol (16:1), and dihomolinolenate (20:3n3 or 3n6), which were positively associated with both BP measures. In contrast, we saw noticeably fewer SBPand DBP-associated metabolites with high loadings for the other two metabolite patterns (0%-11.8%). After adjusting for BMI, only 9 and 17 metabolites remained statistically significantly associated with SBP and DBP (model 2 FDR-adjusted P<0.05), respectively, including sphingomyelins (d18:1/23:0, d18:1/24:0, and d18:2/24:2) and acyl-carnitines (C16 and C14). After adjusting for LDL-C, results for metabolite patterns were similar to main model results (Table S13) and only 19 metabolites remained statistically significantly associated with DBP (Table S14).

In pathway analysis that tested whether the number of positive or negative associations between BP and metabolites from a particular metabolic pathway was more than expected by chance (Table 4, Table S15), we found that diacylglycerol, acylcarnitine (long-chain saturated), phosphatidylcholine, phosphatidylinositol, sphingomyelins metabolic pathways were associated with SBP (FDR-adjusted P<0.05); and corticosteroids, acylcarnitine (long-chain saturated and median chain), monoacylglycerol, phosphatidylinositol, and sphingomyelins metabolic pathways were associated with DBP.

In a subsample of 355 participants with similar distributions of SBP (123.5 [16.7] mmHg) and DBP (79.8 [9.9]) to the full sample (Table S16), we conducted

Table 1. Association Between Metabolite Patterns With SBP and DBP (mm Hg), Coefficient (95% CI)

Patterns were derived from principal component analysis followed by a varimax rotation of 874 metabolites (N=434). Coefficient indicates SBP or DBP associated with each 1 SD of metabolites pattern score in linear regression. Contributing metabolites are metabolites with the highest absolute loadings for the respective pattern (Table S2). Model 1 was adjusted for age, sex, provinces, batch, urbanization index, per-capita household income, education, total energy intake, animal-source food, sodium, physical activity, smoking, alcohol, and estimated glomerular filtration rate. Model 2 was additionally adjusted for body mass index. DBP indicates diastolic BP; GPE, glycerophosphoethanolamine; and SBP, systolic BP.

Coefficient indicates SBP associated with a fold increase of the abundance or per category change of a metabolite in linear regression (N=434). The statistical significance of metabolites with 25-50% BDL was assessed using a Wald test. Model 1 was adjusted for age, sex, provinces, batch, urbanization index, per-capita household income, education, total energy intake, animal-source food, sodium, physical activity, smoking, alcohol, and estimated glomerular filtration rate. Model 2 was additionally adjusted for body mass index. BDL indicates below detection limit; GPC, glycerophosphocholine; GPI, glycerophosphoinositol; PC, phosphatidylcholine; PI, phosphatidylinositol; and SBP, systolic blood pressure.

*Pattern was derived from principal component analysis followed by a varimax rotation. Loadings>0.4 are listed.

†Metabolites also associated with diastolic blood pressure.

integrated microbiota and metabolite analysis to examine the intercorrelation between microbiota and metabolites and whether the microbiota and metabolite data had better BP predictive performance than host sociodemographic and behavioral risk factors. We observed no correlation between the BP-associated, fourth gut microbiota PCoA axis with any of the 54 BP-associated metabolites (Table S17, FDR-adjusted *P*≥0.27). Using random forest regression, we found comparable accuracies across host factors, microbiota, and metabolite data in predicting SBP and DBP (Figure S3, *P*>0.05).

DISCUSSION

In a population-based cohort of middle-aged Chinese adults, we found an association between the overall gut microbiota (between-person diversity) with SBP and DBP, after accounting for a wide range of sociodemographic factors, health behaviors, and kidney function. Using plasma metabolome data, we found that a lipid pattern and several individual metabolites like sphingomyelins, acyl-carnitines, and cholesterol were positively associated with SBP and DBP. Our results suggest that in this population with high prevalence of untreated hypertension (27.6%), gut microbiota, and plasma metabolites may play important roles in hypertension.

Several studies have shown an association between the gut microbiota and BP.^{13,14,18} For example, a recent case-control study of 80 Brazilian adults¹⁴ showed lower microbial biodiversity along with lower proportions of butyrate-producing taxa like *Roseburia, Coprococcus,* and *Lachnospiraceae* but higher proportions of *Enterobacteriaceae* and *Lactobacillus* in individuals with high versus normal BP. The Sun et al's¹⁸ article of 529 middle-aged US adults from CARDIA study (Coronary Artery Risk Development in Young Adults) found an inverse crosssectional association between within-person microbial diversity with SBP and differences in the overall microbial community by SBP. Similarly, we observed differences in the overall gut microbial community by SBP and DBP in the current CHNS study. The US CARDIA cohort is quite different from the China population-based cohort (eg, higher hypertension medication use, different diet and lifestyle in the US cohort). Furthermore, we excluded participants who used antihypertension medication from the current analysis, whereas 29.2% of participants took antihypertension medications in the CARDIA analysis sample.¹⁸ Future prospective studies are needed to confirm the results of our study and previous research.

Metabolomics studies showing associations between microbial metabolites and BP further support the role of gut microbiota in BP regulation.^{16,45} The INTERMAP study (International Population Study on Macronutrients and Blood Pressure) of 4630 middle-aged adults from United States, United Kingdom, Japan, and China showed that urinary alanine and hippurate were positively and negatively associated with BP, respectively.45 The ARIC study (Atherosclerosis Risk in Communities) of 896 Blacks revealed that each one SD increase in baseline serum 4-hydroxyhippurate was associated with 17% higher risk of incident hypertension.16 In our sample, we found that p-cresol sulfate from benzoate metabolism, a product of tyrosine and phenylalanine metabolism by anaerobic bacteria,⁴⁶ was inversely associated with DBP. Additionally, we found comparable predictive accuracies between gut microbiota and plasma metabolome for BP, indicating that microbiota may play a role in metabolites-BP associations, as it has been shown that gut microbiota is involved in host lipid metabolism and modulates plasma metabolome in response to angiotensin II.47,48 Given that many microbiota-mediated metabolites were strongly associated with diet, for example, hippurate derived from dietary polyphenols,49 different dietary patterns across populations may relate to these different results across studies.

Host-derived metabolites like the ketone body β hydroxybutyrate, acyl-carnitines, and long-chain fatty acids have also been suggested in mechanisms of BP regulation.^{15,16,50} For example, nutritional supplementation of a precursor of β -hydroxybutyrate attenuated

Coefficient indicates DBP (mmHg) associated with a fold increase of the abundance of a given metabolite in linear regression (N=434). Model 1 was adjusted for age, sex, provinces, batch, urbanization index, per-capita household income, education, total energy intake, animal-source food, sodium, physical activity, smoking, alcohol, and estimated glomerular filtration rate. Model 2 was additionally adjusted for body mass index. DBP indicates diastolic blood pressure; GPC, glycerophosphocholine; PC, phosphatidylcholine; and PI, phosphatidylinositol.

*Pattern was derived from principal component analysis followed by a varix rotation. Loadings > 0.4 are listed. +Metabolites also associated with systolic blood pressure.

hypertension in hypertensive rats fed a high-salt diet.⁵⁰ In line with our findings, Menni et al. showed that in 3980 TwinsUK females, a few plasma carnitines, longchain fatty acids, and steroids were positively associated with BP, including hexadecanedioate, palmitate (16:0), octanoylcarnitine (C8), 10-heptadecenoate (17:1n7), and dihomolinoleate (20:2n6).¹⁵ In particular, hexadecanedioate, a dicarboxylic acid, consistently showed positive association with BP in 2 replication cohorts with both males and females.¹⁵ Subsequent analysis using rat model demonstrated that oral intake of hexadecanedioate increased BP, supporting a causal role of hexadecanedioate in BP regulation.¹⁵ In another study of 202 African and White men, serum long-chain and mediumchain acyl-carnitines (in Whites only) were positively associated with ambulatory BP.51 Similarly, we found

positive associations between medium- and long-chain acyl-carnitines, long-chain fatty acids, and a lipid pattern driven by long-chain fatty acids with BP. Elevated levels of circulating acyl-carnitines and long-chain fatty acids may contribute to hypertension development, as acyl-carnitines are byproducts of incomplete β -oxidation and can accumulate in blood or urine when fatty acids are in excess for oxidation, thus stimulating proinflammatory pathways involving nuclear factor kappa B.⁵² Likewise, omega-6 fatty acid like linoleate may impair cardiovas-cular health as it can be metabolized to dihomolinoleate and then to arachidonic acid, a precursor for proinflammatory eicosanoids like leukotriene B4.⁵³

In addition, we found that several sphingomyelins and the sphingomyelin metabolic pathway were each positively associated with BP. Ceramide as a precursor for

 Table 4.
 Metabolic Pathways Associated With SBP or DBP

BP indicates blood pressure; DBP, diastolic BP; PC, phosphatidylcholine; PI, phosphatidylinositol; and SBP, systolic BP.

*Enrichment score was calculated using (k/m)/[(n-k)/(N-m)], where k and n are numbers of BP-associated metabolites (model 1 false discovery rate adjusted P<0.05) in a given pathway and all identified pathways (SBP: n=34; DBP: n=39), respectively; m and N are numbers of classified metabolites in a given pathway and all identified pathways (N=904), respectively.

tP value for each pathway was calculated using Fisher exact test and adjusted for false discovery rate (Q value) across pathways containing at least one BPassociated metabolite. sphingolipids is harmful to cardiovascular health, including impaired vasodilation.⁵⁴ Excess sphingolipids occur when fatty acids exceed energy need or storage capacity of a cell.⁵⁵ Several lipidomic studies have identified sphingolipids as candidate blood markers for cardiovascular diseases in humans.⁵⁶⁻⁵⁸ For example, Poss et al⁵⁸ found that 30 serum sphingolipids were elevated in subjects with coronary artery disease (n=462) than controls (n=212) and a sphingolipid risk score was more effective than conventional biomarkers like triglycerides and LDL-C in distinguishing coronary artery disease patients.

The strengths of our study include paired microbiota and metabolite data in a well-characterized cohort with clinically measured BP. Moreover, the rich sociodemographic and behavioral data of the CHNS allowed us to account for a wide range of potential confounders. The low treatment rate for hypertension ensured sufficient sample size and large variation in BP, even after excluding people who took antihypertension medication to minimize medication effects. However, we cannot infer a causal relationship between gut microbiota, host metabolome, and BP due to the cross-sectional design, and our microbial 16S rRNA data did not provide functional information. Future studies are needed to confirm our findings, particularly, population-based studies with repeated measures paired with experimental studies to investigate the causal biological pathways modulating BP.

PERSPECTIVES

Our study provides substantial observational evidence for the associations between gut microbiota and plasma metabolites with BP in a population-based cohort of middle-aged Chinese adults. The overall microbial community varied by BP. Several individual metabolites (eg, lignoceroyl sphingomyelin, cerotoylcarnitine, and dihomolinolenate) and an overall lipid metabolite pattern characterized by long-chain fatty acids were positively associated with BP, suggesting a role of circulating lipids in hypertension. Further analyses with longitudinal data and refined microbial composition data in larger samples are needed to fully elucidate the causal relationship between gut microbiota, host metabolites, and BP, thereby informing effective early interventions and treatments for hypertension.
