To my mother

My father, may his soul rest in peace

And my brothers

ACKNOWLEDGMENTS

Herein, I acknowledge the immense support I have received toward the completion of this degree. I would like to start by thanking my research adviser and mentor, Dr. Richard J. Wittebort for his guidance, continuous support through all the times, particularly the tough ones for both of us. You were always there for me, with patient and sense of humor, never failed to draw a smile on my face. I could not make it without you and for that I am eternally grateful.

My sincere gratitude to my dissertation committee, Dr. Muriel C. Maurer, Dr. Eugene G. Mueller, Dr. Michael H. Nantz and Dr. Donghan Lee. Thank you for your valuable time, assistance and insightful ideas that nourish my work. You were of great help and I learnt so much from you.

I would like to thank the faculty and staff members at the Department of Chemistry in University of Louisville for their constant support and assistance, especially Dr. Lenore K. Hoyt, Sherry Nalley, Steve Riley, Carla Parris and Dr. Jason A. Sievers. Also, my sincere gratitude to the former members of the department; Aaron Howell, Sabrina Haug, Luther "Ben" Hutcherson and Renu Kakar.

Special thanks to Joshua Rimmer from the Physics Department for his help with the homebuilt thermomechanical apparatus and Dr. Jacek B. Jasinski and his coworkers from the JB Speed School of Engineering for their help in the SEM micrographs.

I cherish my friendships that grow through the years in University of Louisville, starting with my lab mate, friend and partner in crime; Dr. Faye Carvajal, thank you for the many laughs you brought to my life, your endless support and for being always there for me. My friend Biyun Shi, thank you for your unique sense of humor that kept coming overseas. My friends: Dr. Nina Saraei, Amareshwari Konutham, Caleb Calvary, Dino Ablan and Hari Krishnan Nambiar, thank you for the joyful times we have shared. You made my life in Louisville unforgettable.

My friends in Jordan, particularly Dima Hami and Rana Qasaymeh, your support and encouragement kept me going, thank you for being part of my life.

Above all, I am indebted to my mother, my late father, my brothers and my nephews and nieces, for their unconditional love and infinite inspiration. You believed in me when I could not, thank you for everything.

ABSTRACT

INVESTIGATIONS OF ELASTIN RECOIL ON MOLECULAR AND MACROSCOPIC LEVELS

Nour Mohammad Jamhawi

April 30, 2021

Elastin is one of the most hydrophobic proteins, and it is extremely flexible when hydrated. The driving force for recoil is the decrease in entropy of the protein and/or the hydrating solvent. This dissertation is a study of both mechanisms. Following an introduction (Chapter 1), Chapters 2 and 3 investigate the recoil mechanism on the molecular level in the hydrating solvent and in the protein, respectively. Chapter 4 examines macroscopic properties of recoil by thermomechanics. Conclusions are discussed in Chapter 5.

Using double quantum NMR, the deuterated water ordering at the elastin surface was studied quantitatively as a function of stretch and in the presence of solutes known to modulate the hydrophobic effect: polyethylene glycol (PEG), sulfate ion, a kosmotrope, and perchlorate ion, a chaotrope. When the purified elastin is stretched, a nearly one order of magnitude increase in the ordering of water is observed, and this is due to the increase in water exposed to the hydrophobic surface. When PEG and sulfate ions are added to the solvent, ordering of the water is significantly decreased due to a more compact protein with reduced solvent exposed surface area. At concentrations below 0.3 mol/kg perchlorate ion,

only minor changes in the magnitude of the ordered water signal are observed because perchlorate interacts with peptide bonds and does not decrease exposed hydrophobic surface area.

Ordering of elastin was studied using static ^{13}C NMR to assess the amplitude of backbone motions in the mature elastic material. It was found that the residual shielding anisotropy is small, 1 – 3 ppm and within the experimental resolution of this experiment, no stretch induced ordering was observed. Thus, cross-linked elastin is dynamically disordered much like soluble minielastins.

The thermomechanical experiments show that elastin is stiffer in the presence of PEG, sulfate and high perchlorate concentrations. These solutes do not interact with the protein and decrease the volume and the length of the fiber, confirming the increase in compaction. Also, they decrease the heat liberated, the change in entropy and the internal energy with stretch. Thus, the hydrophobic effect is the major player in elastin recoil.

CHAPTER 1 INTRODUCTION

1.1 Elastin

Elastin, an extracellular matrix protein, is crucial for elasticity in many vertebrate tissues including arteries, lungs, skin and elastic cartilage. It is a fibrous protein and, in terms of evolution, is a relatively new protein. It provides essential energy storage for the closed circulatory system found in all vertebrates.¹ Unlike rubbers, elastin requires a solvent to recoil. Dry elastin is an insoluble fragile polymer and gains elasticity only when swollen in water.

Tropoelastin is the natural soluble precursor of elastin. It was first isolated in 1969 from copper deficient porcine aorta.² It is 60 – 70 kDa in molecular weight and composed of alternating hydrophobic modules (25 – 40 amino acids) and smaller cross-linking modules.^{3,4} The hydrophobic modules are highly repetitive sequences rich in proline (P), alanine (A), valine (V), leucine (L), isoleucine (I) and glycine (G). Typical cross-linking domains have pairs of lysyl residues separated by two or three alanyl residues embedded within P- or A- rich regions.⁴

Elastogenesis is the formation of a mature elastic matrix. It is a complex process, and involves the coordination of intracellular transcription, translation and processing of tropoelastin precursor protein. Following synthesis, tropoelastin is secreted into the extracellular space for microfibrillar assembly.

In addition to other proteins, assembly requires a unique inverse phase transition known as coacervation. Finally, intra- and intermolecular cross-linking results from the action of lysyl oxidase to produce mature insoluble elastin matrix.³ Lysyl oxidase converts ϵ -amino groups into aldehyde groups that combine with ϵ -amino groups to produce ultimately four lysyl side-chains in a pyridyl ring structure known as desmosine or isodesmosine.⁵ This crosslinking process is random and results in an unordered network.⁶

1.1.1 Elastic Mechanisms of Elastin

The recoil force behind the elasticity of elastin is believed to be entropic.⁷⁻¹⁰ Stretch decreases the entropy of the system and recoil is spontaneous to restore the lost entropy. Two main structure-function groups of models have been proposed to explain the recoil mechanism.^{1,3} But, the precise mechanism has not been elucidated.

Structure-based models are divided into two main groups. The first, introduced by Hovee and Flory, describes elastin as a network of free, randomly moving chains with high entropy that is reduced by stretch.⁹ The fibrillar model relies on the presence of β -turn repeat structures that are less disordered upon stretching.^{4, 11} The latter model is widely accepted; however, direct experimental evidence of stable β -turn structures in natural elastin has not been reported.

Function-based models are also divided into two main groups. In “rubber-like” models, the entropy decreases upon stretch due to backbone ordering. This group of models describes elastin as either a network of random chains⁹ or a protein with secondary structures; more specifically β -turns.^{4, 11} In the second group, entropy decrease upon stretch is from polymer and solvent ordering. The first model of this group, the liquid drop model, was introduced in 1970 by Weis-Fogh and Anderson. In this model, tropoelastin molecules

are hydrophobic globular monomers cross-linked to form the aggregates of elastin. Stretch deforms the globules thereby increasing their surface area and decreasing solvent entropy due to the hydrophobic effect.⁸ The oil coiled model is similar to the liquid drop model in regard to decreased entropy of the exposed solvent but considers tropoelastin fibrillar instead of globular.¹²

It is widely assumed that recoil in elastin is the same as in rubber, i.e., recoil is driven by an increase in polymer entropy. However, this assumption does not account for two important features of elastin: it is not elastic when water is absent, and elastin has evolved into one of the most hydrophobic proteins known. In this research, both theories were investigated with the focus on the hydrophobic effect model. This was achieved through combining three different approaches. First, water ordering was directly observed using novel Double Quantum Nuclear Magnetic Resonance (2Q NMR) experiments as a function of both stretch and in the presence of Hofmeister ions, polyethylene glycol (PEG) and deuterated solvent that systematically modulate the hydrophobic effect. These are the first experiments in which stretch induced water ordering has been directly observed at the molecular level. Second, the effect of stretch on the amplitude and timescale of the protein dynamics was studied using static solid state natural abundance ¹³C NMR of backbone carbonyl groups. Third to complement the NMR measurements, the entropy changes from stretching natural elastin were measured in a newly designed and homebuilt apparatus in the presence of Hofmeister ions and PEG. All experiments were performed on highly purified bovine elastin.

Elastin has inspired the design of wide variety of proteins with different functions, including protein purification, matrices for tissue engineering and drug delivery. The

significance of this research is to understand elastin recoil, which is fundamental to the systematic approach of developing and designing new protein-based elastomers.

1.1.2 Elastin Fibers Purification

²Q NMR experiments were performed first on bovine elastin fibers obtained from Elastin Products Company (Owensville, MO). These fibers were prepared by the neutral extraction method.¹³ Reproducibility and consistency problems plagued these samples, so elastin fibers from freshly obtained bovine neck ligaments were purified using a recently described protocol optimized by Van Kuppevelt et al. that included several organic and aqueous extraction steps coupled with a short trypsin digestion to ensure intact smooth and uniform pure elastin fibers, (Figure 1.1).¹⁴

This protocol starts by washing the fibers with sodium chloride solutions over three nights to remove water soluble proteins. Washes with ethanol, chloroform, methanol, acetone and ethyl ether follow to remove lipid-containing molecules. Afterwards, the fibers are treated with cyanogen bromide to cleave proteins at methionine residues, which are present in almost all proteins but are absent in elastin. The fibers are next treated with urea and β -mercaptoethanol. Because trypsin cuts after basic residues and the predominant basic residue in mature elastin are cross-linked lysyl groups, elastin is digested slowly, and digestion with trypsin (4 h at 37 °C) removes remaining microfibrillar components leaving the remaining elastin fibers intact. The fibers were dried using a vacuum desiccator and were stored at -80 °C.

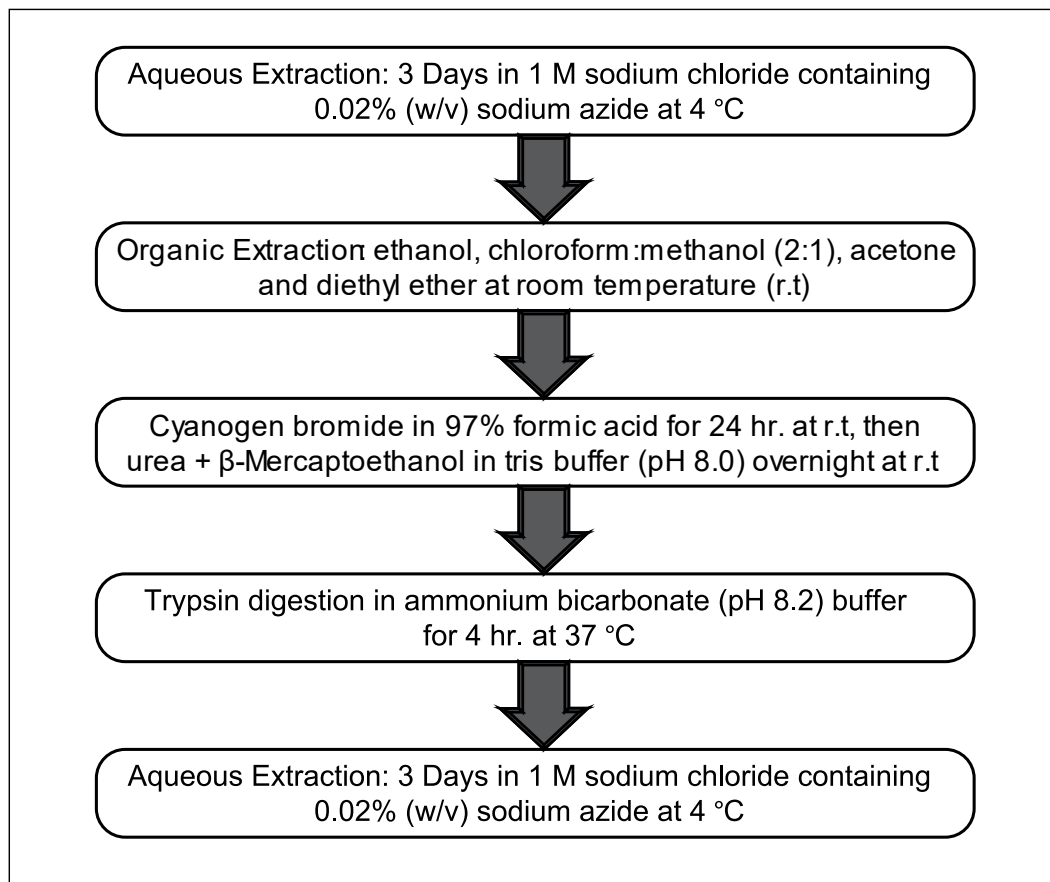

Figure 1.1. Schematic representation of elastin purification procedure from freshly obtained bovine ligamentum nuchae.

The purified elastin fibers were examined using scanning electron microscope (SEM) at the Conn Center for Renewable Energy Research in the University of Louisville with the gracious help of Dr. Jacek B. Jasinski and his coworkers. Dry elastin fibers were sputtered with an ultrathin layer of gold and examined with VEGA3 TESCAN SEM instrument operating at 10 kV. The elastin fibers were pure and intact in agreement with the purification protocol used, (Figure 1.2).¹⁴ Young's modulus was about 0.6 MPa for two different batches of elastin fibers purified using this protocol indicating consistency in the mechanical properties.

Figure 1.2. SEM micrographs of bovine ligamentum nuchae elastin fiber (a) before purification and (b) after purification.

1.2 Hofmeister ions

In 1888, Franz Hofmeister was the first scientist systematically to study the effect of a series of ions on proteins. He ranked separately the anions and the cations based on their ability to precipitate proteins.^{15, 16} This series of ions is known as the Hofmeister ions series, and their effect on proteins is called the Hofmeister effect or the ion-specific effect.

Hofmeister ions fall into two classes: ions that salt-out macromolecules and ions that salt-in macromolecules, (Figure 1.3).¹⁷

SCN ⁻	ClO ₄ ⁻	I ⁻	NO ₃ ⁻	Br ⁻	Cl ⁻	F ⁻	SO ₄ ²⁻	CO ₃ ²⁻
Salting in						Salting out		
Ca ²⁺	Mg ²⁺	Li ⁺	Na ⁺	K ⁺	Rb ⁺	Cs ⁺	NH ₄ ⁺	

Figure 1.3. Ranking of Hofmeister anions and cations. Ions on the left are referred to as chaotropes and the ones on the right are kosmotropes.

Anions have a more profound effect than cations due to their larger size, polarizability and hydration features.^{18,19} Thus, anions rather than cations were chosen to vary in this research. Hofmeister ions used in this research were sodium salts to unify the cation effect and because the sodium ion is considered the border line between kosmotropes and chaotropes in the cation series.

The Hofmeister effect was primarily explained based on ions interaction with water molecules and their effect on the H-bonding network of water, i.e., the ions water affinity and the hydration characteristics. Ions were classified in two groups, kosmotropes (order-making) and chaotropes (disorder-making). Kosmotropes, like sulfate (SO₄²⁻) which is a well-known protein precipitant, are small ions with high surface charge density that interact strongly with water molecules. Chaotropes are larger ions with lower charge density and interact with water to a lesser extent. However, a reverse Hofmeister effect was observed with some macromolecules.

The simplified approach did not take into consideration the possibility of the macromolecule interacting with the Hoffmeister ion at its exposed surface. Studies with different surfaces, hydrophilic and hydrophobic or charged and uncharged, confirm the role of ion-surface interaction as either repulsive or attractive to establish the direct Hofmeister

effect or the reverse.^{20, 21} Several mechanisms were proposed to describe this ion-specific effect in polymer solutions.²²

Cremer et al. studied the specific ion effect on different polymers such as poly(N-isopropylacrylamide) (PINPAM), elastin-like polypeptides and others. They proposed three primary mechanisms, (Figure 1.4).²³⁻²⁷

Figure 1.4. Cremer et al. three mechanisms. (a) polarizing water molecule H-bonded to the amide group. (b) modulating the hydrophobic interactions by surface tension effects. (c) direct binding of the anion with the amide group.

In the first mechanism, strongly hydrated anions are suggested to be responsible for polarizing the water molecules that are hydrogen-bonded to the amide groups in the polymer, leading to dehydrating the polymer backbone and eventually salting it out, (Figure 1.4(a)) In the second mechanism, kosmotropic anions interrupt the hydration of the hydrophobic residues of the polymer by increasing the surface tension. This makes it difficult to create the cavity needed to surround those residues causing shrinkage of hydrophobic surface and eventually salting them out, (Figure 1.4 (b)). In the third mechanism, weakly hydrated anions interact directly with the backbone of the polymer, resulting in a salting in effect, (Figure 1.4 (c)). This salting in effect often reaches a turnover point at a certain concentration, after which salting out can be observed. Cremer et al.

hypothesized that this is the result of saturation of the binding sites at the polymer backbone and the salting out effect is due to increased surface tension. The first two mechanisms are based on the anion effect on the hydration of the polymer, whereas the third mechanism is based on the direct interaction between the anion and the polymer. In this context, anions were only discussed rather than salts (anion and shell cation) because only sodium salts were investigated.

Pegram and Record investigated the effect of Hofmeister salts and other nonelectrolyte osmolytes on air-water surface tension, solubility of nonpolar solutes and biopolymer stability in water as a function of salt concentrations. These effects were interpreted using the Solute Partitioning Model (SPM).²⁸⁻³¹ SPM analyzes the interaction between ions and the biopolymer surface in terms of the hydration characteristics of the surface and the partition coefficient of the ions. It assumes two possible thermodynamic states of the surface in the presence of the ions: the unfolded state and the native state.²² The effect of salts on the conformational change between the two states, as well as any other aqueous process that comes with changes in exposed surface area to water was quantified using an “m-value”. The m-value is the first derivative of the standard free energy of transition between the two states with respect to the salt concentration. It is assumed that the changes in free energy are linear and directly related to the changes in the accessible surface area of the biopolymer (ΔASA) through a constant α , which links the surface hydration term as the number of water molecules per surface area and the ion partitioning term as the partition coefficient of the salt concentration between the surface and the bulk solution (K_p). The m-values, (ΔASA) and K_p were determined experimentally

and then K_p was used to quantify the accumulation or exclusion of the ions from the surface, (Figure 1.5).³²

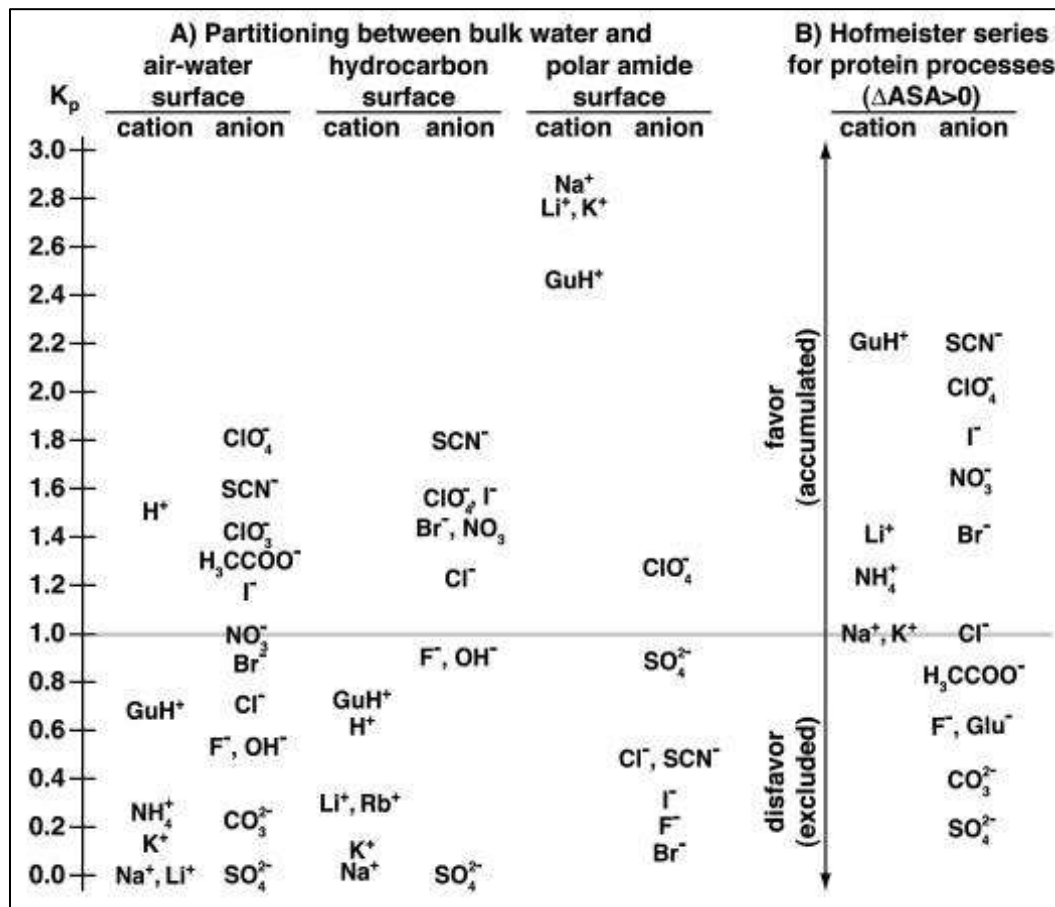

Figure 1.5. Partition coefficients of anions and cations at different model surfaces obtained from SPM.

Poorly hydrated anions accumulate at the air-water surface, whereas strongly hydrated anions are excluded from the surface and almost all cations are excluded. The effect of salts on hydrocarbon model solutes agreed with the ones observed on the air-water surface. This means that weakly hydrated anions have a strong affinity towards the hydrophobic surfaces and accumulate at them. In case of polar amide surfaces, anions are excluded but cations accumulate at the surface. This means that the salt effect is a result of both a cation effect and an anion effect. Pegram and Record concluded that the ordering of the anions is defined

by whether the anions are accumulated or repelled from the nonpolar regions in the biopolymer.

The most recent model, the thermodynamic model, was introduced by Dzubiella and Heyda. It is similar to the SPM and is derived from basic thermodynamic principles. In this approach, two possible thermodynamic states are also assumed, but correction parameters to account for the nonlinear behavior of the weakly hydrated anions (chaotropes) are added.³³ At sufficiently low salt concentration where the linear behavior of the free energy is observed, their model is reduced to the SPM model. Dzubiella et al. were able to fit the experimental data for PNIPAM reported by Cremer et al. to their model and then calculate the thermodynamic parameters. Based on the obtained thermodynamic data, they proposed two different mechanisms to explain the specific ion effects. The first mechanism, the excluded-volume mechanism, is used to explain the linear free energy behavior. Strongly hydrated salts are excluded from the polymer surface and consequently produce depletion volumes around the surface in a manner independent of temperature and concentration. This explains the linear salting out behavior of kosmotropes. The second mechanism is used to interpret the nonlinear behavior of weakly hydrated chaotropes that salt in at low concentration and turnover to salting out at high concentrations. This required second-order corrections to the changes in free energy and entropy that are due to the direct interaction between the salt and the polymer surface. The turnover observed with chaotropes originates from the preferential adsorption of the salt to the globular state (folded) over the coiled state (unfolded) with increasing concentration.³³ Dzubiella and Heyda reported that the nonlinear behavior of added sodium perchlorate (NaClO_4) was significant compared to other weakly hydrated salts, so these investigators used molecular

dynamics (MD) simulations to study the swelling and collapse behavior of a model polymer with respect to NaClO_4 .³⁴ Dzubiella and Heyda concluded from this study that polymer swelling is maximal if both monomer-monomer and monomer-cosolute are weakly attractive, leading to cosolute density inside the coil that is bulk-like and homogenous. However, the highly attractive polymer-cosolute interactions from added NaClO_4 induce the collapsed conformation and display an enhanced density of the cosolute in the globule. Although the collapsed states are similar to the ones observed with kosmotropes, they are a result of a very different mechanism. Dzubiella and Heyda hypothesized that NaClO_4 accumulates within the polymer coil and the collapse is driven by “cross-linking-like bridging effects”.³⁴

1.3 Polyethylene Glycol (PEG)

PEG is a synthetic hydrophilic polymer of repeating units of ethylene glycol ($\text{HO}-\text{CH}_2-\text{CH}_2-\text{OH}$). Unlike Hoffmeister ions, PEG is uncharged and is a macromolecule with a molecular weight that can be systematically varied. With increasing molecular weight and concentration, PEG increases the viscosity of water.³⁵ PEG increases solution density with increased concentration, no relation between solution density and PEG molar mass was observed.³⁵ PEG has a wide spectrum of functions from industry to medicine. One specific function important in biochemistry and related to my research; its ability to precipitate proteins. PEG is an important precipitating agent widely used to improve crystallization of proteins for x-ray diffraction analysis.³⁶

The PEG precipitation mechanism has been explained based on volume exclusion, i.e., the impossibility of both the polymer and the protein, both with high molecular weights, to coexist in the same volume at the same time. So, the polymer is excluded from

the protein surface creating a gradient of osmotic pressure surrounding the protein. When protein molecules get closer to each other, their depletion areas overlap. This increases the protein concentration and its chemical potential resulting in higher attractions between the protein molecules and eventually phase separation (- Figure 1.7).³⁷

Figure 1.6. Schematic representation of depletion interaction induced by neutral polymers like PEG. Grey spheres are the protein molecules, black coils are the polymer molecules, and the depletion areas are the light grey areas.

This theory was developed by many groups starting from Oosawa and coworkers. They derived an attractive force between particles and molecules known not to have any direct interaction. The magnitude of this force is related to the osmotic pressure of the solution and was hypothesized to be responsible for the macroscopic aggregations of suspended particles.³⁸ Ogston et al. used simple thermodynamic expressions; like osmotic pressures to describe the precipitation that is taking place in uncharged binary and ternary polymer solutions using aqueous solutions of PEG and dextran as models.³⁹

Ingham and Atha studied the solubility of various proteins in the presence of different sizes and concentrations of PEG and established the linear dependence of $\log S$ (S is the solubility in g/L) with PEG concentration in all studied proteins. Although no

relation between solution density and PEG molar mass was observed,³⁵ the slope of the solubility curves decreases as the molecular weight of PEG decreases, whereas no changes were observed with temperature and pH. This observation coupled with the failure of concentrated PEG solutions up to 30% (w/v) to have any detectable effect on the melting temperature of ribonuclease A (RNase A) support the theory for no direct interaction between the polymer and the investigated proteins. This agrees with the exclusion model. Ingham and Atha referred to this model as the steric exclusion model.⁴⁰

Lee and Lee investigated the preferential solvent interaction with different proteins as a function of PEG concentration and PEG molecular weight at different pH values by measuring solution density. Their analysis was based on multicomponent thermodynamics.⁴¹⁻⁴³ They concluded that phase separation of the studied proteins in the presence of PEG is due to an unfavorable thermodynamic interaction between the protein and PEG, partially due to the unfavorable interaction between PEG and the charged residues at the protein surface. These effects result in preferential hydration of the protein and an increase in its chemical potential.^{42,43} In agreement with the steric exclusion model, Timasheff et al. reported an increase in β -lactoglobulin⁴⁴ and other investigated proteins⁴⁵ preferential hydration with increasing PEG molecular weight and showed that the exclusion is independent of PEG concentrations. Timasheff and co-workers confirmed the theory of Lee and Lee that the exclusion of PEG from proteins surfaces is primarily steric. However, Timasheff et al. opposed the part of the theory that states it is partially due to unfavorable interaction between PEG and the charged residues at the protein surface. Instead, they showed favorable interactions between hydrophobic proteins and PEG that compete with the exclusion.^{44,45} This point is of importance in the present study because

elastin is one of the most hydrophobic proteins found in nature. Also, in PEG-lysozyme mixtures the addition of low molecular weight PEGs were reported to stabilize the mixture, whereas high molecular weight PEGs were destabilizing, and opposing the depletion theory expectations, PEG induces repulsion among the lysozyme molecules.⁴⁶

In summary, the excluded volume, recently called depletion theory, cannot alone quantitatively explain all PEG proteins interactions, and an attractive interaction between PEG and hydrophobic residues at the protein's surfaces should be taken into consideration.⁴⁴⁻⁴⁸

1.4 Deuterated Water versus Protonated Water ($^2\text{H}_2\text{O}$ versus $^1\text{H}_2\text{O}$)

Deuterated water ($^2\text{H}_2\text{O}$) and protonated water ($^1\text{H}_2\text{O}$) are different in both chemical and physical properties. $^2\text{H}_2\text{O}$ has a higher freezing point, boiling point, density, viscosity and ionization constant pK_w .^{49, 50} Moreover, $^2\text{H}_2\text{O}$ is a more structured liquid^{49, 51}; the $^2\text{H} - \text{O} - \text{O}$ bond is shorter by 3% than the $^1\text{H} - \text{O} - \text{O}$ bond resulting in hydrogen bond shorter by 4% in $^1\text{H}_2\text{O}$.⁵¹ Thus, the solvent isotope effect plays an important role on the physical and chemical properties of proteins in solutions.

Kresheck et al. predicted that the hydrophobic bonds between the amino acids side chains are stronger in $^2\text{H}_2\text{O}$ than in $^1\text{H}_2\text{O}$ through studying the energetics of the solubility of propane, butane and several amino acids in $^1\text{H}_2\text{O}$ and $^2\text{H}_2\text{O}$.⁵² Also, a recent study concluded that more nonpolar amino acid (leucine) is adsorbed onto a polystyrene surface with $^2\text{H}_2\text{O}$ rather than $^1\text{H}_2\text{O}$ as the solvent.⁵³ This means less hydrophobic surface area is exposed in $^2\text{H}_2\text{O}$ than in $^1\text{H}_2\text{O}$.

Many proteins were found to be more stable in their folded state in $^2\text{H}_2\text{O}$ than $^1\text{H}_2\text{O}$. Examples include RNase A (pancreatic enzyme that catalyzes the cleavage of single-stranded ribonucleic acid RNA),^{54, 55} ubiquitin,⁵⁴ domain 1 of rat CD2 (an immunoglobulin G , IgG protein)⁵⁶ and azurin (a bacterial enzyme that plays role in single-electron transfer).⁵⁷ RNase A showed a stronger hydration and an increase in compactness in $^2\text{H}_2\text{O}$.⁵⁴ Additionally, in the case of domain 1 of rat CD2, Parker and Clarke hypothesized that the observed higher stability of the folded protein in $^2\text{H}_2\text{O}$ is due to enhancement in the hydrophobic interactions, which is a result of stronger solvent-solvent interactions (stronger hydrogen-bonding in $^2\text{H}_2\text{O}$).⁵⁶ Also, an increase in protein aggregates is observed in $^2\text{H}_2\text{O}$ for proteins where hydrophobic forces drive aggregation.⁵⁸

Cremer et al. measured the lower critical solution temperature (LCST) for elastin-like poly peptides (ELPs) to be lower in $^2\text{H}_2\text{O}$ in comparison with $^1\text{H}_2\text{O}$ in all the studied circumstances.⁵⁹ They hypothesized this is due to hydrogen-bonding stabilization between $^2\text{H}_2\text{O}$ and what they believed are secondary structures with β -turns present in elastin like peptides (ELPs). Although this hypothesis disagrees with the more recent finding that there is no stable secondary structure in ELPs,⁶⁰ it still indicates that ELPs are more compact in $^2\text{H}_2\text{O}$ than $^1\text{H}_2\text{O}$.

It is worth noting that the Hofmeister effect was found to vary between $^1\text{H}_2\text{O}$ and $^2\text{H}_2\text{O}$. It is believed that this is due to differences on the polymer's accessible area as well as a difference in the ion hydration by $^1\text{H}_2\text{O}$ and $^2\text{H}_2\text{O}$.⁶¹

1.5 Goals and Methods

Elastin is one of the most abundant elastomers in nature. It is essential for many organs and tissues that require elasticity and reversible coil to function. The recoil force is

believed to be entropically driven, and the exact mechanism has not been revealed. This research investigated the physicochemical and mechanical properties of elastin responsible for its elasticity in both microscopic and macroscopic aspects using the following approaches.

1.5.1 Double Quantum Nuclear Magnetic Resonance (2Q NMR)

The change in water ordering as a function of stretching an elastin fiber was measured and this is discussed in detail in Chapter 2. It is hypothesized that stretching elastin fibers decreases the entropy (increase ordering) of the solvent due to an increase in water exposed hydrophobic surface area. This hypothesis was examined using solid state NMR coupled with Multiple Quantum Filtered (MQF) spectroscopy through a novel double quantum (2Q) pulse sequence that has been previously developed and validated by the Wittebort group to study solvent ordering at the surface of elastin.⁶² The ordering of the water at the surface of elastin fiber was measured quantitatively as a function of stretch and in the presence and absence of Hofmeister ions and polyethylene glycol (PEG) that are known to modulate the hydrophobic effect systematically.

1.5.2 ¹³C NMR

The change in backbone ordering of elastin fiber was measured as a function of stretch. If the configurational entropy is responsible for recoil, as in rubber, then changes in backbone ordering with stretch should be observed. This work is discussed in Chapter 3. The time scales and the order parameter, S , for chain motions were determined by measuring ¹³C NMR relaxation times, T_1 and T_2 , and the residual shielding anisotropy of the ¹³C carbonyl groups in the elastin polypeptide backbone.

1.5.3 Thermomechanical experiments

Elastin recoil is entropy driven. Stretching the fiber decreases the solvent and/or the polymer entropy which, in turn, makes recoil spontaneous. This was measured quantitatively as described in Chapter 4. The macroscopic mechanical properties of elastin fibers were studied using thermomechanical methods. Stretch and temperature induced changes in the free energy, entropy, enthalpy and heat capacity were quantitatively measured using a homebuilt apparatus. Experiments were performed in the presence and absence of Hofmeister ions and polyethylene glycol (PEG) that are known to perturb the hydrophobic effect.

CHAPTER 2 2Q NMR STUDY OF SURFACE $^2\text{H}_2\text{O}$ ON ELASTIN FIBERS

2.1 Introduction

Multiple quantum filtered nuclear magnetic resonance (MQF NMR) Spectroscopy is an established approach for characterization and quantification of the anisotropic motion, the motion that results from nuclear spins ordering. The basic principle of this approach is to filter out the large isotropic signal that masks the smaller anisotropic signal in most biological systems, such as elastin. In general, isotropic molecular motion averages out the dipolar and quadrupolar interactions resulting in a high-resolution spectrum. Alternatively, anisotropic molecular motion results in non-zero residual dipolar and quadrupolar interactions that cause the splitting of the lines in the spectrum.

Double quantum filtered (DQF) NMR is the technique used to detect the anisotropic motion and to resolve the residual couplings in spins with spin number $I = 1$ such as ^2H or in coupled spins with $I = 1/2$ such as $^1\text{H} - ^1\text{H}$ coupled spins. In bulk water, molecules reorient isotropically and this averages the nuclear quadrupole coupling in $^2\text{H}_2\text{O}$ to zero. However, $^2\text{H}_2\text{O}$ at a hydrophobic surface is weakly ordered leaving a small, residual coupling. With techniques from multiple quantum NMR, this can be used to filter (remove) the bulk water signal and detect only the signal from molecules oriented at the hydrophobic surface. This technique has been used in many biological systems for different purposes.

It has been used to characterize the different layers of blood vessels and measure their mechanical strain⁶³, to differentiate between the various layers of sciatic nerve⁶⁴, to study the interactions of water with collagen in tendon^{65, 66} and the effect of mechanical stress on these interactions.⁶⁷ Also, DQF NMR was used to study water ordering at the surface of elastin as a function of temperature and applied external strain.^{68, 69} More recently, a novel DQF NMR pulse sequence has been developed by the Wittebort group and used to study the solvent ordering at the surface of elastin.⁶²

Elastin is one of the most hydrophobic proteins in nature. It is an elastomer that gains elasticity only when swollen with water and its elasticity is entropy driven. The recoil is spontaneous to regain the entropy of the system (protein:water) that is lost when elastin is stretched. It is hypothesized that stretching, in addition to decreasing the entropy of the polymer, also decreases the solvent entropy due to exposure to an increased hydrophobic surface area. Primary goal of this dissertation is to deduce the role of hydrophobic hydration as a driving force in elastin recoil. In this Chapter, solvent entropy is studied as a function of applied mechanical strain and in different hydrating solutions that are known to modulate the hydrophobic interaction using the previously developed ²H DQF pulse sequence by the Wittebort group.⁶² studying the solvent at the molecular level is in parallel with the thermomechanical studies in Chapter 4.

2.2 Theory

Nuclear spin number, I , is correlated to the number of subatomic particles in the atomic nucleus. If the nucleus contains an even number of both neutrons and protons, then $I = 0$ and there is no angular momentum associated with this nuclear spin. In other words, it cannot be detected by NMR. If the nucleus contains an odd number of neutrons or

protons, then $I = 1/2, 3/2, 5/2$ and so on. The simplest example is ^1H , $I = 1/2$, which has an even distribution of charge over a sphere. In general, the number of possible orientations for a nuclear spin is equal to $2I + 1$, i.e., for ^1H it is 2 possible orientations, (Figure 2.1 (a)). Finally, if nucleus contains an odd number of both neutrons and protons, then $I = 1, 2, 3$ and so on.

Figure 2.1. Energy levels of (a) spin-1/2, (b) spin-1 in isotropic fluid and (c) spin-1 in solid. ω_0 is the Larmor frequency and ω_q is the quadrupolar coupling.

The nucleus of concern in this Chapter is ^2H . It has a spin number $I = 1$, and subsequently, there are 3 possible orientations (spin states) with different energies, (Figure 2.1 (b-c)). The energies are different because the spin possesses an electrical quadrupolar moment (like any spin with $I > 1/2$) that interacts with the electric field gradient created by the asymmetric distribution of the electron clouds around the nucleus.^{70, 71}

The quadrupolar coupling (ω_q) depends on the nuclear quadrupolar moment (nuclear property), the electric field gradient (molecular property), the phase of matter and

the molecular orientation.⁷¹ In isotropic fluids, ω_q is averaged to zero whereas in anisotropic fluids/solids it is greater than zero.

The elastic fibers of elastin are hydrated; about half of the hydrated fiber weight is water. Some fraction of this water reorients isotropically as in bulk water, and the remaining fraction is in rapid exchange with water ordered on the solvent accessible surface of the fiber. When the elastin is hydrated in $^2\text{H}_2\text{O}$, the quadrupolar coupling, ω_q , of ^2H is averaged to zero in the bulk water and is nonzero ($\omega_q > 0$) for water on the surface of the fiber. To observe only the water at the protein surface, the NMR signal from bulk water is eliminated through double quantum filtration, (Figure 2.2), which was achieved with a novel pulse sequence developed by Wittebort and co-workers.⁶² The residual coupling is used to generate double quantum (2Q) coherence and then measured indirectly after filtering (eliminating) the bulk water signal through the designed pulse sequence with a 64 steps of phase cycling incorporated in the pulse sequence.

The new pulse sequence consists of four main steps, (Figure 2.3). The first step is the preparation of the 2Q coherence through two 90° pulses that partially convert I_z magnetization into 1Q and 2Q coherence. The magnitudes of the 1Q and 2Q coherences depend on the coupling, ω_q . The 180° pulse between the two 90° pulses refocuses the offset so it does not contribute to evolution of the spin system during the first indirect time, t_1 . The second step is evolution, in which the 2Q coherence evolves at twice the Larmor frequency, $2\omega_0$, while the 1Q coherence evolves at the Larmor frequency. So, at constant evolution time (t_2), the 2Q and 1Q are separated in phase. Since 2Q coherence cannot be detected directly, it is converted back into I_z by the next two 90° pulses in the same way it is generated from I_z in the preparation step.

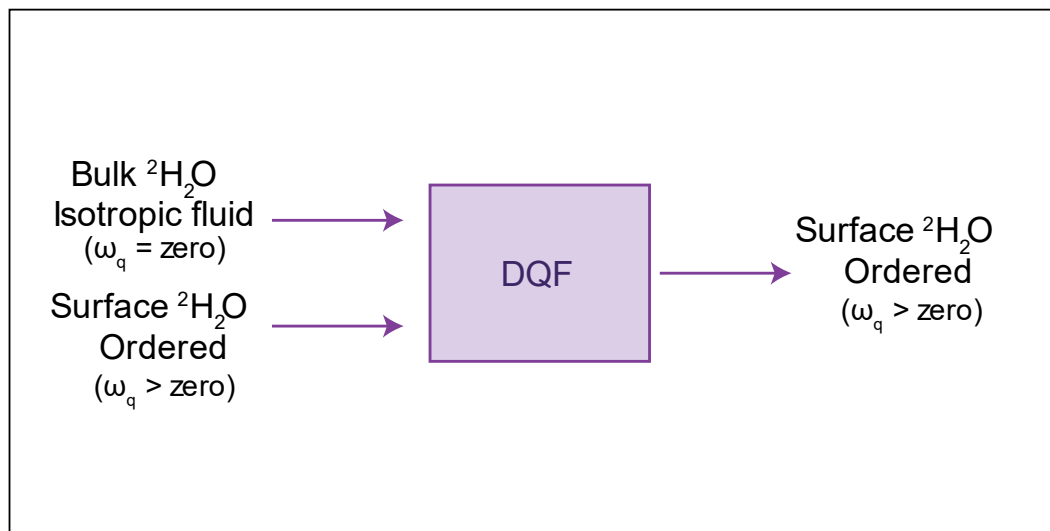

Figure 2.2. Schematic representation of double quantum filtration (DQF) to obtain the 2Q signal.

In the last step, the NMR signal is detected following a 90° pulse which converts I_z into observable magnetization. This is repeated with 64 steps of phase cycling so that only the 1Q signal resulting from 2Q coherence is detected as a function of incrementing the preparation/conversion time, t_1 . The underlying principle of the phase cycle is that shifting transmitter pulses by, for example, 180° inverts the 1Q coherence and leaves the 2Q coherence unchanged.

Two types of experiments were employed: the evolution experiment with fixed t_1 and the preparation experiment with fixed t_2 . After double Fourier transformation of the evolution data table, $S(t_1, t_2)$, peaks from the 1Q and 2Q signals are separated in the indirect dimension, f_2 . Peaks at f_{os} and $2 f_{os}$ are the 1Q and 2Q signals, respectively, where f_{os} is the offset frequency. Only the 2Q peak is observed if the phase cycle is properly implemented. In the 2Q buildup curve, $S_{2Q}(t_1)$, the intensity of the 2Q peak as a function of t_1 , is obtained by Fourier transformation of the preparation experiment and analyzed using Eq. 2.1.

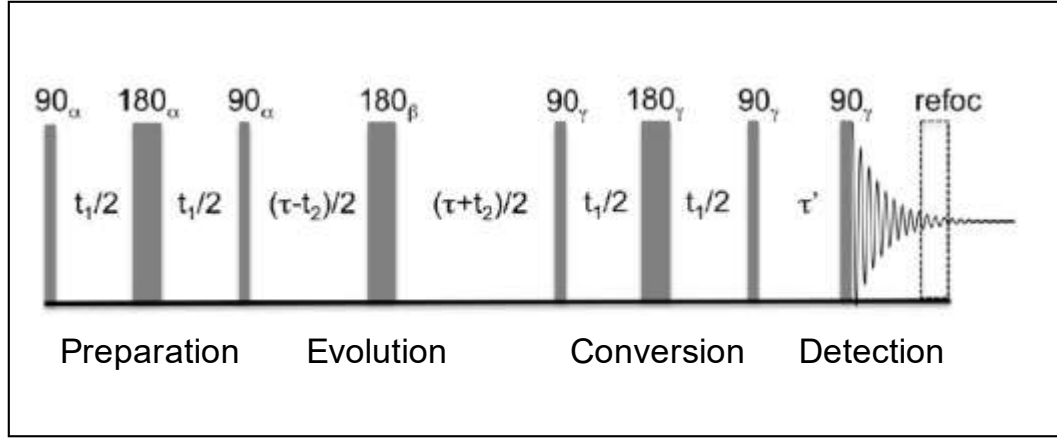

Figure 2.3. The 2Q NMR pulse sequence developed by Wittebort and co-workers.

$$S_{2Q}(t_1) = \frac{1}{2} A_{2Q} \exp\left(-\frac{2t_1}{T_2^{\text{surf}}}\right) [1 - u^{-1} [C(u) \cos \omega_q t_1 + S(u) \sin \omega_q t_1]] \quad \text{Eq. 2.1}$$

$$\text{with } u = (3\omega_q t_1)^{1/2}, \quad C(u) = \int_0^u \cos x^2 dx \quad \text{and} \quad S(u) = \int_0^u \sin x^2 dx$$

where A_{2Q} is the proportionality constant for the number of spins with $\omega_q > 0$, t_1 is the preparation/conversion time, T_2^{surf} is the transverse relaxation time of spins that contribute to the 2Q signal, ω_q is the quadrupolar coupling and θ represents the possible orientations which are averaged for the unoriented samples used in these experiments. Eq. 2.1 accounts for both coherent evolution of the spin system resulting from the quadrupolar coupling and spin relaxation that occurs in the course of the pulse sequence.

The transverse relaxation time, T_2^{surf} is determined in a separate experiment to reduce the number of the parameters in the fit in $S_{2Q}(t_1)$ to two parameters, A_{2Q} and ω_q . This is achieved by adding a Hahn Echo sequence at the end of the 2Q pulse sequence.^{62,}
⁷² Also, the Hahn Echo sequence is used directly in a third experiment to determine the transverse relaxation time of the spins in the bulk, T_2^{bulk} and the signal intensity of 1Q

coherence (A_{1Q}). Ultimately, an important parameter, the fraction of ordered deuterated water within the time of the experiment ($f = \frac{A_{2Q}}{A_{1Q}}$) is measured, (Figure 2.4).

Figure 2.4. (a) A_{1Q} , the peak intensity of the 1Q signal evaluated from the first point of T_2^{bulk} experiment. (b) A_{2Q} , peak intensities are plotted as a function of preparation time t_1 (ms).

2.3 Materials and Methods

2.3.1 Elastin Fibers purification Protocol

The extensive details of the purification protocol adapted from Van Kuppevelt et al¹⁴ that was used to prepare all the samples in this Work is reported here. About 100 g of freshly obtained bovine nuchal ligaments (Animal Technologies, Tyler, TX) were freed carefully from adhering fatty tissue and membranes, and cut using electric food slicer (Model 610, EdgeCraft Corporation, Avondale, PA) to thin uniform strips ($\sim 3 \text{ mm} \times \sim 5 \text{ mm} \times \sim 10 \text{ mm}$).

The thin strips were placed in 3 L Erlenmeyer flask, and the aqueous extraction was performed by adding 1 L of cold 1.0 M NaCl (sodium chloride, Sigma-Aldrich, St. Louis,

MO) that contains 0.02% (w/v) NaN_3 (sodium azide 99%, Alfa Aesar, Haverhill, MA) with constant stirring at 4 °C overnight. This extraction procedure was repeated three times to remove aqueous soluble proteins. Afterwards, the thin strips were recovered by paper funnel filtration and the organic extractions were initiated by suspending the strips in 1 L of ethanol (Ethyl Alcohol Denatured 95%, Aldon Corporation, Avon, NY) with constant stirring for 90 min at room temperature. The series of organic extractions were done using the following solvents: (i) 1 L of chloroform-methanol (2:1) (both Chloroform and methanol are ACS, Pharmaco, Brookfield, CT) for 90 min at room temperature (ii) 1 L of acetone (Acetone ACS, VWR International, Radnor, PA) for 30 min, and (iii) 1 L of diethyl ether (Diethyl ether ACS, Sigma-Aldrich, St. Louis, MD). The strips were recovered and left to dry in a desiccator overnight. These organic extractions were intended to remove lipid-containing molecules.

The dried strips were incubated in 1.5 L 97% formic acid (Alfa Aesar, Haverhill, MA), and cyanogen bromide (Alfa Aesar, Haverhill, MA) was added to a final concentration of 1%, and left to react for 24 h under non-oxidizing conditions at room temperature. The mixture was then diluted with deionized water twice its volume, filtered, and washed with deionized water 50 times. This step of the purification protocol ensures the hydrolysis of most proteins because cyanogen bromide cleaves proteins at methionine residues present in most proteins, but not in elastin.

After the last washing step, the strips were suspended in 1 L of Tris buffer (8.02 pH) that contains 0.5% (v/v) β -mercaptoethanol (\geq 98% pure 2-mercaptoethanol, Bio-Rad Hercules, CA), 6.0 M urea (Urea 99.5%, Acros Organics, Fair Lawn, NJ) and 0.02% (w/v) NaN_3 .⁷³ The suspension was stirred overnight at room temperature. In the next day, the

strips were recovered and washed with deionized water ten times, and then were resuspended in 0.1 M ammonium hydrogen carbonate (99.0%, Alfa Aesar, Ward Hill, MA) solution (pH 8.2) that contains 0.02% (w/v) NaN_3 and 10,000 U of trypsin for 4 h at 37 °C. This short trypsin digestion was optimal to remove the remaining microfibrillar components and leaving the elastin fibers intact as most of the lysyl groups, the target of trypsin hydrolysis, are cross-linked in mature elastin.

In the last step of the purification protocol, elastin strips were washed with deionized water and extracted over three nights in solutions of cold 1.0 M NaCl that contains 0.02% (w/v) NaN_3 at 4 °C. Finally, the purified strips of elastin were washed with deionized water, dried using a vacuum desiccator overnight and stored at -80 °C.

2.3.2 Sample Setup

About 20 mg dried and purified elastin fiber, $\sim 1\text{mm} \times 12\text{ mm}$, was glued with cyanoacrylate gel (Super Glue) to a $\sim 15\text{mm}$ 1/16-inch diameter G10 rod. The fiber was equilibrated overnight against a particular solvent/hydration solution to a known mass and inserted into a 3 mm NMR tube (length $\sim 3\text{ cm}$). Then, the NMR tube was glued on one side and sealed with parafilm on the other. The fiber was stretched to a measured length by moving the rod and fixed in place with parafilm, (Figure 2.5).

Figure 2.5. The hydrated elastin fiber in the 3mm NMR tube. The parafilm is removed to stretch the sample and replaced to maintain the sample length.

The effect of different solutes: 200 PEG (polyethylene glycol 200, Alfa Aesar, Ward Hill, MA), 20 kDa PEG (Polyethylene glycol 20,000, Alfa Aesar, Ward Hill, MA), sodium sulfate (Na_2SO_4 ACS, Fisher Chemical, Fair Lawn, NJ) and sodium perchlorate (NaClO_4 ACS 98.0-102.0%, Beantown Chemical Corporation, Hudson, NH) on the deuterated water (99.9% D, Cambridge Isotope Laboratories, Andover, MA) ordering at the surface of elastin was studied, (Table 2.1), at four different stretch percentages when possible: 0% (relaxed fiber), ~ 15%, ~30% and ~ 40%, Eq. 2.2.

$$\text{Stretching \%} = \frac{\text{Stretched length} - \text{Relaxed length}}{\text{Relaxed length}} \times 100\% \quad \text{Eq. 2.2}$$

Table 2.1. The masses of all elastin fibers used in this Chapter experiments, and the masses of $^2\text{H}_2\text{O}$ once hydrated in the different hydration solutions.

Elastin sample	Hydration solution	Elastin dry mass (mg)	$^2\text{H}_2\text{O}$ mass in hydrated elastin (mg)
Fiber 1	10% 200 PEG	21.6	20.3
	10% 20 kDa PEG	21.6	24.4
	High purity $^2\text{H}_2\text{O}$	21.6	24.5
	50% $^2\text{H}_2\text{O}$	21.6	10.5
Fiber 2	10% 200 PEG	25.9	28.3
	5% 200 PEG	25.9	31.6
	High purity $^2\text{H}_2\text{O}$	25.9	30.6
Fiber 3	10% 20 kDa PEG	17.7	15.8
	5% 20 kDa PEG	17.7	18.7
	High purity $^2\text{H}_2\text{O}$	17.7	ND (Not Determined)
Fiber 4	1 mol/kg NaClO_4	19.8	37.4
	0.5 mol/kg NaClO_4	19.8	31.9
	High purity $^2\text{H}_2\text{O}$	19.8	25.2
Fiber 5	0.1 mol/kg Na_2SO_4	15.8	18.4
	0.5 mol/kg Na_2SO_4	15.8	18.8

2.3.3 NMR Experiments and Spectrometer Instrumentation

Five experiments were conducted to determine the fraction of ordered water (f) and the residual quadrupole coupling (ω_q). The first experiment, a simple Bloch decay, was used to determine the 90° pulse width. The second experiment was an inversion recovery and used to determine the longitudinal or spin-lattice relaxation time (T_1). This was used to set the recycle time, typically set to 5 times T_1 . The third experiment, a Hahn Echo⁷⁴, was used to measure transverse or spin-spin relaxation time (T_2^{bulk}) and to determine the signal intensity, A_{1Q} , which is proportional to the total $^2\text{H}_2\text{O}$ in the sample. The fourth experiment was the 2Q buildup curve with the pulse sequence described in the theory section.^{62, 72} Finally, spin-spin relaxation time (T_2^{surf}) was measured by inserting a Hahn Echo sequence at the end of the 2Q pulse sequence with t_1 set to the delay with the highest 2Q signal.^{62, 72}

^2H NMR spectra were obtained on an 11.7 T (500 MHz) instrument with a Libra data system (Tecmag, Houston TX,) and homebuilt probes and RF electronics. The probe is based on a design previously described.⁷⁵ The 90° pulse width was $\sim 4.5 \mu\text{s}$ with 62 watts RF power at the ^2H frequency (76.05 MHz).

2.4 Results and Discussion

Both the effect of the mechanical strain and the hydration solution on the quadrupolar coupling ($\nu_q = \frac{\omega_q}{2\pi}$) and the fraction of ordered water (f) of the elastin fiber were studied.

The “static” water residual coupling in crystals of $^2\text{H}_2\text{O}$ ice, 200 kHz,⁷⁶ is large compared to the measured residual coupling (ν_q) of $^2\text{H}_2\text{O}$ in hydrated elastin, 15 – 95 Hz

and is found here to vary with stretch, the addition of a solute to the solvent (water) and changing the isotope from $^1\text{H}_2\text{O}$ to $^2\text{H}_2\text{O}$. The transverse relaxation time (T_2) of $^2\text{H}_2\text{O}$ which is 243 ± 14 ms in pure solvent⁷² is reduced significantly to 6 – 22 ms and 6 – 17 ms, when measured with and without 2Q filtration in hydrated elastin fiber, respectively. The shorter relaxation times indicate that the rate of water reorientation in elastin is slow compared to pure water and that this slows with stretch. Without added solute, a nearly tenfold increase in the 2Q signal is observed when the sample length is stretched by ~ 30%. This is due to an increase in the fraction of the water that has access to the predominantly hydrophobic surface of elastin on the timescale of the ^2H NMR experiment. Changes in the residual coupling (ν_q) are observed when changing the hydration solutions. More significant changes take place in the fraction of the water that is weakly ordered (**f**). Stretching this highly hydrophobic protein increases the surface area exposed to the water resulting in an increase in the ordered water which is measured here at the microscopic level.

2.4.1 Hydration of Elastin Fiber in $^1\text{H}_2\text{O}$ versus $^2\text{H}_2\text{O}$

Three batches of elastin fibers were purified using the purification procedure described previously. To confirm the reproducibility and the consistency in physical and mechanical properties of these fibers, three 2 Q build up curves of a representative fiber from each batch hydrated in $^2\text{H}_2\text{O}$ are reported, (Figure 2.6).

Figure 2.6. 2Q signal intensity as a function of time at different stretches of hydrated elastin fibers in $^2\text{H}_2\text{O}$ from the three different purified batches of elastin.

The solutes (PEG, Na_2SO_4 and NaClO_4) used in the studies in this Chapter are also used in the thermomechanical experiments described in Chapter 4. To investigate the difference between $^2\text{H}_2\text{O}$ and $^1\text{H}_2\text{O}$, NMR experiments were carried out in $^2\text{H}_2\text{O}$ and in 50.3% (w/w) $^2\text{H}_2\text{O}/^1\text{H}_2\text{O}$ as the hydrating solvents of the elastin fiber. The results of NMR experiments in both relaxed and $\sim 30\%$ stretched fiber are compared in Figure 2.7 and Table 2.2.

Figure 2.7. T_2^{bulk} , T_2^{surf} and 2Q signal intensities as a function of time in 0% (relaxed) and ~ 30% stretched elastin fiber (Fiber 1) hydrated in $^2\text{H}_2\text{O}$ versus in 50% $^2\text{H}_2\text{O}$ in $^1\text{H}_2\text{O}$.

Table 2.2. The experimental T_1 , T_2^{bulk} and T_2^{Surf} values and the results of the least linear square fit of the 2Q experiments in Figure 2.6 using Eq. 2.1 in both the relaxed (0%) and 30% stretched fiber hydrated in $^2\text{H}_2\text{O}$ and in 50% $^2\text{H}_2\text{O}$ in $^1\text{H}_2\text{O}$.

Hydration solution	Stretch %	T_1 (ms)	T_2^{bulk} (ms)	T_2^{Surf} (ms)	T_2^{Fit} (ms)	ν_q (Hz)	\mathbf{f}
$^2\text{H}_2\text{O}$	0%	67.5 ± 0.7	18.3 ± 0.4	13.4 ± 0.8	18.7	55	0.01
		66.0 ± 0.6	14.8 ± 0.2	10.5 ± 0.2			
	29 %	79.7 ± 0.8	21.0 ± 0.3	16.8 ± 0.5	21.1	38	0.01
		77.6 ± 0.6	15.9 ± 0.3	11.1 ± 0.3			
50.3% (w/w) $^2\text{H}_2\text{O}/$ 49.70 $^1\text{H}_2\text{O}$	30 %	77.6 ± 0.6	15.9 ± 0.3	11.1 ± 0.3	15.9	21	0.36
		79.7 ± 0.8	21.0 ± 0.3	16.8 ± 0.5			

T_2^{Surf} (measured with 2Q filtration) and T_2^{Bulk} (measured without 2Q filtration) directly describe the reorientational rates of water in elastin. Decreases in T_2 values indicate longer solvent reorientation rates. Thus, reducing the solvent deuteration from 100% $^2\text{H}_2\text{O}$ to 50% $^1\text{H}_2\text{O}$, (Table 2.2), leads to increased values of both T_2^{Surf} (measured with 2Q filtration) and T_2^{Bulk} (measured without 2Q filtration). This is due to the weaker H-bonding and reduced viscosity in $^1\text{H}_2\text{O}$. The quadrupolar couplings (ν_q) are small and range from 15 – 55 Hz. In both solutions, the fraction of ordered solvent (\mathbf{f}) increases dramatically with stretch and this is accompanied by a small decrease in T_2 values, both of which indicate increased interaction at the solvent protein interface.

Hydrophobic interactions are observed to be stronger in $^2\text{H}_2\text{O}$ compared to $^1\text{H}_2\text{O}$. This results in increased compaction of hydrophobic proteins and, subsequently, a decrease in the exposed hydrophobic surface area to the solvent.^{52, 53, 56, 58, 77} Consequently, it is expected for a hydrophobic protein like elastin to have smaller surface area exposed to hydration by $^2\text{H}_2\text{O}$ compared to $^1\text{H}_2\text{O}$. In this experiment, 50% (w/w) $^2\text{H}_2\text{O}/^1\text{H}_2\text{O}$ was used, this means less available $^2\text{H}_2\text{O}$ for NMR detection by half (2Q signal declines), but more hydrophobic surface area is exposed to the available $^2\text{H}_2\text{O}$ (2Q signal increases). The two effects counterbalance each other and results in a similar 2Q buildup curve with almost same signal intensity in both relaxed (0% stretch) and 30% stretched fiber, (Figure 2.7). In both solutions, stretching the fiber increases the 2Q intensity by about an order of magnitude. This is an anticipated result due to the increase in the hydrophobic surface exposed to the solvent with stretch which results in more ordered water at the surface.

2.4.2 Hydration of Elastin Fiber in PEG Solutions

Two elastin fibers were hydrated separately in solutions of 200 Da PEG and 20 kDa PEG in $^2\text{H}_2\text{O}$, (Fiber 2 and Fiber 3 respectively), to study the effect of PEG on water ordering at the protein surface. Furthermore, the effect of the mechanical stretch on T_1 , T_2^{bulk} , T_2^{Surf} and 2Q buildup was investigated in each solution at three concentrations: 0, 5% and 10% (w/w) and four stretches: 0 %, ~15 %, ~30 % and ~ 40 % when possible. The results from both fibers are shown in Figures 2.8 – 2.10 and Tables 2.3 – 2.4.

The trends observed in the previous section for both T_2^{Surf} and T_2^{bulk} are maintained in both samples, i.e., T_2^{Surf} is smaller than T_2^{bulk} and both decrease with the increase in stretch and the increase in PEG concentration, (Figure 2.7 and Figure 2.8). T_1 on the other hand varies slightly with no obvious trend, (Table 2.3 and Table 2.4). The quadrupolar

coupling (ν_q) is small and increases by a small amount with an increase in the PEG concentrations. The fraction of the ordered solvent (\mathbf{f}) significantly increases with sample stretch. However, \mathbf{f} , the fraction of surface accessible solvent, is highly dependent on the PEG size and concentration. The \mathbf{f} values are much smaller in 200 Da PEG than 20 kDa PEG. Moreover, \mathbf{f} increases to a lesser extent with stretch as the PEG concentrations increase. Finally, the 2Q signal intensity increases dramatically with the increase in stretch, (Figure 2.9). A roughly ten folds increase in magnitude is observed when the hydrated elastin fiber in $^2\text{H}_2\text{O}$ is stretched 40%. Adding PEG slightly decreases the fiber elasticity, and as its concentration rises from 0% ($^2\text{H}_2\text{O}$) to 10 %, the 2Q signal intensity is drastically reduced. This is seen clearly when the hydrated fiber in 10% (either 200 PEG or 20 k Da PEG) is stretched by 40% and the 2Q intensity only increases 5 folds.

Figure 2.8. T_2^{bulk} and T_2^{surf} intensities as a function of time at different stretch% for hydrated elastin fiber (Fiber 2) in 200 Da PEG solution.

Figure 2.9. T_2^{bulk} and T_2^{surf} intensities as a function of time at different stretch% for hydrated elastin fiber (Fiber 3) in 20 kDa PEG solution.

	15 %	45.0 ± 0.6	8.9 ± 0.2	7.3 ± 0.1	7.25	35	0.10
	26 %	45.1 ± 0.7	7.7 ± 0.1	6.6 ± 0.1	6.5	30	0.35
	38 %	41.3 ± 0.3	6.6 ± 0.1	5.9 ± 0.1	5.95	30	0.59

In order to eliminate any variations of the results due to the use of two different elastin fibers, the effect of molecular weight of PEG was investigated on the same elastin fiber (Fiber 1) by comparing 10% 200 Da PEG hydration solution with 10% 20 kDa PEG on both relaxed and 30% stretched, (Figure 2.11 and Table 2.5).

The most noteworthy effects of the PEG of two different molecular weights are on the fraction of the ordered water (**f**) and the 2Q signal intensity. Stretching the fiber 30% results in a 5-fold increase in the 2Q signal intensity and an increase from 1% to 10% in the fraction of ordered water when the fiber hydrated in 10% 200 Da PEG compared to a 10-fold increase in the 2Q signal intensity and an increase from 1% to 30% in the fraction of ordered water when the fiber hydrated in 10% 200 Da PEG. The more profound effect observed in the 200 Da PEG Solutions is believed to be due to the interaction of the small molecular weight PEG with the intrafibrillar water,^{78, 79} resulting in a more compact fiber with less exposed surface.

The uncharged crowding agent PEG increases the protein- protein interactions through the excluded volume mechanism³⁷, thus it is expected to increase the compaction of the elastin fiber. This shall decrease the hydrophobic surface area exposed to the solvent and, in turn, decrease the water ordering at the surface, which is observed and measured quantitatively. The effect increases with the concentration and is more profound in the smaller molecular weight PEG.

Figure 2.11. T_2^{bulk} , T_2^{surf} and 2Q signal intensities as a function of time at 0% (relaxed) and 30% stretched elastin (Fiber 1) hydrated in 10% (w/w) 200 Da PEG and in 10% (w/w) 20 kDa PEG.

Table 2.5. 10% (w/w) 200 Da PEG versus 10% (w/w) 20 kDa PEG experimental and fit results in the relaxed and 30% stretched fiber, (Fiber 1).

Hydration solution	Stretch %	T_1 (ms)	T_2^{bulk} (ms)	T_2^{Surf} (ms)	T_2^{Fit} (ms)	ν_q (Hz)	f
10% 200 Da PEG	0%	66.0 ± 1.2	14.9 ± 0.9	12.0 ± 1.2	15.8	95	0.01
	28 %	63.5 ± 1.2	14.4 ± 0.5	8.8 ± 0.2	8.8	40	0.10
10% 20 kDa PEG	0%	74.8 ± 1.4	22.4 ± 0.7	11.1 ± 1.0	23	75	0.01
	31 %	69.3 ± 1.1	16.6 ± 0.4	9.5 ± 0.1	9.5	25	0.31

2.4.3 Hydration of Elastin Fibers in Solutions of NaClO₄ versus Na₂SO₄

The effect of Hofmeister ions on the water ordering at the surface of elastin was investigated by hydrating two elastin fibers (Fiber 4 and Fiber 5) separately in different concentrations of NaClO₄ and Na₂SO₄ in ²H₂O. T_1 , T_2^{bulk} , T_2^{Surf} and 2Q buildup were measured in 0, 0.5 and 1.0 mol/kg NaClO₄ and in 0.1 and 0.5 mol/kg Na₂SO₄ when the fiber was relaxed (0% stretched), ~15 %, ~30 – 35% stretched, (Figures 2.12 – 2.14 and Table 2.6).

The trend observed previously is well-preserved, T_2^{Surf} is smaller than T_2^{bulk} , and both decrease with the increase in stretch, but unlike in PEG, both parameters increase as the salt concentration increases, which is believed due to the increase in the surface tension with higher salt concentrations. T_1 , as in the previous studied solutions, varies slightly with no obvious trend, (Table 2.6). As before, the quadrupolar coupling (ν_q) is small in these solutions with not much change with increasing perchlorate concentration, but ν_q does increase with the rise in sodium sulfate concentration. The fraction of the ordered solvent (**f**) significantly increases with the stretch in all solutions, yet it depends on the perchlorate and sulfate concentrations. Very high concentration of perchlorate (1.0 mol/kg) is needed to observe the reduction in **f** compared to only 0.1 mol/kg in sulfate.

Figure 2.12. T_2^{bulk} and T_2^{surf} intensities as a function of time at different stretch% of hydrated elastin (Fiber 5) in Na_2SO_4 solutions.

Figure 2.13. T_2^{bulk} and T_2^{surf} intensities as a function of time at different stretch% of elastin fiber (Fiber 4) hydrated in NaClO₄ solutions.

Figure 2.14. 2Q signal intensity as a function of time and stretch of hydrated elastin in solutions of NaClO₄ (Fiber 4, upper panels) and Na₂SO₄ (Fiber 5, lower panels).

Table 2.6. Elastin hydrated in solutions of NaClO₄ (Fiber 4) and Na₂SO₄ (Fiber 5) experimental T_2^{bulk} and T_2^{Surf} values and the least square fit results of the 2Q experiments at the studied concentrations and constrains.

Hydration solution	Stretch %	T_1 (ms)	T_2^{bulk} (ms)	T_2^{Surf} (ms)	T_2^{Fit} (ms)	ν_q (Hz)	f
² H ₂ O	0 %	51.6 ± 0.4	11.1 ± 0.2	8.7 ± 0.2	11.3	56	0.02
	19 %	52.1 ± 0.4	11.0 ± 0.4	9.0 ± 0.1	7	23	0.33
	33 %	51.7 ± 0.2	9.2 ± 0.2	7.5 ± 0.2	7.8	23	0.83

	28%	54.0 ± 0.4	10.5 ± 0.3	9.2 ± 0.1	10.8	70	0.04

Kosmotropes like sulfate raise the viscosity and the surface tension when added to water, making it difficult to create the required cavity to accommodate nonpolar solutes (cavity model).^{80, 81} Thus, the addition of sulfate reduces the hydrophobic surface exposed to water causing elastin fibers compaction. This is the reason the 2Q signal declined dramatically with the addition of sulfate and was largely eliminated at 0.5 mol/kg, (Figure 2.14).

On the other hand, chaotropes such as perchlorate interact preferentially with the macromolecule and salt in (solubilize) the peptide group, either through specific or nonspecific ion interaction.^{80, 82, 83} Thus, the addition of perchlorate increases the hydrophobic surface exposed to water. This explains why not much difference was observed upon addition of perchlorate until the concentration 1.0 mol/kg was reached. At high concentration, chaotropes, in general, start to behave like kosmotropes in what is called a turnover point. Perchlorate is reported to have significant nonlinear behavior compared to other chaotropes, and Molecular dynamics (MD) simulations were used to study its turnover point.³⁴ The hypothesis is that the polymer collapses and the compaction increases at the turnover point. This effect is similar to that of kosmotropes but due to a different mechanism and assumed to arise from “cross-linking-like bridging effects”.³⁴ This explains the slight decline in the 2Q signal at high concentrations of sodium perchlorate, (Figure 2.14).

CHAPTER 3 ^{13}C NMR DYNAMIC STUDY OF ELASTIN BACKBONE

3.1 Introduction

Elastin is an entropic elastomer that gains elasticity only when hydrated. Stretch decreases the entropy of the system (elastin and water), and recoil is spontaneous to regain entropy.^{9, 84, 85} The source of decreased entropy originates from either the increase in ordered water at the expanded hydrophobic surface with stretch (hydrophobic effect)^{8, 84} or the increase in backbone ordering (configurational entropy) of elastin backbone similarly to rubber.⁹ The source has not been resolved yet. Here, the main focus is on (i) the configurational entropy and its contribution to elastin recoil mechanism and (ii) the dynamics of the backbone in the presence and absent of strain.

Solid State NMR with magic angle spinning was previously used to study nuchal bovine elastin when it is dry (rigid) and hydrated (flexible) by Pometun et al.⁸⁶ The dry elastin spectrum showed separated peaks including the carbonyl peak at about 175 ppm with side bands typical of a stationary peptide, and these bands completely disappeared upon hydration. This indicates that the backbone in the hydrated elastin is highly disordered with large amplitude motions and the carbonyl group order parameter was estimated to be less than 0.1 ($S < 0.1$).⁸⁶ The high degree of mobility of the carbonyl backbone in hydrated elastin was also observed by others measuring only T_1 ,⁸⁷ or T_1 and linewidths which were analyzed using a single correlation time.⁸⁸ In another study, T_1 and $T_{1\rho}$ were measured but

analyzed using only the dipolar relaxation mechanism and a spectral density function with a single correlation time.⁶⁹

This Chapter presents quantitative studies into backbone mobility. The amplitudes and time scales of motions in hydrated bovine elastin were investigated in the presence and absence of mechanical strain using solid state ¹³C NMR without magic angle spinning. The hypothesis is that if configurational entropy contributes to the recoil mechanism, as in rubber, then changes in backbone ordering with stretch should be observed. The backbone order parameter was obtained from the residual shielding anisotropy of the carbonyl NMR signal, and the dynamical timescales of the motions were determined by combining the backbone order parameter with the relaxation rates R_1 and R_2 of the backbone carbonyl (C') groups measured at two NMR frequencies.

3.2 Materials and Methods

3.2.1 Sample Setup and Experimentation:

The ¹³C NMR spectra of both stretched and relaxed elastin without magic angle spinning (MAS) were obtained on a 500 MHz spectrometer equipped with a homebuilt probe and a 700 MHz Varian Inova NMR spectrometer.

The elastin fiber sample used in the 500 MHz NMR spectrometer (140 mg dried and purified and ~ 2 mm × 25 mm) was glued with cyanoacrylate gel (Super Glue) to a G10 rod and hydrated overnight in ²H₂O to a known mass. After insertion into a 5 mm NMR tube (length ~ 5 cm), the tube was glued on one side and sealed with parafilm on the other. A relaxed elastin fiber inserted in a 5 mm NMR tube is shown in Figure 3.1. The hydrated relaxed elastin fiber in the NMR tube. The NMR tube was inserted into

the horizontal coil of the homebuilt $^1\text{H}/^{13}\text{C}$ probe ⁷⁵ of the 11.7 T instrument. The probe has a ^{13}C 90° pulse width of 5.6 μs .

Figure 3.1. The hydrated relaxed elastin fiber in the NMR tube.

To evaluate the residual shielding anisotropy, stationary ^{13}C NMR spectra of the carbonyl backbone were measured with the elastin fiber relaxed and stretched by $\sim 32\%$ (to 132% of its relaxed length). The spin-lattice relaxation time (the longitudinal relaxation time, T_1) and the spin-spin relaxation time (the transverse relaxation time, T_2) of carbonyl carbon backbone were measured using the standard inversion recovery and Hahn echo experiments with relaxation delays of 4s, respectively.^{74, 89}

The inversion recovery experiment starts with a 180° pulse that inverts the equilibrium longitudinal magnetization from z to $-z$. Then, it relaxes due to spin-lattice relaxation during the delay time τ . The equilibrium longitudinal magnetization is fully recovered as τ increases. Finally, the longitudinal magnetization is converted into transverse magnetization by a 90° pulse for detection. This experiment was run at τ values of 0.2, 0.4, 0.8, 1.5, 2, 3, 4.5, 6 and 8 s. T_1 was determined by least squares fit of the signal intensities, $S(\tau)$, to the equation $S(\tau) = S_0 + A e^{-\tau/T_1}$.

In the Hahn echo experiment ($90^\circ - \tau/2 - 180^\circ - \tau/2 - \text{FID}$), the 90° pulse rotates the equilibrium longitudinal magnetization into the x - y plane, and this is followed by a 180° pulse that refocuses the dephased magnetization and generates an echo signal, $S(\tau)$. The spin coherence, $S(\tau)$, is lost as τ increases, and T_2 was found by a least square fit to the equation $S(\tau) = A e^{-\tau/T_2}$.

A sample of ~200 mg dried and purified elastin fiber (~ 2 mm × 29 mm) prepared in a similar manner that described above and analyzed in the 700 MHz spectrometer. The fiber was equilibrated overnight against 10% $^2\text{H}_2\text{O}/^1\text{H}_2\text{O}$ solution to a known mass, inserted into a 5 mm NMR tube and then inserted into the unmodified cryoprobe. ^{13}C NMR spectra without magic angle spinning of the relaxed and ~ 122 % stretched elastin fiber were obtained and the relaxation times, T_1 and T_2 were determined using Carr-Purcell-Meiboom-Gill (CPMG) echo and inversion recovery pulse sequences with 4 s recycle delays.^{89, 90}

3.2.2 The Order Parameter (S) Analysis

Natural elastin is a highly cross-linked proteinaceous material. Because it is highly cross-linked, macromolecular reorientation of the protein does not take place. Thus, the order parameter (S) for backbone motion can be estimated directly from the linewidth of the spectra obtained without magic angle spinning (MAS), and motional averaging of the residual shielding tensor is due only to the flexibility of the protein backbone.

The ^{13}C NMR carbonyl peak of hydrated elastin is well separated from other peaks with a large static shielding anisotropy (~116 ppm), and most of the carbonyl groups are from the protein backbone. These factors make the carbonyl peak the optimum ^{13}C signal

to be used to estimate the order parameter (S) for chain motions. The linewidth of the carbonyl peak is a sum of three contributing factors: (i) the range of carbonyl isotropic chemical shifts of the different amino acid residues in elastin, (ii) the contribution of the spin relaxation time, T_2 , to the linewidth ($\frac{1}{\pi T_2}$) and (iii) the residual shielding anisotropy ($\Delta\sigma_{\text{Res}}$). To account for factor *i*, the carbonyl isotropic chemical shifts were predicted for the amino acid sequence of bovine tropoelastin (the monomer of elastin)⁹¹ using sequence corrected random coil shifts (https://spin.niddk.nih.gov/bax/nmrserver/Poulsen_rc_CS). This routine correctly predicted the experimentally obtained ¹³C carbonyl shifts in a minielastin studied before.^{60, 92} To account for factor *ii*, the experimental spin relaxation time T_2 was convoluted with the chemical shifts using a MATLAB script to generate a simulated carbonyl spectrum that accounts for factors *i* and *ii* described above. The simulated and experimental spectra, (Figure 3.5), are well described by a Lorentzian line shape with signal intensity, $I(\text{ppm})$, given by

$$I(\text{ppm}) = C \frac{W}{1 + \left(\frac{2}{W} (\text{ppm} - \text{ppm}_0)\right)^2}, \quad \text{Eq. 3.1}$$

where C is a constant and W is the linewidth.

The residual anisotropy ($\Delta\sigma_{\text{Res}}$) is then the difference between the linewidths of the experimental and simulated spectra. In turn, the backbone order parameter was calculated as $S = \Delta\sigma_{\text{Res}} / \Delta\sigma_{\text{Stat}}$.⁸⁶ The static anisotropy ($\Delta\sigma_{\text{Stat}}$) is approximately constant for different polypeptides and was estimated for peptide carbonyls using data compiled by Duncan, $\Delta\sigma = \frac{3}{2}(\delta_{33} - \delta_{\text{iso}}) = 116 \text{ ppm}$, where δ_{33} is the largest traceless principal

component of the chemical shift tensor and δ_{iso} is the average of the three principal components of the chemical shift tensor.⁹³

3.2.3 Relaxation Rates Analysis

The relaxation rates, $R_1 = T_1^{-1}$ and $R_2 = T_2^{-1}$, of the ^{13}C carbonyl ($^{13}\text{C}'$) were measured at two NMR frequencies, 500 and 700 MHz, with the elastin fiber relaxed and stretched. This data was used to analyze dynamics of the backbone of the natural purified elastin.

The relaxation rates of $^{13}\text{C}'$ are the result of two relaxation mechanisms that arise from the dipole-dipole (DD) coupling and the chemical shift anisotropy (CSA), Eq. 3.2 – 3.7.⁹⁴⁻⁹⁶ The DD mechanism arises due to the fluctuations in the magnitude and direction of the magnetic field of the spin as a result of dipole-dipole interaction with a neighboring nuclear spin, and the CSA relaxation mechanism results from the fluctuations in the magnitude and direction of the local magnetic field produced by the electron currents of the molecule due to the external magnetic field. The CSA mechanism is dominant in these experiments due to the high magnetic fields used and the large static shielding anisotropy.⁷¹ The standard expressions for the relaxation rates are given below.

$$R_1 = R_1^{\text{DD}} + R_1^{\text{CSA}} \quad \text{Eq. 3.2}$$

$$R_2 = R_2^{\text{DD}} + R_2^{\text{CSA}} \quad \text{Eq. 3.3}$$

$$R_1^{\text{DD}} = \frac{1}{4 r_{\text{HC}}^6} [\mu_0 h \gamma_{\text{H}} \gamma_{\text{C}}]^2 \times [J(\omega_{\text{H}} - \omega_{\text{C}}) + 3J(\omega_{\text{C}}) + 6J(\omega_{\text{H}} + \omega_{\text{C}})] \quad \text{Eq. 3.4}$$

$$R_1^{\text{CSA}} = \frac{3}{4} \delta_{z'}^2 \left(1 + \frac{\eta^2}{3}\right) \gamma_{\text{C}}^2 B_0^2 [J(\omega_{\text{C}})] \quad \text{Eq. 3.5}$$

$$R_2^{\text{DD}} = \frac{1}{8 r_{\text{HC}}^6} [\mu_0 h \gamma_{\text{H}} \gamma_{\text{C}}]^2 \times [4J(0) + J(\omega_{\text{H}} - \omega_{\text{C}}) + 3J(\omega_{\text{C}}) + 6J(\omega_{\text{H}}) + 6J(\omega_{\text{H}} + \omega_{\text{C}})] \quad \text{Eq. 3.6}$$

$$R_2^{\text{CSA}} = \frac{1}{8} \delta_{z'}^2 \left(1 + \frac{\eta^2}{3}\right) \gamma_{\text{C}}^2 B_0^2 [4J(0) + 3J(\omega_{\text{C}})] \quad \text{Eq. 3.7}$$

where r_{HC} is the distance between the ^1H and ^{13}C and set to be 1.69 Å, μ_0 is the permeability of vacuum (1.256637×10^{-6} H/m), h is Planck's constant (6.626×10^{-34} Js), γ_{H} is the gyromagnetic ratio of ^1H (2.67522×10^8 rad s $^{-1}$ T $^{-1}$), γ_{C} is the gyromagnetic ratio of ^{13}C (6.7283×10^7 rad s $^{-1}$ T $^{-1}$), ω_{H} and ω_{C} are the Larmor frequencies of ^1H and ^{13}C (respectively), $\delta_{z'}$ is the largest traceless principal component (-77 ppm), η is the asymmetric parameter for the ^{13}C carbonyl (0.81), and B_0 is the static magnetic field of the NMR spectrometer.^{71, 93, 95, 96}

The spectral density, $J(\omega)$, used here is the extended Lipari- Szabo model free spectral density in the limit that overall reorientation of the protein is quenched due to cross-linking, $\tau_{\text{M}} \rightarrow \infty$,⁹⁶⁻⁹⁹

$$J(\omega) = \frac{2}{5} \left(\frac{(1 - S_{\text{F}}^2) \tau_{\text{F}}}{1 + (\omega \tau_{\text{F}})^2} + \frac{(S_{\text{F}}^2 - S^2) \tau_{\text{S}}}{1 + (\omega \tau_{\text{S}})^2} \right) \quad \text{Eq. 3.8}$$

S^2 is the generalized order parameter for fast and slow chain motions, τ_{F} and τ_{S} are the effective correlation times for fast (F) and slow (S) internal motion, and S_{F}^2 is the generalized order parameter for fast chain motions ($S^2 = S_{\text{F}}^2 S_{\text{S}}^2$). S_{F}^2 was constrained to the range of 0.4 – 0.6 that was found in studies of minielastins.⁹⁶

The experimentally determined R_1 and R_2 values at the two magnetic fields (500 MHz and 700 MHz) were fit using Eq. 3.2 – 3.7 with the spectral density function, Eq. 3.8,

to determine the timescales of the backbone motions in natural elastin using MATLAB scripts. Because the relaxation rates for relaxed and stretched were the same within the experimental error, their average rates were used in the data fit. The optimum fit parameters (S_F^2 , τ_F and τ_S) were obtained by a grid search for the minimum chi square (χ^2) defined in Eq. 3.9.^{95, 96}

$$\chi^2 = \sum_{500, 700 \text{ MHz}} \left[\left(\frac{R_{1,e} - R_{1,c}}{\sigma_{R_{1,e}}} \right)^2 + \left(\frac{R_{2,e} - R_{2,c}}{\sigma_{R_{2,e}}} \right)^2 \right] \quad \text{Eq. 3.9}$$

The subscripts “e” and “c” indicate the experimentally measured relaxation rates and the calculated rates, respectively, σ is the experimental standard error of the relaxation rates, and the sum is over the two NMR frequencies, 500 MHz and 700 MHz.

A second MATLAB script was used to calculate standard errors of the optimum fit parameters. Five hundred data sets of relaxation rates, R_1 and R_2 , were generated randomly with a normal distribution that used the optimum fit rates and the experimental uncertainties as the Gaussian means and standard deviations, respectively. Then, fit parameters were obtained for each data set with the same routine that was used to fit the experimental rates. This created a distribution of values for each fit parameter, and error limits were calculated as the standard deviation of this distribution. The root mean square deviation (RMSD) of the relaxation rates back calculated from the fit parameters was within two standard deviations of the experimental error (σ) of the experimental relaxation rates.⁹⁶

3.3 Results and discussion

Static, natural abundance ^{13}C NMR was used to study backbone ordering and the timescales of dynamics in natural, purified elastin when relaxed and when subjected to

mechanical strain. ^{13}C spectra were acquired at two magnetic fields. the spectra of stretched elastin (red) are essentially superimposable on the relaxed spectra (black) at both magnetic fields, (Figure 3.2). This is particularly apparent in the spectrum obtained on the 700 MHz instrument with higher signal to noise. Also note that the carbonyl signal (170 – 180 ppm) is well separated from other carbon signals.

R_1 and R_2 relaxation data, (Figure 3.3), was used to determine the relaxation rates, (Table 3.1). Within experimental error, both R_1 and R_2 are unaffected by applying mechanical strain. For further analysis, averages of the stretched and relaxed values were used. Intriguingly, R_2 at both magnetic fields is ~ 3 orders of magnitude faster than R_1 . Also, R_1 increases at the higher magnetic field but R_2 is the same within experimental error. Previously reported values of R_1 and $R_{1\rho}$ obtained from material prepared by harsh purification techniques were similar to the ones obtained in this work.^{69, 72, 100, 101}

Figure 3.3. T_1 and T_2 of ^{13}C carbonyl of hydrated elastin both relaxed (black lines) and stretched (red lines) in 500 (upper panels) and 700 MHz spectrometers (lower panels).

Table 3.1. Carbonyl ^{13}C R_1 and R_2 of relaxed and stretched hydrated bovine elastin in 500 MHz and 700 MHz spectrometers.

Experiment		R_1 of $^{13}\text{C}'$ (s^{-1})	R_2 of $^{13}\text{C}'$ (s^{-1})
500 MHz spectrometer	Relaxed	0.26 ± 0.03	$(2.0 \pm 0.4) \times 10^3$
	132% stretched	0.26 ± 0.03	$(1.7 \pm 0.2) \times 10^3$
	Average	0.26 ± 0.02	$(1.8 \pm 0.2) \times 10^3$
700 MHz spectrometer	Relaxed	0.38 ± 0.03	$(1.4 \pm 0.3) \times 10^3$
	122% stretched	0.35 ± 0.03	$(1.9 \pm 0.6) \times 10^3$
	Average	0.37 ± 0.02	$(1.7 \pm 0.3) \times 10^3$

The linewidth of the carbonyl peak was used to estimate the generalized order parameter using the residual shielding anisotropy ($\Delta\sigma_{\text{Res}}$) as described in section 3.2.2. The linewidths of the experimental spectra (black lines) were fit to a Lorentzian function, Eq. 3.1, are 9 – 10 ppm when the fiber is relaxed or stretched, (Figure 3.4).

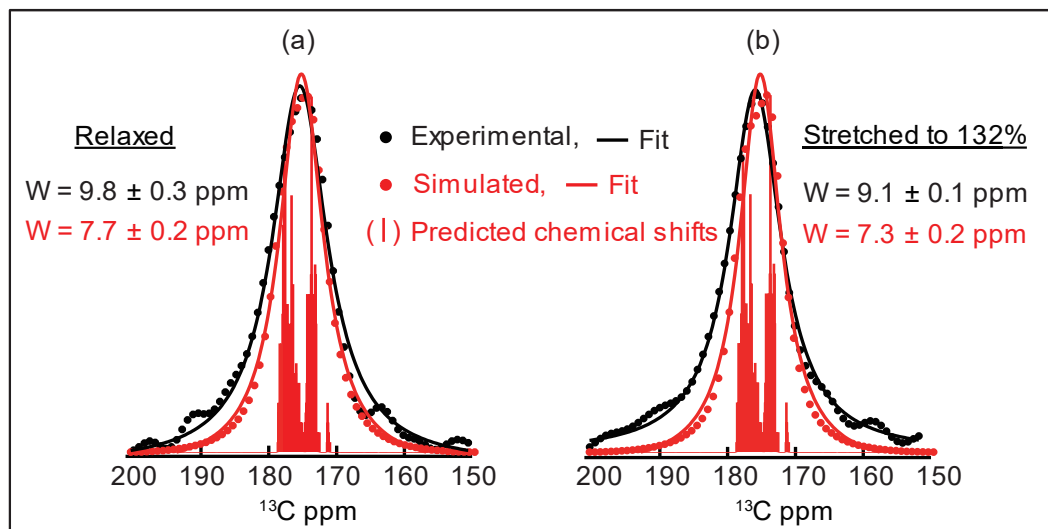

Figure 3.4. Static natural abundance ^{13}C NMR carbonyl spectra, experimental (black) and simulated (red) of hydrated elastin both (a) relaxed and (b) stretched by 132% in 500 MHz spectrometer.

The simulated spectra (red lines in Figure 3.4) account for both the isotropic chemical shifts and the finite line width due to spin-spin relaxation. Narrow lines with the simulated isotropic shifts are the red bars^{60, 92, 96} and these were convoluted with the experimentally determined R_2 ($R_2/\pi = 640$ Hz (5 ppm) in relaxed and 540 Hz (4.3 ppm) in stretched spectrum). The linewidths, 7 – 8 ppm, for the simulated peaks were obtained in same manner as the experimental spectra by fitting to Eq.3.1. Then, $\Delta\sigma_{\text{Res}}$ is the difference between the linewidths of Lorentzian fits of the experimental and the simulated spectra, and it is in the range of 1 – 3 ppm. Thus, the estimated value of the order parameter ($S = \Delta\sigma_{\text{Res}} / \Delta\sigma_{\text{stat}}$) for backbone dynamics in purified elastin is in the range 0.01 – 0.03 and the generalized order parameter (S^2) is ~ 0.001 . This is similar to the S^2 values that were determined for the minielastins (24x' and 20x') in solution using ^{15}N or ^{13}C NMR relaxation data. Stretch induced ordering of the backbone was not observed within the resolution of these experiments.⁹⁶

The generalized order parameter ($S^2 \approx 0.001$) combined with the average relaxation rates, (Table 3.1), and the constraint ($0.4 < S_F^2 < 0.6$) were used to determine the timescale of elastin's backbone motions using Eq. 3.2 – 3.8. In this way, four experimental parameters (the average R_1 and R_2 values obtained at two NMR frequencies) were used in 3-parameters fit. The χ^2 surfaces show that the correlation times $\tau_S = 2.3 \pm 0.4 \mu\text{s}$ and $\tau_F = 210 \pm 50 \text{ ps}$ were well constrained by the data and that $S_F^2 = 0.49$, is less well determined, (Figure 3.5 and Table 3.2).

Compared to soluble minielastins, the elastin backbone is also highly disordered, $S^2 \sim 0$; however, the correlation time for the slow backbone motion (τ_S) is dramatically lengthened, and the correlation time for fast motions (τ_F) is similar to that in soluble minielastins and longer by only a factor of four.⁹⁶ I conclude that cross-links, which occur every 20 – 40 residues in elastin, are highly flexible and have little effect on the amplitude of chain mobility. Because only the rate of the slow backbone motion is substantially affected by cross-linking, these dynamical modes likely occur on length scales comparable to the spacing between cross-links, whereas fast backbone dynamics are at the residue level.

Figure 3.5. χ^2 surfaces of fit parameters to the NMR relaxation rates.

Table 3.2. Fit parameter values obtained by least squares fitting of Eq. 3.2 – 3.8 to the average values of the NMR relaxation data in table 3.1.

Parameter	value
S_F^2	0.49 ± 0.07
τ_F (ps)	210 ± 50
τ_S (μ s)	2.3 ± 0.4
rmsd R_1 (s^{-1})	0.0015
rmsd R_2 (s^{-1})	674

CHAPTER 4 THERMOMECHANICAL PROPERTIES OF ELASTIN

4.1 Introduction

The mechanical properties of natural elastin were studied by Weis-Fogh et al. and later, more extensively by Gosline and coworkers using microcalorimetry.^{8, 84, 102} They assumed no changes in the fiber volume upon stretch, so they defined the work of stretch of the hydrated elastin as the stored energy (ΔA). They found that the heat released (Δq) upon stretching hydrated elastin is larger than (ΔA) of stretch. Insofar as elastin stretch is reversible, which is confirmed herein, the 2nd law of thermodynamics requires that the entropy change upon stretch, $\Delta S = -\Delta q/T$, is large and negative. Thus, the internal energy and the entropy changes for stretching are both large and negative, so spontaneous recoil is driven by a large increase in entropy and elastin is known as an entropic elastomer. In the ideal spring model, approximately correct for rubber, the heat released upon stretch is much smaller and the change in internal energy is negligible.¹⁰³

Weis-Fogh measured the heat liberated at room temperature upon stretching the fiber by ~ 35% to be five times greater than the applied mechanical work. This corresponds to an internal energy change of ~ -5 mcal/35mg with an applied mechanical work of ~ 1.3 mcal/35mg.⁸

The more extensive study performed later by Gosline on hydrated bovine elastin found that the ratio of the internal energy change to the applied mechanical work varies inversely with stretch. The ratio of the heat released to work done at 22 °C is 91 for 2% stretch and 3 for 70% stretch. Also, the internal energy change upon stretch varies significantly with temperature over the range of 2 °C – 65 °C. It is large and negative at low temperatures and increases until it reaches ~ zero at 65 °C.⁸⁴ This temperature dependence is similar to that associated with hydrophobic interactions. In the hydrophobic effect, water interacting with a hydrophobic surface decreases the entropy of water^{84, 102} and this is known to be the dominant force in protein folding.^{104, 105} Whereas in the widely accepted Flory model of rubber elasticity, the decrease in entropy upon stretch is due to a decrease in configurational entropy of the polymer.⁹ This has not been proven and the alternative, recoil driven by hydrophobic forces, has not been disproven.

An important aspect of Flory's disagreement with Gosline is that Gosline's calculation of the large decrease in energy had neglected any change in volume with temperature and stretch. In thermodynamic terms, Gosline had assumed that the relevant thermodynamic state function was Helmholtz free energy (ΔA) and Flory correctly pointed out that Gosline's measurements were made at constant pressure, in which the correct state function is Gibbs free energy, $\Delta G = \Delta A + P\Delta V$. Flory et al reported no changes in the volume of elastin fiber only when it is hydrated in the presence of a diluents like glycol-water (3:7) mixture or 30% PEG. With these conditions, no change in the internal energy of elastin is reported upon stretch.^{7, 9} However, Flory and co-workers disregarded that their system is a three-component system and neglected the effect of glycol on both the fiber and water. Later, Flory modified his elastic theory for elastin to include the effects of

solvent interacting with the protein surface, but he did not explicitly consider hydrophobic interactions. It is worthy to note that rubber is fully elastic in the absence of solvent, whereas elastin, the most hydrophobic protein known, is fully inelastic in the absence of water. A full understanding of recoil in elastin should also account for other differences. Unlike rubber, the stretch/recoil cycle for elastin is fully reversible (vide infra), the elastic modulus of elastin is much less, and elastin has a much lower extension without rupture.

Strain-induced changes in free energy (ΔG) and entropy (ΔS) have not previously been reported to my knowledge and the large release of heat upon stretch indicates that the change in length as a function of temperature is a sensitive method for determining a complete force (F) as a function of length (l) and temperature (T) state function for elastin. From the state function, $F(l,T)$, all relevant thermodynamic properties can be determined. Importantly, volume changes with both temperature and force at constant hydration are readily determined and reported using a novel apparatus. Thus, in this Chapter, all relevant thermodynamic properties have been determined as a function of temperature and stretch in (i) pure water, (ii) with the addition of Hoffmeister ions or polyethylene glycol and (iii) when $^1\text{H}_2\text{O}$ is replaced with $^2\text{H}_2\text{O}$. By performing all experiments on a single elastin fiber, the exceptional reversibility of the stretch contract cycle of elastin and its unusual physical robustness are confirmed.

Kosmotropes, like sulfate ion perturb the hydrophobic effect and make it difficult to create the cavity needed to accommodate hydrophobic solutes by increasing surface tension.^{80, 81} PEG has a similar effect but through preferentially increasing protein hydration.^{37, 42, 44} On the other hand, chaotropes, like perchlorate ion perturb protein

structure by interacting with the amide backbone, either through specific or nonspecific ion interactions.^{80, 82, 83}

Compared to $^1\text{H}_2\text{O}$, $^2\text{H}_2\text{O}$ is a more structured liquid and has stronger solvent-solvent hydrogen-bonds.^{49, 51} $^2\text{H}_2\text{O}$ stabilizes β -turns structures and destabilizes α -helices.⁵⁹ It is believed that $^2\text{H}_2\text{O}$ stabilizes folded proteins more than $^1\text{H}_2\text{O}$ by affecting the hydrophobic interactions and/or hydrogen-bonding.⁵⁴⁻⁵⁷ Thus, $^2\text{H}_2\text{O}$ is also expected to perturb the hydrophobic effect.

4.2 Theory

Based on the 1st law of thermodynamics, $dU = \delta q + \delta W$, where U is the internal energy of the system (hydrated elastin), δq is the energy added as heat, and δW is the work done on the system. Based on the 2nd law of thermodynamics for reversible processes, $\delta q = TdS$ and $\delta W = -PdV + Fdl$, where T is the absolute temperature, S is the entropy, P is the pressure, V is the volume, F is the applied force and l is the length. Consequently,

$$dU = TdS - PdV + Fdl.$$

Using the definition of enthalpy, $H = U + PV$,

$$dH = dU + PdV + VdP$$

$$dH = TdS + VdP + Fdl$$

Using the definition of Gibbs free energy, $G = H - TS$

$$dG = dH - SdT - TdS$$

$$dG = -SdT + VdP + Fdl$$

Using the property of the total differential $dG(l,T,P)$, two useful results are obtained,

$$dG(T, l, P) = -SdT + VdP + Fdl$$

$$\left(\frac{\partial G}{\partial l}\right)_{T,P} = F \text{ and } \left(\frac{\partial G}{\partial T}\right)_{l,P} = -S$$

Integrating the first equation gives

$$\Delta G_{T,P} = \int_{l_0}^{l_1} F dl \quad \text{Eq. 4.1}$$

Equating cross derivatives of the first and second equation, gives the Maxwell relation,

$$-\left(\frac{\partial S}{\partial l}\right)_{T,P} = \left(\frac{\partial F}{\partial T}\right)_{l,P},$$

and after integration,

$$\Delta S_{T,P} = - \int_{l_0}^{l_1} (\partial F / \partial T)_{l,P} dl \quad \text{Eq. 4.2}$$

The change in enthalpy ΔH_T and the heat capacity ΔC_P can be calculated from the following equations,

$$\Delta H_T = \Delta G_T + T\Delta S_T \quad \text{Eq. 4.3}$$

$$\Delta C_P = \left(\frac{\partial \Delta H}{\partial T}\right)_P \quad \text{Eq. 4.4}$$

Eq. 4.1– 4.4 are the fundamental relations used in this study for the analysis of the experimentally obtained $F(l,T)$ data of stretching elastin. The changes in Gibbs free energy (ΔG_T) and entropy (ΔS_T) are obtained by integrating the force and the slope of the force versus temperature with respect to the length, respectively. From these, the change in enthalpy (ΔH_T) and the heat capacity ΔC_P are readily obtained.

4.3 Materials and Methods

4.3.1 The Homebuilt Apparatus

The apparatus used for the thermomechanical experiments in this Chapter is a box-shaped (rectangular prism) tank that has 5 faces. The upper face ($8.0 \times 3.0 \times 1.5$ cm) is the lid of the tank and contains two holes designed to insert the heating rod (side) and the thermometer (middle). The right and the left side faces of the tank ($30.0 \times 6.0 \times 1.5$ cm) have an upper groove that matches the dimension of the lid, (Figure 4.1, right panel). The inner right-side face contains a groove to fit a 200 mm ruler. Also, the right side has two holes (0.25 cm in diameter): one is 4 cm down from the lid and the other is 2 cm above the base. Two hollow aluminum rods (0.25 cm outer diameter and 0.2 inner diameter) go through these holes that are connected to pipes, and in turn connected to a pump. The remaining two faces ($30.0 \times 3.0 \times 1.5$ cm) form the front and the back faces of the tank. The whole apparatus is made of Delrin (Online Metal Supply LLC, Houston, MO) except the front and the back faces that are made of Plexiglass (Online Metal Supply LLC, Houston, MO) to give clear vision for the camera. The five faces are fixed together and to a bigger base ($18.0 \times 18.0 \times 1.5$ cm) by screws, (Figure 4.1, left panel). The base has a screw that run through it to the inner compartment of the tank, intended to hold the sample.

Figure 4.1. Schematic presentation of the assembled homebuilt apparatus.

4.3.2 Sample Setup

A 0.24 g dried and purified nuchal bovine elastin fiber ($\sim 77 \text{ mm} \times 1.6 \text{ mm} \times 6.4 \text{ mm}$; $\sim 240 \text{ mg}$) was glued to rods at both ends. The upper rod was attached to a thread and the lower rod was fixed to the screw in the base of the homebuilt apparatus, (Figure 4.2).

Outside of the sample compartment, the thread was passed over a light, low friction pulley and attached to calibrated masses to vary the force applied to the fiber. Thus, the applied force equals the attached mass in kg multiply by the gravitational acceleration (9.8 m/s^2). The temperature was regulated through a homebuilt controller with a platinum

resistance thermometer and a rod heater in connection with a proportional-integral-derivative controller (Omron PID e5cc controller with pt100 sensor).

Figure 4.2. The thermomechanical setup. The fiber length, temperature and masses are recorded by the camera.

Temperature variation over each measurement was within 0.1 K and the equilibration times between $l(F)$ and $l(T)$ measurements were 5 min and 3 – 5 min, respectively. Furthermore, the solvent/solution inside the compartment was circulated using a pump that was connected to the pipes in the right side of the apparatus. The fiber length was measured with a 36-megapixel camera (Sony A7R) giving a length accuracy of 0.1 mm which was calibrated using the 200 mm ruler inside the apparatus that was included in every photograph. ImageJ software, was used to convert pixels into mm.

Length versus force, $l(F)$, at fixed temperatures and length versus temperature, $l(T)$, at fixed forces were measured for hydrated purified bovine elastin fiber in the following aqueous solutions: deionized water, 0.1 mol/kg sodium sulfate (Na_2SO_4 ACS, Fisher Chemical, Fair Lawn, NJ), 0.3 mol/kg sodium sulfate, 15% (w/w) 20 kDa PEG (Polyethylene glycol 20,000, Alfa Aesar, Ward Hill, MA), 30% (w/w) 20 kDa PEG, $^2\text{H}_2\text{O}$ (99.9% D, Sigma-Aldrich, St. Louis, MO), 0.3 mol/kg sodium perchlorate (NaClO_4 ACS 98.0-102.0%, Beantown Chemical Corporation, Hudson, NH) and 1.0 mol/kg NaClO_4 .

$l(F)$ was measured from 0.09 N to 0.72 N at fixed temperatures from 278 to 318 K in 5 K increments when possible. $l(T)$ was measured from 274 to 328 K in 1 K increments at fixed forces of 0.09 N, 0.23 N, 0.40 N and 0.72 N when possible.

4.3.3 Data Processing

Complete state functions, $l(F,T)$, for each of the solutions described above were obtained by combining experiments of $l(F)$ at different temperatures and $l(T)$ at different forces. The linear $l(F)$ data and non-linear $l(T)$ are well-fit by a polynomial that is 1st-order in F and 3rd-order in T over the range of F and T studied here. The two sets of experiments

were combined into a 2-dimensional array and are well-fit to the following polynomial, i.e., virial equation of state using MATLAB scripts:

$$l(F, T) = c_0 + c_1F + c_2T + c_{12}FT + c_3T^2 + c_4T^3 \quad \text{Eq. 4.5}$$

Both the goodness of the fit statistics, (Table 4.1), and the virial coefficients of the above equation, (Table 4.2), were obtained from MATLAB Curve Fitting Toolbox™.

Table 4.1. Goodness of the fit statistics.

Solution	SSE (m ²)	R-square	Degree of freedom	adjusted R-square	RMSE (m)
¹ H ₂ O	2.00 × 10 ⁻⁵	0.998	302	0.998	2.57 × 10 ⁻⁴

The sum of squares due to error (SSE) measures the total deviation of the experimental fiber length (l) to the fit obtained using equation 4.5. $SSE \sim 0$ indicates the fit has a small random error. R-square is the square of the correlation between l and the fit values. This value is close to 1, indicating that a greater proportion of variance is accounted for by the fit. The adjusted R-square considers the residual degree of freedom, the number of data points minus the number of fitted coefficients. The adjusted R-square being close to 1 indicates a good fit. The root mean squared error (RMSE), the fit standard error, estimates the standard deviation of the random component in the data. As SSE, the closer it gets to 0 the better the fit.

The state function $F(l,T)$ in Eq. 4.6 is obtained by solving Eq. 4.5 for F .

$$F(l, T) = \frac{(l - c_0 - c_2 T - c_3 T^2 - c_4 T^3)}{c_1 + c_{12} T} \quad \text{Eq. 4.6}$$

Finally, the changes in entropy (ΔS_T), Gibbs free energy (stretch work = ΔG_T), enthalpy (ΔH_T) and heat capacity (ΔC_p) with stretch were determined using Maxwell relations as defined in the theory section,^{7, 106, 107} numerical integration and differentiation functions in MATLAB and Eq. 4.1 – 4.4, 4.6. Tables of thermodynamic parameters calculated in this way for all solutions at different temperatures and strains are listed in Appendix A (Table A.3 – A.7).

4.4 Results and Discussion

The hydrated elastin fiber length increases linearly with an increase in the applied mechanical force at all temperatures and decreases nonlinearly with the increase in temperature at constant force in all solutions. Solvent deuteration, addition of a Hoffmeister

kosmotrope (sulfate ion) or a protein precipitant (PEG) significantly alter these changes. However, the effect of the Hoffmeister chaotrope is significantly less.

The reversibility and the reproducibility of the results were confirmed in the following section, followed by an extensive description of the results for the hydrated elastin fiber in $^1\text{H}_2\text{O}$ and finally $^2\text{H}_2\text{O}$ results were compared to the results obtained in the other hydrating solvent/solutions.

4.4.1 Reversibility and Reproducibility

The reversibility of the fiber length with varying force at constant temperature was confirmed by running two cycles of stretch and relax measurements. This test was applied to all $l(F)$ experiments and within the standard errors of the fitted slopes and intercept, repeated stretch and relax cycles are fully reversible, (Figure 4.3). Averages of these two cycles were used for further analysis.

Figure 4.3. Length versus force of two cycles of stretch and relax of the hydrated elastin fiber in $^1\text{H}_2\text{O}$ at 298 K and their linear fits.

The reversibility of the fiber length with varying temperature at constant force was confirmed by measuring the length of the fiber while the fiber was cooled back to room temperature in representative $l(T)$ experiments, (Figure 4.4). Within the error limits of the measurement, temperature reversibility is also seen.

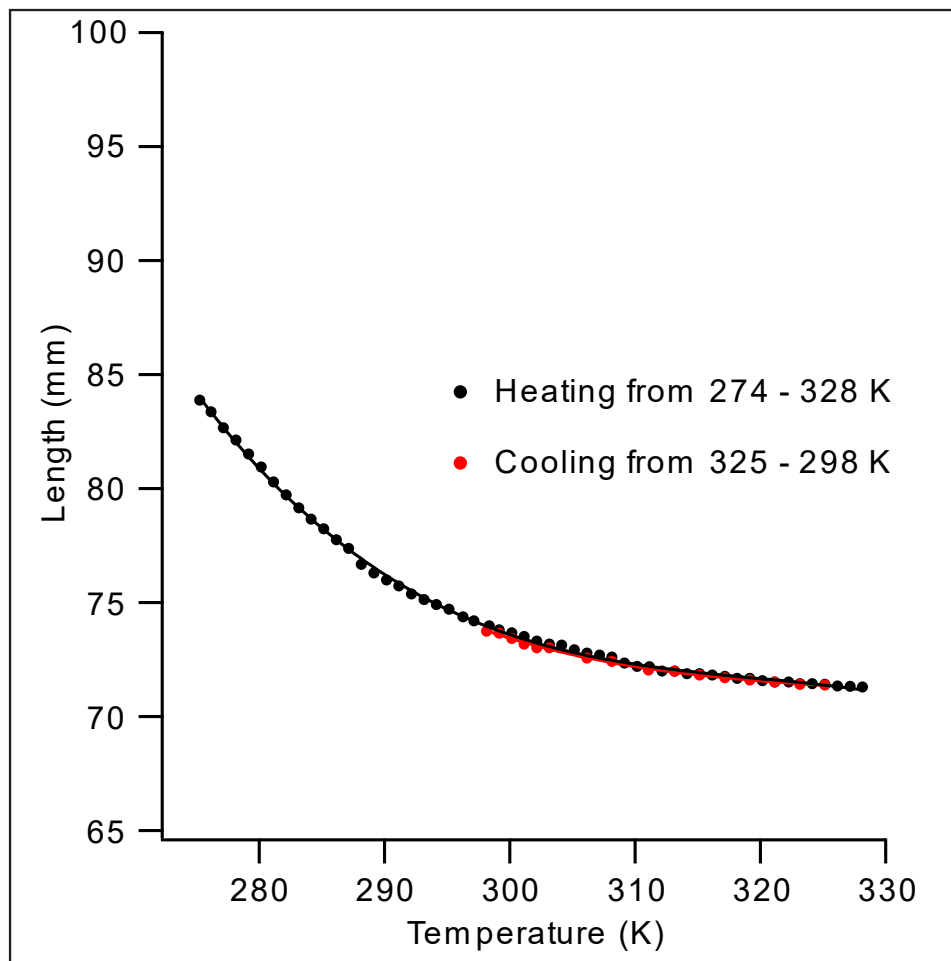

Figure 4.4. Length versus temperature at 0.23 N of the hydrated elastin fiber in 0.1 mol/kg Na_2SO_4 of heat and cool cycle.

All experiments at different solutions were performed on the same fiber to minimize experimental variations. In order to confirm no changes took place in the fiber as a result of the stretching and thermal cycles, the $l(T)$ curve at 0.40 N in $^1\text{H}_2\text{O}$ was accurately reproduced after finishing each of the investigated solutions, (Figure 4.5).

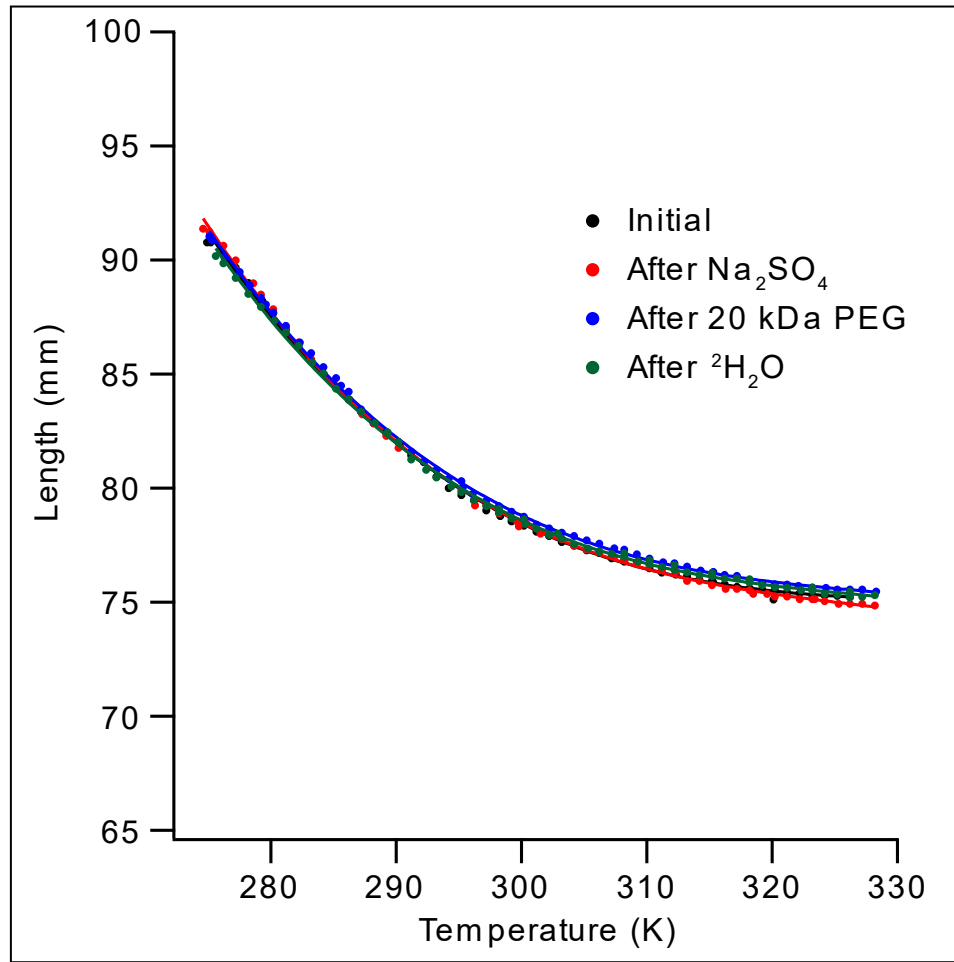

Figure 4.5. Length versus temperature at 0.40 N of the hydrated elastin fiber in ¹H₂O initially and after finishing each of the studied solutions.

4.4.2 Hydration of Elastin fiber in ¹H₂O

4.4.2.1 $l(F)$ Experiments in ¹H₂O

The first set of experiments were performed on the hydrated elastin fiber in deionized water (¹H₂O). $l(F)$ shows that the length increases linearly with increasing applied mechanical force at all studied temperatures, (Figure 4.6). $l(F)$ data was fit to Eq. 4.7, (Table 4.3).

$$l(F)_T = a + bF \quad \text{Eq. 4.7}$$

The relaxed length (the fit intercept (a) in Eq. 4.7) decreases as temperature increases, i.e., the fiber shrinks with the increase in temperature. Also, the slope of the fit (b) decreases as the temperature increases. It is important to note that the slope is an indirect measure of the elasticity of the fiber. As the slope decreases, the fiber becomes stiffer.

Figure 4.6. The length of the hydrated elastin fiber in $^1\text{H}_2\text{O}$ as a function of the mechanical force of stretching at all studied temperatures.

Table 4.3. The linear fit parameters of $l(F)$ of hydrated elastin in $^1\text{H}_2\text{O}$ at all investigated temperatures.

Temperature (K)	$l(F)$ slope (b)	$l(F)$ intercept (a)
278	20.6 ± 0.1	80.16 ± 0.06
283	20.2 ± 0.1	76.96 ± 0.04
288	19.6 ± 0.1	74.75 ± 0.04
293	19.0 ± 0.1	72.80 ± 0.04
298	18.4 ± 0.1	71.26 ± 0.04
303	17.8 ± 0.1	70.27 ± 0.05
308	17.4 ± 0.1	69.64 ± 0.05
318	16.8 ± 0.1	68.68 ± 0.05

4.4.2.2 Young's Modulus in $^1\text{H}_2\text{O}$

Young's modulus (E) is a mechanical property used to measure the stiffness of polymers. It correlates the stress to the strain according to Eq. 4.8.

$$E = \frac{\sigma}{\varepsilon} \quad \text{Eq. 4.8}$$

The stress (σ) is defined as the applied force (F) per cross sectional unit area of the polymer (A_{cross}), $\sigma = \frac{F}{A_{cross}}$ and the strain (ε) is the proportional deformation of the polymer ($\varepsilon = \frac{\Delta l}{l_0}$), where Δl is the change in the polymer length and l_0 is the relaxed or unstretched length.

Young's modulus increases as the material gets stiffer.

Young's modulus of the hydrated elastin fiber in deionized water was calculated at different temperatures using the dry fiber cross sectional area ($6.38 \times 10^{-6} \text{ m}^2$), the initial relaxed lengths (l_0) obtained from $l(F)$ linear fits, and the change of length, Δl , with the applied force from $l(F)$ experimental data. E is well fit to a 3rd-order polynomial, $E(T) = a_0 + a_1 T + a_2 T^2 + a_3 T^3$, with chi square (χ^2) equal 2.94×10^{-6} , (Figure 4.7). E is 0.61 MPa at 278 K, decreases to reach a minimum at 288 K and then increases to ~ 0.64 when the temperature is raised to 310 K, which implies that elastin fiber stiffens with the increase in temperature above 288 K (15 °C).

Figure 4.7. Young's modulus (E) of the hydrated elastin in $^1\text{H}_2\text{O}$ as a function of temperature and its fit.

4.4.2.3 $l(T)$ Experiments in $^1\text{H}_2\text{O}$

The fiber length as a function of temperature, $l(T)$, at several fixed forces, (Figure 4.8), was investigated and found to decrease substantially with the rise in the temperature.

The decrease is nonlinear at all studied forces and $l(T)$ is well fit to a 3rd-order polynomial,

$$l(T) = b_0 + b_1 T + b_2 T^2 + b_3 T^3.$$

Figure 4.8. The length of the hydrated elastin fiber in $^1\text{H}_2\text{O}$ as a function of temperature at all studied forces.

4.4.2.4 Surface Fit of $l(F,T)$ Data in $^1\text{H}_2\text{O}$

The two experiments, $l(F)$ and $l(T)$, were combined to yield the state function $l(F,T)$ (Eq. 4.5), from which the resulting state function $F(l,T)$ (Eq. 4.6) was used to calculate the changes in entropy (ΔS_T), Gibbs free energy (ΔG_T), enthalpy (ΔH_T), and heat capacity (ΔC_p) as a function of temperature at constant strain and as a function of strain at constant temperature.

The large number of highly reproducible data points (>300), and the root mean square error (RMSE) of the fit, 2.2176×10^{-4} m, indicate the high-quality thermodynamic parameters that are obtained from these thermomechanical experiments, (Figure 4.9).

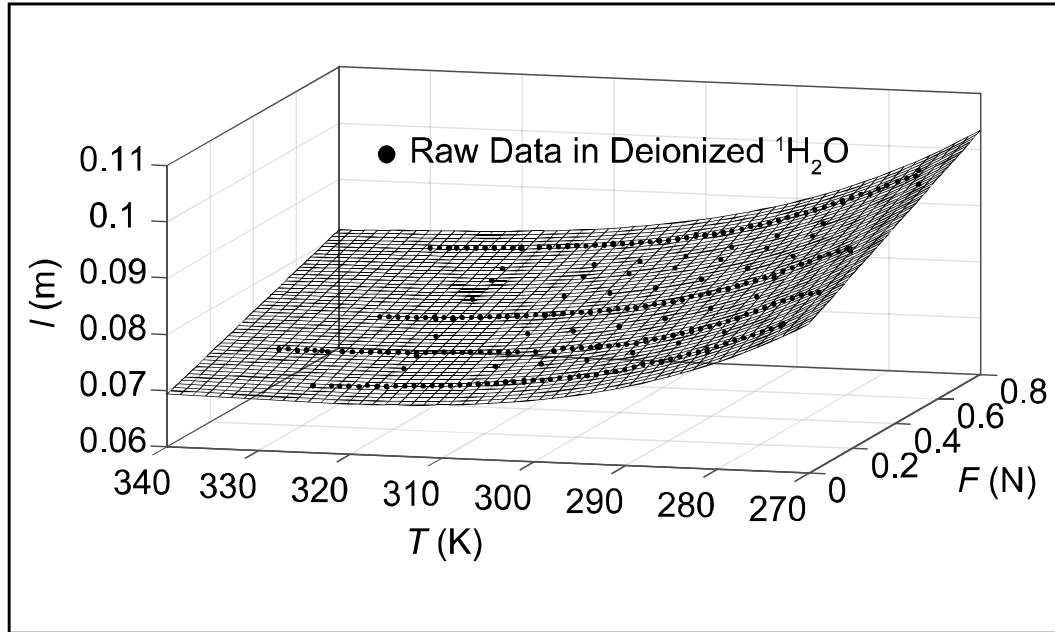

Figure 4.9. Experimental $l(F,T)$ of the hydrated elastin fiber in deionized $^1\text{H}_2\text{O}$ stretched from 70 mm to 97 mm at 278 K (5 °C) to 340 K (67 °C) (filled black circles) and the surface fit (mesh surface).

4.4.2.5 Elastin Compared to an Ideal Entropic Elastomer

The temperature dependence of the thermodynamic parameters of recoil are compared between elastin and an ideal entropic elastomer, (Figure 4.10). The comparison is made for equal changes in Gibbs free energy (ΔG_T). Rubber is approximately ideal; however, elastin is quite different.

Figure 4.10. The energetics of recoil of 20% stretched elastin fiber hydrated in $^1\text{H}_2\text{O}$ (solid lines) in comparison to the expected energetics of recoil of an ideal entropic elastomer (dash lines) for the same change in the free energy.

Stretching elastin fiber is confirmed to be reversible, thus the energetics of recoil are equal in magnitude to those calculated for stretch with an opposite sign, ($\Delta X_{\text{recoil}} = -\Delta X_{\text{stretch}}$, $X = G, H$ and S). As expected, the free energy of recoil (ΔG_{recoil}) is negative, and the recoil is spontaneous. For both elastin and the ideal elastomer (rubber), the driving force of recoil is entropic, $T\Delta S < \Delta H$. Otherwise, elastin's energetics of recoil, (solid lines in Figure 4.10) differ completely from that of the ideal entropic elastomer, (dashed lines in Figure 4.10). The ideal entropic elastomer has an enthalpic component ΔH_{ideal} close to zero

at all temperatures and thus ΔG_{recoil} is about the same as $-T\Delta S_{\text{recoil}}$.^{84, 103} In elastin, ΔH_{recoil} and $T\Delta S_{\text{recoil}}$ are large and positive and approach the ideal elastomer only at high temperature, $\sim 45^\circ\text{C}$. This is a direct consequence of the large experimentally observed temperature dependence of the fiber's length.

This dependence of the energetics of recoil on temperature is in agreement with hydrophobic interactions as suggested by the limited data of Gosline.^{84, 102} In general, processes driven by hydrophobic interactions are entropic at low temperatures and this decreases with increasing temperature.¹⁰⁸

4.4.2.6 Thermodynamic Energetics of Stretch in $^1\text{H}_2\text{O}$

The effect of temperature at constant strain (20%) on ΔG , ΔH , $T\Delta S$ and the heat capacity change (ΔC_p) of hydrated elastin in deionized $^1\text{H}_2\text{O}$ is investigated, (Figure 4.11 (a, c)). The work of stretch (ΔG_T) is small (~ 6 mJ) and almost constant through the studied temperatures, while both the entropic component ($T\Delta S_T$) and the enthalpic component (ΔH_T) are large and negative and their magnitudes decrease substantially with the increase in temperature, i.e., temperature decreases the contribution of both components to the free energy of the stretch. However, the magnitude of $T\Delta S_T$ is always higher than the magnitude of ΔH_T , confirming that elastin is an entropic elastomer. The change in the heat capacity (ΔC_{pT}) decreases linearly with the increase in temperature. The effect of temperature on both ΔH_T and $T\Delta S_T$ of stretch parallels that of the coacervation process, which takes place in the water-soluble monomer of elastin; tropelastin. Coacervation is the inverse phase transition process, in which tropelastin aggregates with the increase in temperature and facilitates the assembly and the crosslinking to form mature fibers. This process is coupled with an increase in both entropy and enthalpy with the increase in temperature.¹⁰⁹ The

results in this work show that both the entropy and the enthalpy become less negative with temperature at constant strain, coupled with a decrease in both the fiber length and volume.

Figure 4.11. Stretch energetics of the hydrated elastin fiber (0.24 g dry mass) in $^1\text{H}_2\text{O}$ as a function of (a, c) temperature at constant strain 20% and (b, d) strain at constant temperature 298 K.

The effect of strain at constant temperature (298 K) on ΔG , ΔH , $T\Delta S$ and ΔC_p of hydrated elastin in deionized $^1\text{H}_2\text{O}$ is studied, (Figure 4.11 (b, d)). As expected, the work of stretch (ΔG_T) increases with the increase in strain. The magnitude of both the enthalpic component (ΔH_T) and the entropic component ($T\Delta S_T$) increases with strain, i.e., become more negative, with the entropic component magnitude always higher confirming elastin

is entropic. The large release of heat (ΔH_T) with stretching elastin was first observed by Weis-Fogh in calorimetry studies.⁸ The ratio of the work to the heat released with stretch determined in this study from the $l(F,T)$ state function is in good agreement with his calorimetric results, as well as with the later more extensive study performed by Gosline.⁸

84

Early on, Tanford identified that an increased heat capacity is a thermodynamic signature of hydrophobic hydration.¹¹⁰ In this work, the heat capacity (ΔC_{pT}) increases linearly with the increase in strain. This indicates that stretch increases hydrophobic hydration and which is verified experimentally using double quantum filtered NMR (Chapter 2). Qualitatively, the effects of increasing temperature and stretch are in opposite directions. This is, of course, different from most materials in which increasing temperature results in expansion.

4.4.2.7 Volume Changes as a Function of Temperature and Stretch in $^1\text{H}_2\text{O}$

Finally, the changes in volume as a function of force and temperature were determined. Then, Gibbs and Helmholtz free energies were related ($\Delta G = \Delta A + P\Delta V$) and the change in the internal energy ($\Delta U = \Delta G + T\Delta S - P\Delta V$) was calculated.

The fiber shape is approximately rectangular prism and volume = length \times width \times thickness. The fiber length and width were measured directly from photos, and the thickness was calculated assuming the change in thickness is proportional to that in width using the dry dimensions as a reference.

Gosline et al found no change in volume with stretch; however, their experiments were not adequately described.⁸⁴ Elastin fiber investigated in this work shows about 5% linear

increase in volume within the maximum experimentally achieved stretched, (Figure 4.12 (a)). In agreement with Gosline's observations,¹⁰⁶ about 40% volume decrease is observed when the temperature is increased from 0 to 55°C, (Figure 4.12 (b)).

Figure 4.12. The volume of the hydrated elastin fiber in $^1\text{H}_2\text{O}$ as a function of (a) force at constant temperature and (b) temperature at constant force.

4.4.3 Hydration of Elastin fiber in $^2\text{H}_2\text{O}$, Solutions of Hoffmeister ions and PEG

To further investigate the hydrophobic effect, the elastin fiber was hydrated in $^2\text{H}_2\text{O}$, and in aqueous ($^1\text{H}_2\text{O}$) solutions containing 20 kDa PEG, sodium sulfate (Na_2SO_4) or sodium perchlorate (NaClO_4), all of which are known to modulate the hydrophobic interactions. The same approach that was used to study elastin in deionized water ($^1\text{H}_2\text{O}$) in the previous section is applied here.

4.4.3.1 Young's Modulus (E) and the Spring Constant (k) in the Investigated Solutions

Young's modulus is defined as, $E = \frac{F/A}{\Delta l/l_0}$, where F is the applied force, A is the cross-sectional area of the dry fiber, Δl is the extension and l_0 is the relaxed length, i.e., the constant term in the linear fit of the $l(F)$ data (Appendix A, Table A.1 and Table A.2). E for all studied solutions was calculated, (Appendix A, Table A.3).

The work of stretch (ΔG) of the fiber from l_0 to $l_0 + \Delta l$ is related to Young's modulus by $W = \frac{EA(\Delta l)^2}{2l_0}$. Thus, the work of stretch is inversely related to l_0 . One of the unusual properties of elastin are the changes of the relaxed length (l_0) with temperature and the hydration solvent/solution, (Figure 4.13). Consequently, the work of stretch is significantly affected by this property. To compare the stiffness in different hydration solvent/solutions, the spring constant(k) from Hooke's law ($F = k \times \Delta l$) is used. Spring constant(k) is related to Young's modulus by $k = \frac{EA}{l_0}$.

The values of the spring constant (k) are 48.5 – 63.1 N/m and, in general, increase with temperature, i.e., the fiber is stiffer with the increase in temperature, (Table 4.4).

The spring constant (k) is directly proportional to the mechanical force, as k increases, the mechanical force and the work required to stretch the fiber also increase. A slight increase in k is observed in $^2\text{H}_2\text{O}$ and 0.1 mol/kg Na_2SO_4 solution compared to $^1\text{H}_2\text{O}$. The values of k are comparable in 0.3 mol/kg Na_2SO_4 , 1.0 mol/kg NaClO_4 and 15 % (w/w) PEG solutions, and higher than in $^1\text{H}_2\text{O}$. The highest values are in 30% (w/w) PEG. The precipitating agent, PEG, is known to increase protein-protein interactions and decreases the solvent exposed hydrophobic surface. This is accompanied by an increase in the fiber

rigidity or stiffness as the spring constant results show. The chaotrope, NaClO_4 , known to salt in proteins, shows only a slight increase in fiber rigidity at low concentration and a considerable increase in stiffness at higher concentrations in which it turns over to kosmotropic behavior.^{22, 111}

Table 4.4. Spring constant (k) (N/m) for all investigated solutions at different temperatures.

4.4.3.2 Fit Surfaces of $l(F,T)$ in the Investigated Solutions

$l(F, T)$ state functions obtained under different solvent conditions are compared to the $^1\text{H}_2\text{O}$ state function, (Figure 4.13). Compared to $^1\text{H}_2\text{O}$, the $^2\text{H}_2\text{O}$ and 0.1 mol/kg Na_2SO_4 surfaces are similar with small decreases in height (l_0) and the temperature dependent slope. More significant decreases in both features are observed in 0.3 mol/kg Na_2SO_4 and 15% 20 kDa PEG. The most significant decrease is in 30% 20 kDa PEG where the relaxed length is substantially decreased at low temperature, the change with temperature is nearly eliminated, and the surface essentially converges to the deionized water surface at high temperatures. NaClO_4 has a distinct effect. At 0.3 mol/kg concentration, the surface approximately overlaps with the $^1\text{H}_2\text{O}$ surface, and at 1.0 mol/kg concentration, it is similar to the 0.1 mol/kg Na_2SO_4 surface.

The relaxed lengths of all studied solutions as a function of temperature from 276 – 328 K (3 – 55 °C) were calculated using Eq. 4.5 by setting F to be equal to zero, (Figure 4.14).

Replacing $^2\text{H}_2\text{O}$ with $^1\text{H}_2\text{O}$ increases the strength of solvent-solvent hydrogen-bonding making the hydrophobic hydration of the protein more difficult and, in turn, making the protein more compact with less surface area.^{49, 53, 54, 77} A decrease in fiber length upon a deuteration is verified, (Figure 4.14 (a)).

Figure 4.13. The state function $l(F, T)$ (filled circles) of the stretch of the hydrated elastin fiber in all investigated solutions in compare to $^1\text{H}_2\text{O}$ and their surface fit.

Figure 4.14. The computed relaxed lengths of elastin fiber in all studied solutions as a function of temperature.

The Hoffmeister kosmotrope, SO_4^{2-} , does not bind to protein, is repelled from its surface, and increases solvent surface tension making the cavity formation that is required for hydrophobic hydration at the protein surface more difficult.^{23, 24, 27, 112} Thus, sulfate ion is expected to increase elastin compaction, which is confirmed by the substantial decrease in relaxed fiber length, (Figure 4.14 (a)). Consequently, higher concentrations lead to more substantial decreases in the relaxed length.

The crowding agent, PEG, increases protein-protein interactions through preferential hydration^{37, 42, 43} and this is confirmed by the very large decrease in relaxed length, (Figure 4.14 (b)).

The Hoffmeister chaotrope, ClO_4^- , directly interacts with the amide groups in the protein backbone leading to disruption of both secondary structure and protein folding.^{24, 27, 82, 112} This explains the observed increase in relaxed length that is opposite to the effects of sulfate, PEG and solvent deuteration, (Figure 4.13 (c)).

4.4.3.3 Stretch Thermodynamic energetics in All Studied Solutions

The energetics of stretch (ΔG_T , ΔH_T , $T\Delta S_T$ and ΔC_p) were determined as functions of strain at constant temperature (298 K), (Figure 4.15 and Figure 4.16), and temperature at a constant strain of 20%, (Appendix A, Figure A.3 and Figure A.4), in all investigated solutions.

ΔG_T is small and increases nonlinearly with strain from 0 – 38 mJ in all solutions, (Figure 4.15 (a₁ – a₃)). The overall effect of isotopic substitution (²H₂O), or adding Hoffmeister ions (SO₄²⁻, ClO₄⁻) or PEG on ΔG_T is small, i.e., the values are comparable to ¹H₂O and ΔG_T as a function of strain is, to a good approximation, unaffected by varying the solvent conditions. Since strain is displacement, Δl , normalized by the relaxed length, l_0 , which decreases in the order of ¹H₂O > ²H₂O > 0.1 mol/kg SO₄²⁻ > 15% PEG > 0.3 mol/kg SO₄²⁻ > 30% PEG, ΔG_T increases in the reverse order for constant displacements, ¹H₂O < ²H₂O < 0.1 mol/kg SO₄²⁻ < 15% PEG < 0.3 mol/kg SO₄²⁻ < 30% PEG.

Both the entropic ($T\Delta S_T$) component and the enthalpic (ΔH_T) component are negative. Nonetheless, the magnitude of $T\Delta S_T$ is always greater than ΔH_T confirming that the entropic gain is the driving force for elastin recoil in all solutions. The magnitude of both ΔH_T and $T\Delta S_T$ increases with the increase in strain, (Figure 4.15 (b₁ – b₃) and (c₁ – c₃)).

Figure 4.15. Energetics of stretching hydrated elastin (0.24 g dry mass) at 298 K (ΔG_T , ΔH_T and $T\Delta S_T$) versus strain in all studied solutions.

Changing the solvent conditions substantially changes the enthalpic and the entropic driving forces. Solvent deuteration has essentially equivalent changes on ΔH and $T\Delta S$ as 0.1 mol/kg sulfate, whereas larger changes are observed at 0.3 mol/kg. A small decrease in magnitude of both ΔH and $T\Delta S$ is observed in agreement with the increase in the hydrophobic interactions caused by both the kosmotrope ion and the deuterated solvent.

The effect of perchlorate on ΔH and $T\Delta S$ is small compared to the effects of deuteration and sulfate ion (at the same concentration). These small effects are completely consistent with the observations that elastin is highly disordered in Chapter 3, i.e., adding a protein denaturant has little effect on its properties. The increased changes in thermodynamic parameters at high perchlorate concentration (1.0 mol/kg) is attributed to the turnover behavior observed in chaotropes at high concentration wherein they behave like kosmotropes.

PEG causes very large decreases in the magnitudes of both the heat released (ΔH) and the loss in strain entropy ($T\Delta S$). In fact, the magnitude of ΔH approaches zero at the high PEG concentration (30%). To control the volume changes in elastin, Flory used 30% glycol solutions and these conditions enabled him to calculate ΔA , which was equal to the entropic component $-T\Delta S$. Subsequently, Flory theorized that elastin behaves as an ideal elastomer.^{7,9} However, he ignored the effect of the third component in his system, PEG, on the elasticity of elastin.

The change in heat capacity (ΔC_p), as in $^1\text{H}_2\text{O}$, increases with strain at constant temperature, i.e., the hydrophobic hydration is increased with strain, (Figure 4.16), and decreases with temperature, (Figure A.3).¹¹⁰

Solvent deuteration and addition of 0.1 mol/kg sulfate has a minor effect on ΔC_p , whereas a substantial decrease is observed with the higher concentration 0.3 mol/kg sulfate, (Figure 4.16 (a)). This is an anticipated effect, since an increase in ΔC_p is associated with hydrophobic hydration,^{105, 110} and with higher concentration of sulfate the fiber is more compact as the length measurement show, i.e., less hydrophobic surface is exposed to hydration.

Figure 4.16. The heat capacity change of stretching the hydrated elastin fiber (0.24 g dry mass) as a function of strain in all studied solutions in comparison to $^1\text{H}_2\text{O}$.

PEG causes the largest decrease in ΔC_p , which approaches zero at the higher concentration (30%), (Figure 4.16 (b)). This dramatic effect is in agreement with the effect of PEG on the fiber length and volume. The most compact fiber with the least solvent exposed surface area has the smallest heat liberation with strain.

Perchlorate at 0.3 mol/kg concentration has a minor effect on ΔC_p , whereas the higher concentration, 1.0 mol/kg, has a similar effect as the 0.3 mol/kg sulfate due to the turnover behavior, (Figure 4.16 (c)).

4.4.3.4 Volume Changes in All Investigated Solutions

The volume of the hydrated elastin fiber as a function of both force, (Figure A.5), and temperature, (Figure A.6), was measured in the different hydration solvent/solutions in the same manner as in deionized water $^1\text{H}_2\text{O}$, with qualitatively similar results. The volume increase is linearly with the applied force and the decrease with temperature is larger and non-linear. Deuteration ($^2\text{H}_2\text{O}$) has no significant effect on the changes in volume in comparison to the deionized solvent ($^1\text{H}_2\text{O}$). Sulfate eliminates the increase in volume with force and retains the decrease in volume with temperature. A more significant effect is observed with PEG. The changes in volume with both force and temperature are eliminated. Perchlorate has the opposite effect. It binds to backbone peptide groups and expands the protein giving more surface to the hydration solvent. A significant increase in volume is observed with respect to force and a minor effect with temperature.

The $P\Delta V$ work at constant temperature in the investigated solutions was calculated using the experimentally measured volume versus length, $V(l)$. The slope of $V(l)$ from a linear least square fit was multiplied by the extension (Δl) and one atmospheric pressure (101325 Pa) to evaluate $P\Delta V$ at different strains. This was performed in the studied solutions at 293 K and compared to the work of stretch (ΔG_T) to determine the change in internal energy (ΔU_T), (Table 4.5).

Table 4.5. The $P\Delta V$ work computed from $V(l)$ data and compared with the work of stretch ΔG to stretch elastin fiber by 20% at 293K hydrated in the investigated solutions.

Solution	$V(l)$ slope (m^2)	Relaxed length (l_0 in m)	Δl (m)	$P\Delta V$ (mJ)	ΔG (mJ)
$^1\text{H}_2\text{O}$	$3.8 \pm 0.3 \times 10^{-6}$	7.29×10^{-2}	1.46×10^{-2}	5.65 ± 1.52	5.63
$^2\text{H}_2\text{O}$	$7.6 \pm 0.8 \times 10^{-6}$	7.16×10^{-2}	1.43×10^{-2}	11.05 ± 1.25	5.41
0.1 mol/kg Na_2SO_4	$6.4 \pm 0.7 \times 10^{-6}$	7.07×10^{-2}	1.41×10^{-2}	9.11 ± 1.03	5.33
0.3 mol/kg Na_2SO_4	$2.3 \pm 0.9 \times 10^{-6}$	6.84×10^{-2}	1.37×10^{-2}	3.20 ± 1.29	5.11
0.3 mol/kg NaClO_4	$1.4 \pm 0.2 \times 10^{-5}$	7.51×10^{-2}	1.50×10^{-2}	20.98 ± 2.35	5.96
1.0 mol/kg NaClO_4	$4.8 \pm 0.9 \times 10^{-6}$	7.42×10^{-2}	1.48×10^{-2}	7.20 ± 1.37	6.08
15% 20 kDa PEG	$2.2 \pm 0.3 \times 10^{-6}$	7.08×10^{-2}	1.42×10^{-2}	3.15 ± 0.43	5.67
30% 20 kDa PEG	$3.4 \pm 0.4 \times 10^{-6}$	6.77×10^{-2}	1.35×10^{-2}	4.69 ± 0.51	5.48

The state functions, $H \equiv U + PV$, $A \equiv U - TS$ and $G \equiv H - TS$, with the combined 1st and 2nd laws of thermodynamics can be used to relate the work of stretch (ΔG) with the work of expansion ($P\Delta V$), the change in internal energy (ΔU) and Helmholtz Free energy (ΔA). Stretching the fiber from l_0 to $l_0 + \Delta l$ at constant temperature and pressure, the followings relations are obtained.

$$\Delta G = \Delta A + P\Delta V \quad \text{Eq. 4.9}$$

And

$$\Delta U = \Delta G + T\Delta S - P\Delta V \quad \text{Eq. 4.10}$$

The changes in the internal energy (ΔU) calculated using Eq. 4.10 as a function of strain, (Figure 4.17). In general, the magnitude of ΔU increases as the strain increases (become more negative). But this is highly dependent on the solution conditions. The 0.3 mol/kg perchlorate solution, which increases solvent exposed hydrophobic surface has the highest magnitude of ΔU , whereas the solutions/solvent that decrease the hydrophobic surface and volume exposed to hydration ($^2\text{H}_2\text{O}$, sulfate and PEG) decrease the magnitude of ΔU to almost zero in 30% PEG.

Figure 4.17. The change of internal energy (ΔU) for the hydrated elastin fiber (0.24 g dry mass) in all studied solutions as a function of strain at 293 K.

Although Gosline incorrectly neglected the volume changes upon stretch and used Helmholtz free energy to calculate the change in internal energy, the internal energy does decrease substantially even when the volume changes are taken into account, which is confirmed here. Flory, on the other hand, incorrectly assumed that volume changes could be neglected when the solvent contains glycol or PEG. Additionally, the thermodynamic parameters and the mechanical properties are correlated to the hydrophobic interactions by changing the solvent conditions. ($^2\text{H}_2\text{O}$, sulfate and PEG) increase the hydrophobic effect and make the fiber shorter with smaller volume and increases the fiber stiffness. In other

words, simply changing the solvent in this way drives recoil. Moreover, changing the solvent conditions in such manner, decreases the magnitude of the heat liberated, the entropy, and the internal energy with stretch. However, 0.3 mol/kg ClO₄, does not increase the hydrophobic interaction. Instead, it interacts directly with the protein backbone and increases solvent exposed hydrophobic surface area. This has little effect on the fiber stiffness or entropy because elastin is already highly disordered. Nevertheless, it does increase the internal energy change because of its effect on the fiber volume.

CHAPTER 5 CONCLUSIONS

The principal goal of this dissertation is to understand the mechanism of recoil in natural elastin, nature's most abundant elastomeric material. This understanding of recoil mechanism is fundamental to the systematic approach of developing and designing new protein-based elastomers. Elastin has inspired the design of wide variety of proteins with different functions, including protein purification, matrices for tissue engineering and drug delivery. Unlike rubber, elastin is only elastic when fully hydrated wherein water accounts for approximately half of the mass of the elastic material. Thus, a molecular understanding of elastin function necessarily required study of the protein and the hydrate.

NMR spectroscopy is used to study the interaction of the hydrate with this unusually hydrophobic protein using 2Q filtered $^2\text{H}_2\text{O}$ NMR. In this experiment, the degree to which the water is ordered and the amount of water interacting with the hydrophobic surface were determined. Likewise, NMR spectroscopy is used to study the timescales of motions in elastin via ^{13}C NMR relaxation of backbone carbonyl atoms, and the amplitude of these motions was determined by measuring the residual chemical shielding anisotropy of backbone carbonyl atoms. Both timescales and the amplitude of motions were studied in stretched and relaxed elastin. Elastin's biological function is to impart elasticity to a variety of tissues in vertebrates. This is a macroscopic function, and a novel thermomechanical instrument was designed, built and used to fully quantitate the

thermomechanical properties of purified elastin. The thermomechanical experiments as well as the NMR experiments were used to probe elastin at the molecular and macroscopic levels using purified elastin material prepared by a recently reported protocol that retains fiber structure while removing other proteins such as fibrin and collagen from the elastic matrix. The old protocols used to purify elastin rely, in general, on harsh conditions such as hot alkali extractions and autoclaving methods. These protocols result in substantially damaged elastin fibers that are highly fragmented and lack important amino acid sequences present in intact fibers, and so hamper any effective study of elastin recoil.¹¹³ In this work, elastin fibers were purified using a novel more recent protocol that optimizes the conditions to yield pure, intact and smooth fibers.

Using 2Q NMR, ordering of deuterated water ($^2\text{H}_2\text{O}$) at the surface of the most hydrophobic protein known, elastin, was observed and measured quantitatively. Stretching the fiber up to 30% increases the ordered water by one order of magnitude showing for the first time that the hydrophobic effect, i.e., ordering of water at a hydrophobic surface, contributes to the spontaneous, entropy driven recoil in elastin. Moreover, the ordered water magnitude is highly dependent on the solvent conditions. Addition of PEG, sulfate or high concentrations of perchlorate (1.0 m), all of which increase the hydrophobic interactions thereby reducing solvent exposed surface area, result in less ordered solvent at the surface in a concentration dependent behavior. At lower concentrations, perchlorate is chaotropic and interacts weakly with peptide groups. This “salts in” the protein’s peptide bonds and has a much small effect on the ordered water magnitude with stretch, whereas at high concentration (1.0 m) starts to behave like a kosmotrope and decreases the ordered water magnitude.

Structure and dynamics in mature elastin were studied using solid state ^{13}C NMR without magic angle spinning. The residual shielding anisotropy of backbone carbonyls in the highly cross-linked protein was found to be 1 – 3 ppm and thus small compared to the static shielding anisotropy, 116 ppm, for peptide carbonyl atoms. Since the protein is highly crosslinked, rotational diffusion cannot occur, and the residual anisotropy corresponds to an overall order parameter ~ 0.01 for motions of the protein backbone. A backbone order parameter approaching zero was also recently determined in Wittebort laboratory for several minielastins in solution.^{60, 96} Thus, structural ordering of the protein as a result of coacervation and/or crosslinking does not occur. The vanishing order parameter also indicates that elastin is more disordered than other intrinsically disordered proteins. Furthermore, no changes in carbonyl backbone ordering took place with stretch. The backbone of elastin is highly disorder relaxed and stretched.

Novel thermomechanical methods were utilized to determine the essential thermodynamic parameters, ΔG , ΔH , ΔS , ΔC_P and ΔU that are associated with elastin stretch and recoil. Complete reversibility of the stretch and recoil cycle was confirmed. Rather than using calorimetry, complete state functions, $l(F,T)$, were determined from which the thermodynamic parameters were obtained using Maxwell relations. The energetics of recoil in elastin are substantially different from the expected energetics of recoil in an ideal entropic elastomer. Rubber, for example, is approximately ideal indicating different recoil mechanisms in these two elastomers. Unlike most materials, both elastin and rubber shrink when warmed, however, the shrinkage of elastin upon warming is significantly larger than rubber. The compaction of elastin in the presence of PEG, sulfate or high concentrations of perchlorate anticipated by the 2Q experiments is confirmed and linked with the increase

in stiffness observed as a decrease in fiber length, volume and an increase in the spring constants when temperature is increased, or the solute is added. A signature feature of the hydrophobic effect is its temperature dependence. The entropic driving force of the hydrophobic effect is negligible above ~ 45 °C in proteins and these experiments show that the compaction of elastin, i.e., the temperature induced shortening of an elastin fiber, levels to a constant value at this temperature.

An unresolved difference in the recoil mechanism of elastin between P.J. Flory, the preeminent polymer chemist of the 20th century, and the biologists, Torkel Weis-Fogh and John Gosline, has persisted. Flory argued that elastin is like rubber and recoil is driven by an increase in polymer disorder. Weis-Fogh and Gosline argued that the large amount of heat evolved upon elastin stretch leads to a decrease in the internal energy, and this is a characteristic of the hydrophobic effect and indicates that recoil is driven by the hydrophobic effect. Flory pointed out that Gosline incorrectly based his calculation on defining the stretch work at constant temperature and pressure as the change in Helmholtz free energy (ΔA) when, in fact, this was the change in the Gibbs free energy (ΔG) and, consequently, the contribution of volume change to the change in the internal energy change had been neglected. By measuring the increase in volume with stretch, my work confirms that the internal energy still significantly decreases with stretch, in agreement with Gosline's results that support the idea that the hydrophobic effect is the main contributor to elastin recoil. I have also found, in agreement with Flory, that the decrease in internal energy and volume change are significantly decreased when 30% polyethylene glycol (PEG) was added. However, Flory did not consider the effect of glycol on elastin's elasticity. PEG, a crowding agent, increases hydrophobic protein:protein interactions that

causes fiber compaction and increase the stiffness of the fiber. The low stiffness of elastin is a key property in cardiac function. Increases in arterial stiffness, as results from aging, inevitably results in hypertension.

The one order of magnitude increases in $^2\text{H}_2\text{O}$ ordering with stretch coupled with no changes in carbonyl backbone ordering of elastin, and the unique energetics of elastin recoil confirm that the hydrophobic effect is the key player in driving elastin recoil.

APPENDIX A

All studied solutions show a decrease in the slope of $l(F)$ with the increase in temperature with the 30% (w/w) 20 kDa PEG solution shows the minimum slope and almost constant within the studied temperatures indicating an increase in the fiber stiffness with temperature, (Figure A.1).

The length decreases substantially in all solutions as a function of temperature with the 30% 20 kDa PEG solution shows almost constant length within the increased in temperatures at the studied forces, (Figure A.2).

Figure A.1. The length of the hydrated elastin fiber as a function of force at different temperatures in the examined solutions.

Figure A.2. The length of the hydrated elastin fiber as a function of temperature at different forces in the examined solutions.

The energetics of stretch: ΔG_T , ΔH_T , $T\Delta S_T$ and ΔC_p were determined as a function of temperature at constant strain 20%, (Figure A.3 and Figure A.4).

Figure A.3. The heat capacity change of stretching hydrated elastin (0.24 g dry mass) by 20% as a function of temperature in in all studied solutions in comparison to $^1\text{H}_2\text{O}$.

ΔC_p , like in water, decreases linearly in all investigated solutions. Solutions that increase the compaction of elastin fiber; $^2\text{H}_2\text{O}$, sulfate and high concentration perchlorate, decrease the change in ΔC_p until reaches about zero in the high concentration PEG solution. Because of the decrease hydrophobic hydration that accompany these solutions.

Figure A.4. Energetics of stretching hydrated elastin (0.24 g dry mass) by 20% (ΔG_T , ΔH_T and $T\Delta S_T$) as a function of temperature in all studied solutions in comparison to $^1\text{H}_2\text{O}$.

ΔG_T is small (5.3 – 6.8) mJ and decreases slightly with the increase in temperature in all solutions. Both the entropic ($T\Delta S_T$) component and the enthalpic (ΔH_T) component are negative. However, the magnitude of $T\Delta S_T$ is always greater than ΔH_T . In resemblance to the coacervation process discussed before in the $^1\text{H}_2\text{O}$ results, both ΔH_T and $T\Delta S_T$ increase with the increase in temperature, i.e., become less negative. The magnitude of both

ΔH_T and $T\Delta S_T$ decreases as the fiber become more compact in $^2\text{H}_2\text{O}$, sulfate and high concentration perchlorate hydrating solutions.

The volume as a function of both force, (Figure A.5), and temperature, (Figure A.6), were measured when the elastin fiber was hydrated in the studied solutions in the same mannar as in deionized water $^1\text{H}_2\text{O}$. The fiber shape is rectangular prism to a good estimation and so its volume = length \times width \times thickness. The fiber length and width were measured directly from the photos, whereas the thickness was calculated assuming the change in thickness is proportional to that in width using the dry dimensions as reference.

Figure A.5. The volume of the hydrated elastin fiber as a function of force at different temperatures in the studied solutions.

Figure A.6. The volume of the hydrated elastin fiber as a function of temperature at different forces in the examined solutions.

CURRICULUM VITAE

Nour M. Jamhawi

Department of Chemistry | University of Louisville

2320 South Brook St | Louisville, KY, 40292

n.jamhawi@louisville.edu

EDUCATION

Ph.D., Chemistry/ Physical biochemistry Expected April 2021

University of Louisville (UofL), Louisville, Ky, USA.

Dissertation: Investigations of Elastin Recoil on molecular and Macroscopic levels

M.Sc., Chemistry/ Physical biochemistry August 2018

University of Louisville, Louisville (UofL), Ky, USA.

M.Sc., Medicinal Chemistry and Pharmacognosy March 2010

Jordan University of Science and Technology (JUST), Irbid, Jordan.

Thesis: Synthesis and Study of the Hydrolysis kinetics of Monobasic and Dibasic Aminoalkylesters of Ketorolac.

B.Sc., Pharmacy February 2004

Jordan University of Science and Technology (JUST), Irbid, Jordan.

WORK EXPERIENCE

Head of Inpatient Pharmacy, August 2011 – June 2014

King Abdulla University Hospital (KAUH), Irbid, Jordan

Inpatient Pharmacist,

June 2005 – August 2011

King Abdulla University Hospital (KAUH), Irbid, Jordan

RESEARCH SKILLS

Physical Biochemistry laboratory

August 2014– Now

Advisor: Dr. Richard J. Wittebort

UofL, Louisville, Ky, USA

- Running solid state NMR experiments to study the weakly ordered water in elastin using double quantum pulse sequence.
- Running thermomechanical experiments in a homebuilt apparatus analogous in principle to the dynamic mechanical analyzer (DMA) to calculate the free energy and entropy of elastin recoil.
- Data analysis using different software including, NMRpipe, Igor, ImajeJ, MATLAB and others based on need.

Medicinal Chemistry laboratory

August 2006 – March 2010

Advisor: Dr. Amjad M. Qandil

JUST, Irbid, Jordan

- Synthesis of different esters of the non-steroidal drug Ketorolac, purification and characterization of the products using IR and NMR.
 - Studying the stability of the products in different conditions using HPLC techniques.
 - Data analysis using different software including Kaleidagraph.
-

PUBLICATIONS

CONFERENCE PARTICIPATION

- Nour Jamhawi, Tatiana Krivokhizhina and Richard Wittebort, Hydrophobic Effect a Key player in the Elasticity Mechanism of Elastin. Poster presentation at the 2nd Annual NMR Gateway meeting, Ohio state university, coulombs, OH, 4th November 2017.
- Nour Jamhawi and Richard Wittebort, Elastin's Mechanism of Elasticity. Poster presentation at the 10th European Elastin Meeting, Radboud UMC, Nijmegen, Netherlands, 14-16th June 2018.
- Nour Jamhawi and Richard Wittebort, MQ NMR & Thermomechanics, Elastin's Elasticity. Poster presentation at the 32nd Gibbs Society of Biological Thermodynamics, Touch of Nature Conference Center, Cardonale, IL, 6-9th October 2018.

TEACHING EXPERIENCE

Teacher Assistant, August 2014 – present.
University of Louisville (UofL), Louisville, Ky, USA.

- Chemistry 201 (General Chemistry)
- Chemistry 202 (General Chemistry)
- Chemistry 105 (Chemistry for Health Professionals)
- Assisted in mentoring for undergraduate projects (2 undergraduate students)

PROFESSIONAL MEMBERSHIP

Biophysical Society 2018 – Now
