Abstract. Falls are a major health concern in older adults. Falls lead to mortality, immobility and high costs to social and health care services. Early detection and classification of falls is imperative for timely and appropriate medical aid response. Traditional machine learning models have been explored for fall classification. While newly developed deep learning techniques have the ability to potentially extract high level features from raw sensor data providing high accuracy and robustness to variations in sensor position, orientation and diversity of work environments that may skew traditional classification models. However, frequently used deep learning models like Convolutional Neural Networks (CNN) are computationally intensive. To the best of our knowledge, we present the first instance of a Hybrid Multichannel Random Neural Network (HMCRNN) architecture for fall detection and classification. The proposed architecture provides the highest accuracy of 92.23% with dropout regularization, compared to other deep learning implementations. The performance of the proposed technique is approximately comparable to a CNN yet requires only half the computation cost of the CNN based implementation. Furthermore, the proposed HMCRNN architecture provides 34.12% improvement in accuracy on average than a Multilayer Perceptron.

1 Introduction

Falls are a significant cause of death and injury in older adults [1]. 43% of the older adults fall in a span of 5 years and 25% of those living alone in a span of one year [2]. 62% of fall incidents cause injuries resulting in lack of mobility and high mortality rates [2,3]. Falls incur high costs to health care services [1]. Early classification and detection of falls is imperative for life saving health response

services. Fall detection systems are known to reduce death incidents by 80% due to prompt medical aid and hospitalization [4].

Current fall detection systems have a significant focus on traditional machine learning algorithms, such as decision tree, random forest algorithm, k-nearest neighbour, support vector machine and principal component analysis [5–7]. While, deep learning techniques offer significant benefits over traditional machine learning classification models [8]. Deep learning has the ability to potentially extract high level features from raw accelerometer signals [9] within a context-aware setting [10] and can provide a robust and accurate method to variations in work environments, sensor positions and orientations [11–13]. For example, a model developed for a waist band sensor with traditional machine learning techniques may not apply to the arm or wrist band sensor because of the variations in acceleration values across different parts of the body [12]. Similarly, a mobile phone based sensor classification model may not work well with variations in mobile phone position and orientation, since sensors generate different signals in different contexts, to which traditional machine learning models do not provide robust and accurate classification [13,14]. Variability in activities of individuals may also play a role in accuracy of the classification model, e.g. certain physically demanding work and sports environments may result in wrist band accelerometer values not related to falls and may skew the classification model [13]. Deep learning models have been proposed for fall detection, including Convolutional Neural Networks (CNN) [15, 16], combination of CNN and Long Short-Term Memory (LSTM) [17–19] and AutoEncoders (AE) [20]. However, the deep learning techniques are computationally intensive both in terms of time cost and hardware resources [21]. Random Neural Networks (RNN) introduced by Gelenbe [22] have been reported to have exact and simple computational algorithms due to their "product form" [23]. Gelenbe et. al introduced the deep learning architectures for Random Neural Networks in [23] and improved it for a multichannel dataset in [24].

In this paper, we propose a Hybrid Multichannel Random Neural Network architecture for fall detection and classification, but without the dense clusters of the Multichannel Random Neural Network in [24]. In contrast to the use of dense clusters, the proposed design is simple and computationally inexpensive for classification of 1D sensor signals for fall activity. The multichannel hybrid architecture consists of RNN layers and fully connected feed forward Multilayer Perceptron (MLP) with Rectified Linear activation Units (ReLU). The underlying concept of the proposed architecture is for the RNN layers to provide low-dimensional feature space relevant to each accelerometer axis, separately. While, merging at the fully connected Multilayer Perceptron with ReLU activation functions is used to learn a non-linear function over the entire extracted feature space. It has the effect of diminishing non-relevant features from accelerometer axes representing movement dimensions that may be least relevant to activities and falls. The accelerometer data used for our work consists of values for three axes of motion a_x, a_y and a_z for falls and various activities of daily

life. The data from the three accelerometer axes (128 sample window each) are input to each of the channels in the proposed architecture resulting in an input layer of size 3×128 and a fall or no fall decision is obtained from the network. The proposed scheme is discussed in Section 4. The methodology used for training and testing of the proposed architecture is discussed in Section 5. Results are tabulated and discussed in Section 6 where computational time cost and performance accuracy is determined and compared with CNN and MLP implementations. The proposed HMCRNN scheme is also compared with a MCRNN architecture with the same structure and size. The next Section discusses relevant related work.

2 Related Work

There have been a number of recent applications of deep learning techniques for activity and fall detection, including CNN and LSTM [25]. Quero et. al [15] detect falls from vision based sensors and apply 3 different CNN models to raw data. The work also evaluates the effect of kernel size and number of layers on classification accuracy and reports up to 92% accuracy with three CNN layers. Lu et. al [19] developed a 3D CNN for fall detection, which used both spatial and temporal information for video classification. In addition, the output of 3D CNN is used as an input for the LSTM network for higher accuracy. ConvLSTM [17] applies deep learning to raw accelerometer data for fall risk assessment and compares the performance of three deep learning models CNN, LSTM and a combination of CNN with LSTM. However, our work is based on fall event detection rather than fall risk assessment. Chen et. al [16] performed multi-class classification on accelerometer signals for falls and daily activities of life with a CNN consisting of 3 convolutional and 3 pool layers. Ordez et. al [18] utilised a CNN in addition with a recurrent LSTM for multimodal activities dataset including falls from a number of sensors. However, a major draw back of CNNs is that they are computationally intensive [26].

Deep learning with Random Neural Networks (RNN) was introduced by Gelenbe et. al in [23], which has been further explored by Gelenbe et. al in [24, 27–29]. The work in [23, 24, 27] is based on the concept that the structure of human brain is composed of clusters of dense nuclei. They developed a mathematical model based on dense clusters also known as the "Dense" RNN, where each cluster is composed of neurons with statistically identical structure of connections implemented as a spiking recurrent RNN. A training procedure based on unsupervised and supervised learning is also proposed, which converts training into a convex optimization problem that can utilise better or comparable solutions for higher speed convergence than the gradient descent algorithm. In [24,27] a Multichannel architecture of "Dense" RNN is proposed and applied for different applications, such as recognition of 3D objects, classification of chemical gases and activities of daily life. Recent advancements have implemented RNN models to predict the toxicity levels of chemical compounds based on their physical-chemical structure [30]. In [31] a deep learning model based on dense random

neural networks for the detection of denial-of-service network attacks against Internet of Things gateways is presented. Our proposal utilises the original single cell architecture of RNN [30], however with a hybrid Multichannel RNN and MLP network for improved accuracy. Furthermore, we achieve high accuracy comparable to CNN without the dense RNN clusters and the proposed learning algorithms in [24, 27, 31]. Our work utilises RMSProp algorithm introduced by Hinton [32], which adapts resilient propagation (RProp) [33] algorithm for stochastic gradient descent (SGD) [34]. Riedmiller et. al [33] have utilised RProp algorithm for learning in RNN. While, Basterrech et. al [35] combined RProp with the gradient descent algorithm and used the Levenberg-Marquardt optimisation and momentum to achieve high convergence speeds than the gradient descent algorithm.

Our work is based on a Multichannel RNN implementation, however for our fall classification problem which has raw accelerometer window sizes of 128 samples, two RNN hidden layers are utilised for extracting a significant feature space. This paper presents a hybrid implementation of MLP and RNN to achieve accuracies comparable to a CNN implementation. We achieve an added advantage of lower computational time complexity than CNN by not using dense clusters and achieve comparable performance in accuracy to CNN architecture with the RMSProp [32] training algorithm.

3 Random Neural Network

The RNN was introduced in groundbreaking work [22] and the behaviour of large RNN networks was first considered in [36]. In RNN, the state of a neuron is described by its potential, which is a non-negative integer and represents the accumulation of signals. Neurons in RNN layers exchange excitatory and inhibitory spiking signals probabilistically. The excitatory and inhibitory spikes are represented by +1 and -1, respectively. Hence, given a potential $v_n(t)$ of a neuron n at time t, then $v_n(t) \in \mathbb{R}_0^+$, where an inhibitory spike can only cancel a positive signal and has no effect if $v_n(t) = 0$. If $v_n(t) = 0$, neuron n is in an idle state, otherwise if $v_n(t) > 0$ neuron n is in excited state. The neuron in RNN transmits signals randomly, according to an exponential distribution with firing rate $r(n)$ and mean value of times between signals as $1/r(n)$. The signals are transmitted to the next neuron m either as a positive excitatory signal with probability $p^+(n, m)$ or as a negative inhibitory signal with probability $p^-(n, m)$. The signal may also leave the network with probability $d(n)$. The sum of all probabilities must be equal to unity, mathematically:

$$\sum_{m=1}^{N} [p^+(n, m) + p^-(n, m)] + d(n) = 1, \forall n \tag{1}$$

where N represents the total number of neurons. Given the arrival rates of external excitation and inhibition as $\Lambda(n)$ and $\lambda(n)$ respectively, the probability

of firing of neuron n is [37]:

$$q_n = \frac{\lambda^+(n)}{r(n) + \lambda^-(n)} \tag{2}$$

where,

$$\lambda^+(n) = \sum_{m=1}^{N} q_m r(m) p^+(m,n) + \Lambda(n) \tag{3}$$

$$\lambda^-(n) = \sum_{m=1}^{N} q_m r(m) p^-(m,n) + \lambda(n) \tag{4}$$

The output q_n is an activation function of excitatory inputs $\lambda^+(n)$ divided by a sum of inhibitory inputs $\lambda^-(n)$ and a firing rate $r(n)$. $w^+(n,m)$ and $w^-(n,m)$ are non-negative rates for positive and negative signals, respectively, represented as:

$$w^+(n,m) = r(n)p^+(n,m) \geq 0 \tag{5}$$

$$w^-(n,m) = r(n)p^-(n,m) \geq 0 \tag{6}$$

Expression for firing rate $r(n)$ can be derived from Equations 1, 5 and 6, as:

$$r(n) = (1 - d(n))^{-1} \sum_{m=1}^{N} [w^+(n,m) + w^-(n,m)] \tag{7}$$

$$\lambda^+(n) < [r(n) + \lambda^-(n)] \tag{8}$$

where Equation 8 is a sufficient condition for existence of unique solution in RNN. The values $w^+(n,m)$ and $w^-(n,m)$ represented by Equations 5 and 6 are equivalent to weights in a classical neural network (Gelenbe [22]) and can be trained using traditional learning algorithms, such as gradient descent.

3.1 Gradient Descent Algorithm for RNN

A standard gradient descent algorithm for training RNN is presented in this section based on the work in [38] and generalised in [39]; an early application of this algorithm is presented in [40]. Let the training set (X, Y) consist of L input-output pairs, where $X = \{\boldsymbol{x_1}, \ldots, \boldsymbol{x_L}\}$ are successive inputs and $Y = \{\boldsymbol{y_1}, \ldots, \boldsymbol{y_L}\}$ are the respective output vectors, where each vector $\boldsymbol{y_l} = (y_{1l}, \ldots, y_{Nl})$ and each element $y_{nl} \in [0, 1]$. The l^{th} input pattern $\boldsymbol{x_l}$ is represented by the pair $(\boldsymbol{\Lambda_l}, \boldsymbol{\lambda_l})$ of positive and negative flow rates, where $\boldsymbol{\Lambda_l} = [\Lambda_l(1), \ldots, \Lambda_l(N)]$ and

$\boldsymbol{\lambda_l} = [\lambda_l(1), \ldots, \lambda_l(N)]$ are vectors. The x_{nl} data input of the l^{th} training pattern is:

$$\begin{cases} \Lambda_l(n) > 0,\ \lambda_l(n) = 0 & \text{If } x_{nl} > 0 \\ \Lambda_l(n) = 0,\ \lambda_l(n) > 0 & \text{If } x_{nl} \leq 0 \end{cases} \tag{9}$$

The error cost function E_l of l^{th} input-output pair for the gradient descent algorithm is:

$$E_l = \frac{1}{2} \sum_{n=1}^{N} \alpha_n (q_n - y_{nl})^2, \alpha_n \geq 0 \tag{10}$$

where $\alpha_n \in [0, 1]$ decides whether neuron n is an output neuron, q_n is a differentiable function and y_{nl} is the desired value. The function of gradient descent is to minimize the error cost function described in Equation 10. Let two RNs a and b be connected, then weights $w^+(a, b)$ and $w^-(a, b)$ are updated according to the expression:

$$w_t^+(a, b) = w_{t-1}^+(a, b) - \eta \sum_{n=1}^{N} \alpha_n (q_n - y_{nl}) \left[\partial q_n / \partial w^+(a, b)\right]_{t-1} \tag{11}$$

$$w_t^-(a, b) = w_{t-1}^-(a, b) - \eta \sum_{n=1}^{N} \alpha_n (q_n - y_{nl}) \left[\partial q_n / \partial w^-(a, b)\right]_{t-1} \tag{12}$$

where η is the learning rate, $\partial q_n / \partial w^+(a, b)$ and $\partial q_n / \partial w^-(a, b)$ are the activation function derivatives with respect to weights, for which the matrix form is proved by Gelenbe in [38]. The partial derivative terms in Equations 11 and 12 can be computed by defining a vector $\mathbf{q} = (q_1, \ldots, q_N)$ and a matrix $\mathbf{W}$ of size $N \times N$, where $\mathbf{W}$ is:

$$\mathbf{W} = [w^+(n, m) - w^-(n, m) q_m] / [r(m) + \lambda^-(m)],\ n, m = 1, \ldots, N. \tag{13}$$

Also, defining vectors $\boldsymbol{\gamma}^+(a, b)$ and $\boldsymbol{\gamma}^-(a, b)$ with N entries, where each entry n is defined as:

$$\gamma_n^+(a, b) = \begin{cases} \frac{-1}{r(n) + \lambda^-(n)} & \text{if } a = n, b \neq n \\ \frac{1}{r(n) + \lambda^-(n)} & \text{if } a \neq n, b = n \\ 0 & \text{otherwise} \end{cases} \tag{14}$$

$$\gamma_n^-(a, b) = \begin{cases} \frac{-1 + q_n}{r(n) + \lambda^-(n)} & \text{if } a = n, b = n \\ \frac{-1}{r(n) + \lambda^-(n)} & \text{if } a = n, b \neq n \\ \frac{-q_n}{r(n) + \lambda^-(n)} & \text{if } a \neq n, b = n \\ 0 & \text{otherwise} \end{cases} \tag{15}$$

One can use the above notation to derive from Equation 2 the following vector equations:

$$\partial \boldsymbol{q} / \partial w^+(a, b) = \partial \boldsymbol{q} / \partial w^+(a, b)\ \mathbf{W} + \boldsymbol{\gamma}^+(a, b) q_a \tag{16}$$

$$\partial \boldsymbol{q}/\partial w^{-}(a,b) = \partial \boldsymbol{q}/\partial w^{-}(a,b)\ \mathbf{W} + \boldsymbol{\gamma}^{-}(a,b)q_a \tag{17}$$

Equation 16 and 17 can be equivalently written as:

$$\partial \boldsymbol{q}/\partial w^{+}(a,b) = \boldsymbol{\gamma}^{+}(a,b)q_a[\ \mathbf{I} - \mathbf{W}]^{-1} \tag{18}$$

$$\partial \boldsymbol{q}/\partial w^{-}(a,b) = \boldsymbol{\gamma}^{-}(a,b)q_a[\mathbf{I} - \mathbf{W}]^{-1} \tag{19}$$

where $\mathbf{I}$ is a size $N \times N$ identity matrix. The training algorithm stops when a certain defined convergence criteria is met or maximum number of iterations are reached.

4 Proposed Hybrid MCRNN

The proposed architecture for fall classification and detection is a Hybrid Multichannel Random Neural Network (HMCRNN). It consists of Multichannel Random Neural Network layers where each channel is fully connected. The separate channels are merged at a Multilayer Perceptron (MLP) with two hidden layers and an output layer. Each channel in HMCRNN consists of two hidden layers with 128 and 64 random neurons respectively, resulting in 3×128 and 3×64 neurons in the two hidden random neural network layers. The output activation vector $\boldsymbol{q}_{\text{RNN}}$ for an RNN layer implementation in Tensorflow/Keras can be derived from Equation 2, using Equation 3, 4, 5 and 6. The activation function q_n for a neuron n can be given as:

$$q_n = \frac{\sum_{m=1}^{N} q_m w^{+}(m,n)}{r(n) + \sum_{m=1}^{N} q_m w^{+}(m,n)} \tag{20}$$

where $\Lambda(n)$ and $\lambda(n)$ are 0 for neurons with no external input. For an entire RNN layer with $n = 1, \ldots, N$ neurons, weight matrices $\mathbf{W}^{+}$ and $\mathbf{W}^{-}$ can be used to represent weights as:

$$\mathbf{W}^{+} = [w^{+}(m,n)],\ m,n = 1,\ldots,N \tag{21}$$

$$\mathbf{W}^{-} = [w^{-}(m,n)],\ m,n = 1,\ldots,N \tag{22}$$

while the activation function outputs of neuron from the previous layer can be represented as a vector $\mathbf{x}$, where $\mathbf{x}$ is:

$$\mathbf{x} = [q_m],\ m = 1,\ldots,N \tag{23}$$

The final RNN layer can be represented in matrix form as:

$$\boldsymbol{q}_{\text{RNN}} = \frac{\mathbf{W}^{+} \cdot \mathbf{x}}{\boldsymbol{r}_{\text{RNN}} + \mathbf{W}^{-} \cdot \mathbf{x}} \tag{24}$$

Where $\boldsymbol{q}_{\text{RNN}}$ is a vector of activation values of the RNN layer. $\mathbf{W}^{+}, \mathbf{W}^{-} \in \mathbb{R}^{+}$ corresponding to matrix forms of Equations 5 and 6 represent weight parameter

matrices, while $\boldsymbol{r}_{\text{RNN}}$ is a vector of constants. The 3 channels are fully connected to 92 neurons at the first MLP layer followed by 16 neurons in the second MLP layer. The hidden MLP layers uses the ReLU activation function. The output activation vector $\boldsymbol{q}_{\text{MLP}}$ for a ReLU MLP layer with a preceding RNN layer is given as:

$$\boldsymbol{q}_{\text{MLP}} = f_{ReLU}(\mathbf{W}_{MLP} \cdot \boldsymbol{q}_{\text{RNN}} + \boldsymbol{b}) \tag{25}$$

Where $\mathbf{W}_{MLP}$ and $\boldsymbol{b}$ are weight matrix and bias vector of the MLP layer, respectively. $\boldsymbol{q}_{\text{RNN}}$ is the output activation vector for the preceding RNN layer. The final output layer is a single input neuron with a sigmoid activation function for binary classification. The proposed HMCRNN is implemented with and

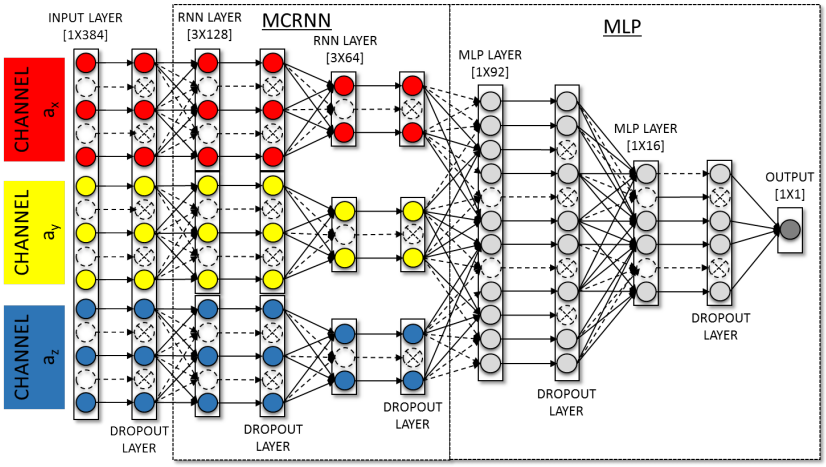

Fig. 1: Hybrid deep MCRNN with dropout layers in Tensorflow/Keras

without dropout regularization [41] in Tensorflow and Keras. Figure 1 shows a typical dropout regularization implementation in Keras, where each layer including the input and hidden layers are followed by a dropout layer. The dropout layer works by randomly dropping or turning off a fraction of units, see Section 5 on methodology for fractions used. The three raw accelerometer signals a_x, a_y and a_z from each of the three axes of motion x, y and z respectively, are normalised between 0 and 1. The normalised signals are used as inputs to the HMCRNN for classification of fall activity. Each RNN channel layer processes the three accelerometer signals separately. The output of these layers are then processed with the merged and fully connected MLP layers.

The proposed hybrid HMCRNN architecture was trained and tested for fall detection with the RMSProp optimization of the gradient decent algorithm. The RMSProp optimization exploits the moving average of the square of gradients to normalize the gradient. It balances step size and avoids the vanishing or

exploding of the gradient with the propagation of energy. It is equivalent to the first update vector of the Adadelta [42], and can be expressed as:

$$\mathbb{E}[grad^2]_t = \gamma \mathbb{E}[grad^2]_{t-1} + (1-\gamma) grad_t^2 \tag{26}$$

$$\phi_{t+1} = \phi_t - \frac{\eta}{\sqrt{\mathbb{E}[grad^2]_t + \varepsilon}} \tag{27}$$

Where $\mathbb{E}[grad^2]_t$ and $grad_t^2$ are the running average and gradient at time t respectively, while $\mathbb{E}[grad^2]_{t-1}$ is the running average at time $t-1$. γ is the moving average constant. The $\phi_{t+1} \in \mathbb{R}^d$ represents the model's parameter at time $t+1$, η is the learning rate and the second term of Equation 27 represents the parameter update vector. The training and testing methodology for all the networks is discussed in the next section.

5 Methodology

Fall Dataset: The data used for our work is a publicly available accelerometer dataset by Kwolek et. al [43] for falls and various Activities of Daily Life (ADL) including walking up/down stairs, sitting on a chair, lying down, picking up objects, standing up and sitting down. The fall and ADL data is acquired with an Inertial Management Unit (IMU). The IMU device used is a motion sensing platform with an overall sampling rate of 256 Hz. The data is transmitted in real-time, wirelessly through Bluetooth for processing. The IMU device consists of a 16-bit tri-axis gyroscope and a 12-bit tri-axis accelerometer. The accelerometer sensor of the device was used for analysis and classification of falls in our work. The accelerometer sensor measures acceleration in units of G-force (g) for three axes of motion a_x, a_y and a_z with obtained values ranging from -8 to 8g. The sensor was worn near the pelvis by five volunteers who performed three kinds of falls, namely forward, lateral and backward apart from ADLs.

The received accelerometer values are normalised between 0 and 1 to satisfy the RNN constraints, as outlined by Gelenbe in [38]. The sensor values are divided into 128 sample windows for classification of falls and ADLs. The duration of activities vary and 128 samples capture basic movements, such as falling, sitting down, and lying down within the dataset used for fall classification. The activities that span longer or shorter durations are divided into integer multiples of 128 sample windows with zero padding. Tri-axes accelerometer values for 128 sample segments are illustrated in Figure 2 for fall activity. Samples from each of the activities were used for training and validation of the proposed architecture.

Experimental Specifications: The training and testing of fall activity dataset for classification was performed on a hardware platform with Intel core i5 quad core CPU and 8 GB of RAM with Ubuntu 16.04 Xenial operating system. The proposed system was designed, implemented and tested in Tensorflow and Keras. Four deep multilayer neural networks, namely MLP, CNN, Multichannel Random Neural (MCRNN) and the proposed "Hybrid" architecture Multichannel

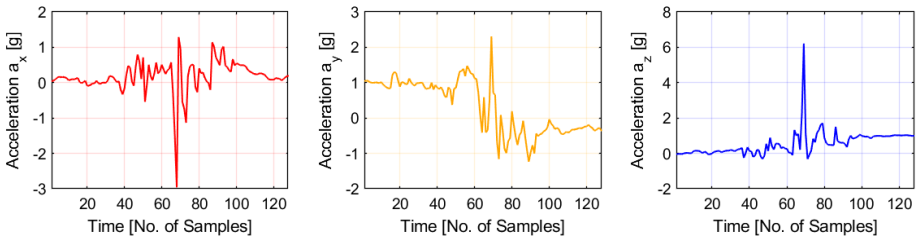

Fig. 2: Tri-axes accelerometer signals a_x, a_y and a_z for fall activity

Random Neural Network (HMCRNN) were implemented. The MLP, CNN and HMCRNN were implemented with sigmoid output activation functions for binary classification between falls and no fall activities. Our CNN output is also based on the sigmoid activation function, since it is well known that the multi-class softmax activation function reduces to a sigmoid for two class problems [44]. The structures were chosen to give best results on the fall activity dataset [43]. The structures of deep neural networks with input, hidden and output layers are summarized in Table 1 and are discussed below.

Table 1: Deep neural network structures

Deep Network	Input Layer	Hidden Layers	Output Layer
Deep MLP	384	384-192-92-16	1 (Sigmoid)
CNN	3x8x16	Conv-Conv-MaxPool-FC	1 (Sigmoid)
MCRNN	3x128	3x128-3x64-1x92-1x16	1 (Sigmoid)
HMCRNN	3x128	3x128-3x64-1x92-1x16	1 (Sigmoid)

The deep MLP has fully connected dense layers with an input layer of size 384, four hidden layers of size 384-192-92-16 and a single node output layer with sigmoid activation functions, resulting in a total of 6 layer MLP. The CNN structure in Gelenbe et. al [24] is used for comparison with the HMCRNN. It consists of two convolution layers, one pooling and a fully connected layer, apart form input and output layers. The three channel input (3×128) from each of the accelerometer's axes a_x, a_y, a_z is reshaped into ($3 \times 8 \times 16$) before input to the convolutional layer. While, Gelenbe et. al [24] reshape due to their large input vector size of 3000 samples. We observe that reshaping provides better performance for our three axis accelerometer fall dataset. The convolutional layers use 30 kernels with [2×2] size. While, pooling layer is a max-pool layer and is flattened before connecting to the Fully Connected (FC) layer. The MCRNN structure consists of 3-channel layers followed by merged layers. It consists of 3×128 input layer followed by 2 multichannel hidden layers 3×128-3×64 and 2 FC dense MLP layers 1×92-1×16, followed by a single node output layer.

The proposed HMCRNN for fall detection and classification consists of a single 3×128 input layer followed by 2 multichannel RNN hidden layers 3×128-3×64 and 2 FC MLP dense layers 1×92-1×16, followed by a single node output layer, resulting in a total of 6 layers. All the networks were trained and tested on the fall dataset with the stratified k-fold procedure.

Stratified K-Fold Procedure: The fall dataset was split into 4 folds, with 3 folds for training and 1 fold for testing, resulting in a split of 75%-25% between training and test data. All the networks were trained with the RMSProp optimizer [32] for all four permutations of stratifed k-fold. The learning parameters for RMSProp algorithm are given in Table 2.

Table 2: Learning algorithm parameters

Learning Parameters	
Learning Algorithm	RMSProp
Learning Rate, η	0.001
Moving Average Parameter, γ	0.9
Epochs, ϵ	40

The final results were obtained from mean and standard deviation of the stratified k-fold permutations.

Dropout Regularization: The training and testing procedures were repeated with regularization to reduce over fitting of the training model and improve testing accuracy. The dropout technique introduced by Srivastava et. al [41] was used for regularization. Dropout procedure was applied to both input layer and the hidden layers. The dropout value of 15% was initially used and increased up to 30% to evaluate higher performance for testing. The best testing performance was used as the final value with the dropout method.

6 Experimental Results and Discussion

The test results give the highest accuracy of 91.5% for 6-layer HMCRNN architecture, as illustrated by Network III in Table 3. However, if the number of layers are increased to 7 by either adding RNN or MLP layer, the accuracy decreases to approximately 82%. Accuracy of the network further decreases with increasing the number of layers to 8. Similarly, a decrease in number of layers to 5 results in lower accuracy of 85%. The proposed network is optimal with the highest accuracy of 91.5%, while an increase or decrease in layers results in lower accuracy.

The test results of the proposed 6-layer HMCRNN, MLP, MCRNN and CNN are presented as percentages of confusion matrix values in Table 4 for comparison. The percentage values for True Positive (TP), True Negative (TN), False

Table 3: Impact of HMCRNN layers on accuracy

Network		I	II	III	IV	V	VI
Total Layers		5	5	6	7	7	8
Hidden Layers	RNN Layers	1	2	2	2	3	3
	MLP Layers	2	1	2	3	2	3
Total Neurons		877	977	1069	1133	1165	1230
Accuracy		85.7	85.78	91.5	82.84	82.92	75.82

Positive (FP) and False Negative (FN) classifications are averaged over all 4-folds. It is clear from Table 4 that HMCRNN gives the highest true positive values for falls at 38.56% as compared to other classifiers, as well as the lowest false classifications overall of 8.5%.

Table 4: Positive and negative classifications

Classifier	TP (%)	TN (%)	FP (%)	FN (%)
MLP	2.10	55.09	0	42.81
MCRNN	18.63	48.61	8.58	2.42
CNN	37.17	52.86	2.94	7.03
HMCRNN	38.56	52.94	4.25	4.25

The FP values for all the classifiers are further analysed in Table 5 and provide insight into the activities misclassified or confused by classifiers as falls. Table 5 shows that the classifiers MCRNN, CNN and HMCRNN misclassify "lying down" as falls. CNN and HMCRNN produce the highest false positive values for falls due to the "lying down" activity. Furthermore, amongst all the activities, only lying down activity is misclassified as falls by CNN. Also, MCRNN misclassifies both lying and sitting activities as falls, while the false positives for MLP are zero in Table 5. This is due to the poor classification response of MLP with a lower positive classification value of 2.1 % (TP) and 0% (FP), as illustrated in Table 4.

The final training and testing accuracies of fall detection with and without the dropout regularization are illustrated in Table 6. The MLP architecture with 6 layers (Table 1) provides 57.2% testing accuracy. No improvements in testing accuracy of MLP is observed with dropout even though dropout results in a slight decrease in training accuracy. MCRNN performs better than MLP at 69.85% with dropout. However, the performance accuracy of MCRNN is considerably low as compared to the proposed HMCRNN and CNN implementations. The CNN architecture provides an improvement of 20% over a traditional MCRNN with an accuracy of 91.22%. While, the proposed hybrid HMCRNN has the highest testing accuracy for fall detection at 92.23% with dropout, which is comparable to the CNN performance of 91.22%.

Table 5: False Positives: Activities misclassified as falls

Activities	MLP (%)	MCRNN (%)	CNN (%)	HMCRNN (%)
Sitting down	0	1.47	0	0
Sitting on chair	0	2.94	0	0
Sitting down/Standing up	0	1.39	0	0
Lying down	0	1.39	2.94	2.86
Lying on bed	0	1.39	0	0
Picking up objects	0	0	0	1.39
Walking	0	0	0	0
Total FP	0	8.58	2.94	4.25

Table 6: Accuracies of deep neural networks on fall dataset

Deep Network	Training Accuracy (%)	Testing Accuracy (%)
MLP	58.59 (+/-2.85)	57.19 (+/-1.63)
MLP-Dropout	57.62 (+/-0.67)	57.19 (+/-1.63)
CNN	96.66 (+/-0.84)	90.03 (+/-4.59)
CNN-Dropout	96.19 (+/-0.04)	91.22 (+/-6.25)
MCRNN	70.04 (+/-5.39)	67.24 (+/-2.29)
MCRNN-Dropout	69.23 (+/-2.36)	69.85 (+/-1.35)
HMCRNN	95.89 (+/-2.31)	91.5 (+/-2.61)
HMCRNN-Dropout	95.12 (+/-2.25)	92.23 (+/-1.82)

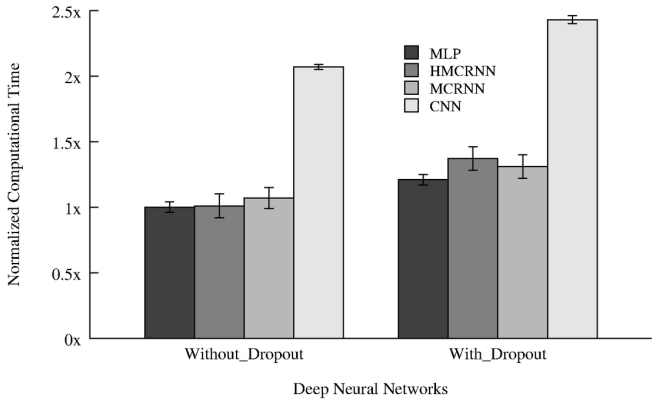

Fig. 3: Normalized time cost w.r.t. "MLP without dropout"

The CNN architecture is computationally intensive and has a high computational time cost of $\sim 2\times$ compared to the proposed HMCRNN architecture. The HMCRNN computational time cost is 51% less without dropout regularization and 43% less with dropout than the CNN architecture. The total computational time cost of each deep learning architecture is illustrated in Figure 3, normalized to an MLP implementation without dropout regularization. The total time costs of the three architectures MLP, MCRNN and HMCRNN for falls and activities dataset, are comparable with a maximum of 7% difference without dropout and 13% with dropout regularization.

The proposed work demonstrates comparable accuracy to CNN architecture and lower computational time with a hybrid network for fall detection and classification. While, activity recognition utilising RNN models have achieved high-accuracy classification with dense RNN clusters and enhanced learning algorithms [24, 27], the proposed hybrid approach is orthogonal to the dense RNN structure and the efficient learning algorithms in [24, 27, 31]. The proposed work can therefore benefit from the opportunities of enhanced learning algorithms and dense RNN clusters to further improve accuracy.

7 Conclusion and Future Work

Falls are a health hazard in older adults and lead to high mortality rates. Deep learning techniques have been explored for fall detection to achieve high accuracy. However, frequently used deep learning models like CNN achieve high accuracy at the cost of high computational time. In contrast to CNN based techniques, a novel computationally efficient RNN based hybrid architecture is presented. The proposed Hybrid Multichannel Random Neural Network (HMCRNN) architecture for fall classification and detection exploits raw accelerometer signals to provide high accuracy of classification. HMCRNN performs better than the Multichannel Random Neural Network (MCRNN) with an improvement of 20%. HMCRNN implementation offers a high accuracy of 92.23% for fall detection, comparable to the CNN performance of 91.22% at a much lower computational cost. The CNN architecture takes up to $\sim 2\times$ the computational time of the HMCRNN for the fall dataset. The proposed scheme offers 51% less total time cost without dropout regularization and 43% less with dropout regularization for fall classification. In comparison to an MLP implementation, our scheme incurs 10% higher computational time cost on average with a 34.12% improvement in accuracy. Future work intends to use multiple datasets including smart phone accelerometer data for classification of falls. Additionally, this will also extend the present work to include a larger number of activities such as running, slow and fast walking etc.
