Worldwide there is an increasing demand for clean water and sanitation systems and any different solutions are under evaluation, including advanced oxidation processes such as photocatalysis. This work describes the scalable synthesis process of an electrospun composite membrane made of Nylon and embedded  $\alpha/\beta$ - $\text{Bi}_2\text{O}_3$  nanoparticles that can be activated by visible light instead of UV light typically used with other nanomaterials (e.g.  $\text{TiO}_2$ ). As a proof of concept, the efficacy of the  $\alpha/\beta$ - $\text{Bi}_2\text{O}_3$  electrospun composite membrane in the visible light inactivation of pollutants and pathogens was demonstrated in a Continuous-flow Photocatalytic Membrane Reactor, highlighting the great potential of this advanced photocatalytic process for clean water and sanitation.

## **Bi<sub>2</sub>O<sub>3</sub>/Nylon multilayered nanocomposite membrane for the photocatalytic inactivation of waterborne pathogens and degradation of mixed organic pollutants**

### **Abstract**

A powder semiconductor  $\alpha/\beta$ - Bi<sub>2</sub>O<sub>3</sub> was synthesized via solid state thermal annealing and further composited with a multilayered Nylon fibrous membrane via electrospaying. The successful integration of nano-sized  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> in the Nylon membrane was confirmed by XRD, FESEM images, UV-Vis, FT-IR and Raman analyses. The nanocomposite membrane displayed a visible-responsive catalytic ability with an energy bandgap of 2.78 eV estimated from the data of DRS. The activity of the composite membrane was examined in a continuous mode reactor for the degradation of separate and mixed solutions of anionic (Indigo Carmine) and cationic (Rhodamine B) organic pollutants. Moreover, the composite membrane exhibited antibacterial properties towards *E. coli*, a waterborne pathogen, as revealed by the obtained growth inhibition during Kirby-Bauer and in liquid culture tests. The inactivation of *E. coli* was confirmed by live/dead cell staining using fluorescence imaging. Finally, a mixed solution of organic dyes, as well as the recycle of the membrane and various concentrations of xenobiotics, showed the stability and potential of the  $\alpha/\beta$ - Bi<sub>2</sub>O<sub>3</sub> composite membrane for the removal of organic pollutants and inactivation of the waterborne pathogen.

**Keywords:** Bi<sub>2</sub>O<sub>3</sub>, Nanocomposite membrane, Wastewater, Photocatalysis, Antimicrobial, *E. coli*.

## 1. Introduction

Nowadays, there is an increasing demand for clean water and sanitation. One of the emerging technologies to get sustainable clean water can be based on advanced oxidation processes (AOP). Among them, the heterogeneous photocatalysis is an AOP process in which semiconductor materials are illuminated with solar/UV light to originate redox reactions and enable the treatment of organic, inorganic species, and microbes [1, 2]. However, its suitability in real applications is still challenged by various essential aspects. One of these is the cost-effective recovery of dispersed particles, their filtration and recycling [3-5]. Indeed, for high photoactivity, nano-scale particles are preferred because of prominent surface area, better dispersion in the bulk reactors, and optimum activation from the irradiation source [6, 7]. Though, these particles are hard to recover and reuse; moreover, they increase the operational cost of the water treatment [3, 4]. Alternatively, various studies have suggested diverse materials as fixed supports for the active particles, with a focus on carbon, silica, and mineral-based porous supports that could allow a good contact between the immobilized semiconductors and the targeted contaminant for continuous treatment. Examples of such supports are silica-based [8-10], activated carbon [11, 12], synthetic clay laponite [13], glass, steel mesh [14-16], and recently some polymers such as polyimide [17]. However, with such immobilized fixed supports, the photocatalytic response is reportedly lower than using bulk materials, because of low dispersion, reduced transparency, limited mass transfer, and weak interaction of the immobilized semiconductor with the targeted contaminants [3]. Thus, these limitations slower the advancement of non-slurry application alternatives, as the immobilization supports should satisfy requirements of chemical inertness, transparency to the irradiation source, and adequate channels and permeations to capture the targeted contaminants in the bulk reactors [18, 19].

1  
2  
3 Merging membrane and photocatalytic technologies has been considered recently. In this case the  
4 semiconductor materials could be incorporated/embedded within the porous membrane to  
5 maximize the degradation efficiency. Such an approach turned into a great achievement in treating  
6 wastewater. The porous network of tiny channels in the membrane could be used to embed the  
7 semiconductor materials, and further to capture and adsorb the contaminants, so as their removal  
8 could be maximized. Recent results have shown that adding semiconductor particles to the  
9 membrane has improved water flux [20], refined permeability and selectivity [21], boosted  
10 antifouling properties [22] and raised adsorption sites, which ultimately enhanced the adsorption  
11 of the membrane [23]. Different kinds of materials were used to prepare photocatalytic membranes  
12 such as ceramics, zeolites, but mostly polymers [24]. However, irradiation and generation of  
13 oxidizing species in the reaction environment cause abrasion and leaching of the semiconductor  
14 from the membrane itself [24]. Therefore, for its chemical, thermal, and mechanical stability,  
15 Nylon polymer could be a promising option for semiconductor embedding and composite usage  
16 as a photocatalytic membrane. Indeed, electrospun Nylon-6 nanofibers have a large surface area  
17 and active sites that could improve the adsorption of pollutants for the subsequent degradation  
18 [25]. Moreover, the electrospun nanofibers have demonstrated improved properties in dye removal  
19 [26], advanced filtration [27], and antibacterial properties [28].

42 Besides the degradation and removal of organic and inorganic pollutants, various studies have  
43 explored the potential of semiconductor-polymeric composite membranes for the inactivation and  
44 removal of pathogens through the same principle i.e. the attack of the cell membrane through  
45 reduction-oxidation reactions and consequently the reduction in their growth [28, 29]. Some of the  
46 reported semiconductor composite membranes include embedded oxides of silver, titanium,  
47 cerium, zirconium, and iron, and have shown antimicrobial response against common pathogens

1  
2  
3 i.e. *Escherichia coli*, *Staphylococcus aureus*, *Enterococcus sp.*, *Pseudomonas aeruginosa*,  
4  
5 *Klebsiella pneumonia* [30-33]. Amongst various semiconductors, the bismuth-based materials,  
6  
7 such as BiVO<sub>4</sub> [34], Bi<sub>2</sub>O<sub>3</sub> [35, 36], BiOX(Cl, I, Br) [37], and bismuth-based composites [38, 39],  
8  
9 have been proven efficient in water treatment due to their ability to produce Reactive Oxygen  
10  
11 Species (ROS). Among them, Bi<sub>2</sub>O<sub>3</sub> has emerged as the most effective visible light-responsive  
12  
13 material with promising optical, electrical, thermal, and photocatalytic properties [40]. Moreover,  
14  
15 it also has a tunable bandgap between 2.1 to 2.8 eV compared to 3.2 eV of TiO<sub>2</sub>. The solar light  
16  
17 viable bandgap is a result of the Bi<sub>2</sub>O<sub>3</sub> hybrid valence band arising from contributions of Bi 6s and  
18  
19 O 2p orbitals; in contrast, the TiO<sub>2</sub> valence band only has O 2p orbitals contributions [41].

20  
21 To the best of our knowledge, Bi<sub>2</sub>O<sub>3</sub>-polymeric nanocomposite membranes have rarely been  
22  
23 investigated against the removal of both organic pollutants and waterborne pathogens. Therefore,  
24  
25 this study was conducted to exploit and investigate the potential of Bi<sub>2</sub>O<sub>3</sub> integration in a Nylon-6  
26  
27 membrane. Once synthesized, the membranes were characterized by XRD, FESEM, UV-Vis, FT-  
28  
29 IR and Raman analyses, to check the proper integration of the  $\alpha/\beta$ - Bi<sub>2</sub>O<sub>3</sub> nanomaterials in the  
30  
31 Nylon membrane. Afterward, the degradation efficiency of the composite membranes against  
32  
33 single and mixed solutions of anionic (Indigo Carmine) and cationic (Rhodamine-B) organic dye  
34  
35 pollutants and against a pathogenic strain of *E. coli*, was evaluated by using a Continuous-flow  
36  
37 Photocatalytic Membrane Reactor (CPMR), paving the way for a new approach in getting water  
38  
39 purification.

## 2. Experimental section

### 2.1 Materials and chemicals

Nylon-6 pellets (density of 1.084 g/mL), formic acid, ethanol, polyethylene glycol (PEG), Triton-  
X, bismuth (III) nitrate pentahydrate (Bi(NO<sub>3</sub>)<sub>3</sub>·5H<sub>2</sub>O) and Indigo Carmine (IC), Rhodamine B

1  
2  
3 (RhB), were purchased from Sigma Aldrich, Italy. Sodium chloride (NaCl) was purchased from  
4 Daejung Co. Ltd., Korea. The bacterial culture media (agars and broths) were purchased from  
5 Oxoid, England. For the live/dead cells staining, a LIVE/DEAD® BacLight™ Bacterial Viability  
6 Kit was purchased from ThermoFisher Scientific, USA; this kit included two staining dyes, SYTO-  
7 9 and Propidium Iodide (PI), at 20 mM concentration each. All the materials and chemicals were  
8 used as received.

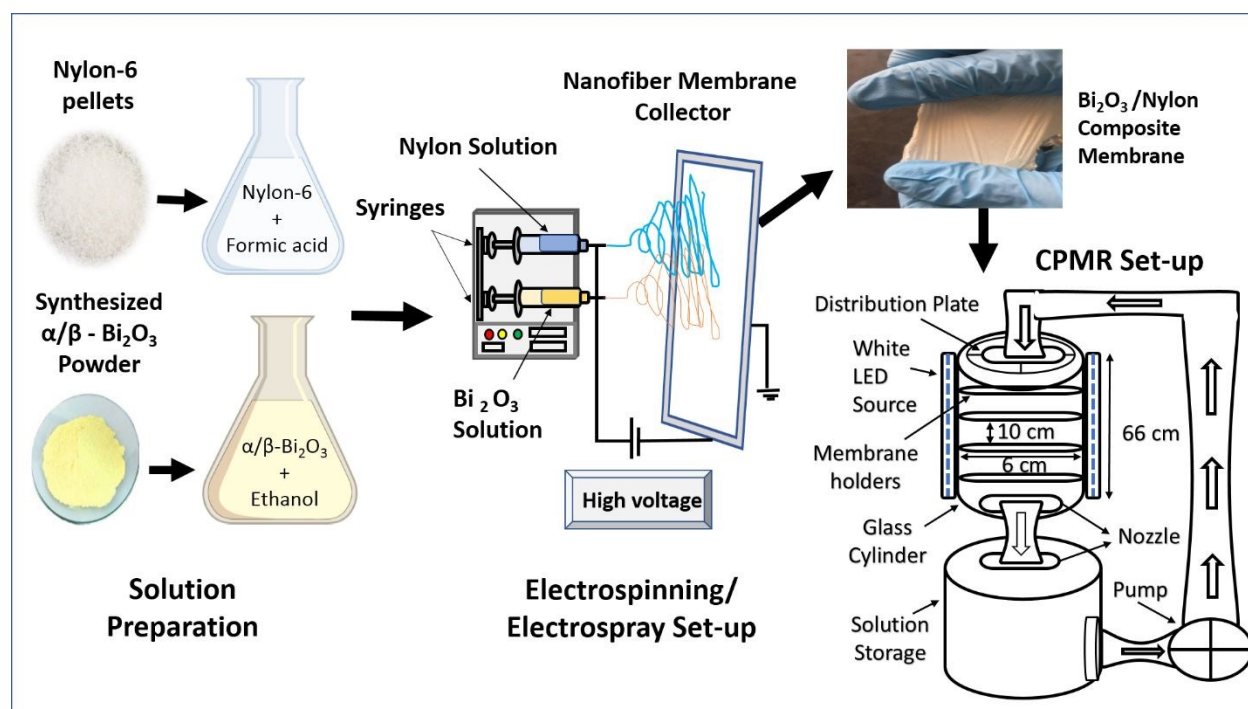

## 2.2 Synthesis of $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub>

9  
10 The  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> powder was synthesized from Bi(NO<sub>3</sub>)<sub>3</sub>:5H<sub>2</sub>O solid thermal annealing route. The  
11 synthesis details are published elsewhere [42]. In brief, the measured quantity of Bi(NO<sub>3</sub>)<sub>3</sub>:5H<sub>2</sub>O  
12 was placed in a ceramic crucible and directly heated inside the muffle furnace at an initial  
13 temperature of 150 °C for 30 min. Afterward, the temperature was raised to 250 °C and kept  
14 constant for 2 h, and finally, the temperature was increased to 550 °C for 45 minutes to obtain the  
15  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> composite. This composite (in bulk form) was already reported as a visible-responsive  
16 semiconductor for the degradation of organic compounds [42].

## 2.3 Preparation of Bi<sub>2</sub>O<sub>3</sub>/Nylon composite membrane

17  
18 The obtained  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> powder 10wt.% was dissolved in ethanol. Measured drops of PEG and  
19 Triton-X were gradually added in the ethanol mixture at continuous mixing i.e. to ensure well-  
20 segregated particle suspension and homogenization. The obtained solution was stirred for 18 hours  
21 and then sonicated for 30 minutes to get a homogeneous yellow colored solution. The Nylon-6  
22 solution was made by dissolving 22 wt.% Nylon pellets in formic acid, by stirring it continuously  
23 at 100 rpm for 6 hours to produce a neat and transparent Nylon-6 solution. Then, the Nylon-6  
24 solution was electrospun to produce a multilayered nylon fibrous membrane. The multilayers  
25 referred to the electrospun and stacked fibrous layers of Nylon that overlaid one after one. The  
26  
27  
28  
29  
30

applied voltage was altered between 18 and 24 kV to obtain thick and ultra-thin spiderweb type multilayered nano-fibers [43]. The injection flow rate was set to 0.95 mL/h at a 12 cm tip to collector distance. Electrospinning was followed by electro spray of  $\alpha/\beta$ - $\text{Bi}_2\text{O}_3$  solution on the surface of the obtained Nylon electrospun multilayers i.e. for successful integration of  $\alpha/\beta$ - $\text{Bi}_2\text{O}_3$ . Fig. 1 depicts the scheme of the electrospinning process for the preparation of bare and  $\alpha/\beta$ - $\text{Bi}_2\text{O}_3$  composite membranes and the digital image of obtained membrane. The obtained membranes were referred to as bare-Nylon and  $\text{Bi}_2\text{O}_3/\text{Nylon}$  composite. Visually, the surface of the obtained  $\text{Bi}_2\text{O}_3/\text{Nylon}$  membrane showed a homogeneous pale-yellow non-dusty appearance as an indication of the embedded  $\text{Bi}_2\text{O}_3$  particles.

**Figure 1** Schematic layout of membrane preparation and photocatalytic tests.

## 2.4 Characterization of the bare and composite membrane

To observe and analyze the microstructure and morphology of the obtained bare and composite membranes, an in-lens detector of a Zeiss Supra 40 Field Emission Scanning Electron Microscope

(FESEM) was used to acquire secondary electron contrast images with 5 keV electrons (Zeiss SMT, Oberkochen, Germany). An Energy-Dispersive X-Ray Spectroscopy (EDX) analysis was performed during FESEM imaging. To this aim all the peaks were used for the elemental analysis (3 iterations), that was carried out with 15 keV electrons. To analyze the size and phase composition of the obtained membranes, Panalytical X'Pert MRD Pro Cu  $K\alpha$  X-ray source in Bragg/Brentano configuration was used. The sample was scanned at a  $2\theta$  range of 20–60°. A Varian Cary 500 spectrophotometer equipped with an integration sphere was used to record the diffuse reflectance spectroscopy (DRS) and transmittance spectra of the bare and composite membranes. Tauc plots of the Kubelka Munk function were used to calculate the energy bandgap ( $E_g$ ) value. The FT-IR analysis was performed in Attenuated Total Reflection (ATR) mode to identify the chemical changes in the membrane after the incorporation of  $\alpha/\beta$ - $\text{Bi}_2\text{O}_3$ . The spectra were collected with a  $4\text{ cm}^{-1}$  resolution by accumulating 64 scans each spectrum on a Nicolet 5700 FTIR Spectrometer (Thermo Fisher) equipped with a diamond crystal and a DTGS detector (at room temperature) in the  $400\text{--}4000\text{ cm}^{-1}$  range. Raman spectra were acquired with a 785 nm laser source using an InVia Qontor Raman microscope (Renishaw plc, Wotton-underEdge, UK) equipped with a 20x objective, in backscattering configuration. The output laser power was attenuated to 25 mW and the acquisition time was 50 s.

## 2.5 Photocatalytic evaluation

### 2.5.1 Continuous-flow photocatalytic membrane reactor (CPMR)

Fig. 1 shows the schematic diagram of the in-house fabricated CPMR for the evaluation of the efficacy of the membranes on selected dyes and bacteria. The CPMR includes a cylindrical tube made of borosilicate glass with four membrane holders (each  $6 \times 6\text{ cm}$ ) for placing the prepared membrane in a straight position at a distance of 10 cm from each other. A white LED light source

1  
2  
3 for the activation of integrated  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub>, with a measured irradiance of around 70 W/m<sup>2</sup> (at the  
4 cylinder's center of all positioned membranes) and an emission spectrum between 400-700 nm,  
5  
6 was attached outside of the cylinder. Beneath the cylindrical tube, the storage tank was connected  
7  
8 via a peristaltic pump i.e. for the circulation of stock solution (2 L) over the membrane (i.e. inside  
9  
10 the cylindrical tube) at a constant flow of 25 mL/min. For dark conditions, the LED light remained  
11  
12 switched-off; besides, aluminum foil was wrapped on the cylindrical tube.  
13  
14

### 15 16 17 2.5.2 Photocatalytic discoloration tests

18  
19 Anionic IC and cationic RhB dyes were selected as model pollutants because of their common use  
20  
21 in photocatalytic evaluation [42]. For the preliminary experiments, both dyes were tested  
22  
23 separately at a concentration of 5 ppm. Initially, to achieve adsorption/desorption equilibrium, the  
24  
25 LED lights remained switched-off for the first 30 minutes. Afterward, the solution was irradiated  
26  
27 to analyze the photocatalytic removal and assess the degradation kinetics. 3 mL of the samples  
28  
29 were collected in a predefined time sequence of photocatalytic treatment, centrifuged for 5 minutes  
30  
31 for the analysis, and afterward returned to the stock solution to avoid any interference to the system  
32  
33 kinetics. The centrifuged samples were analyzed using a double beam UV-Vis spectrophotometer  
34  
35 (Perkin Elmer-LAMBDA 365) for recording the time-dependent intensity reduction and changes  
36  
37 in the absorbance spectra of the model pollutants. For the mineralization degree of the treated dye  
38  
39 solutions, total organic carbon (TOC) analysis was carried using the TOC-L SHIMADZU TOC  
40  
41 analyzer. For TOC analysis, the control and the treated samples of both dyes were collected and  
42  
43 analyzed using the protocol reported in the literature [44]. The stability of the membrane was  
44  
45 evaluated by testing the same membrane up to three cycles using the IC solutions at a fixed  
46  
47 concentration of 5 ppm. Before reuse, the recovered membranes were thoroughly rinsed with  
48  
49 distilled water.  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 For the composite membrane performance against the mixed regime of dyes, i.e. of different  
4 chemical structures and ionic behaviors, separately prepared solutions of IC and RhB (at a molar  
5 concentration of  $1 \times 10^{-6}$  M) were mixed at even proportion. The prepared mixed stock of 2 L was  
6 evaluated on the CPMR, under similar operating conditions, briefed earlier.  
7  
8  
9

### 10 11 12 2.5.3 Photocatalytic bacterial inhibition/inactivation 13

14  
15 Initially, the inhibition of *E. coli* ATCC (8739) was performed on agar plates, using the bare and  
16 composite membrane cut into  $10 \times 10$  mm<sup>2</sup> pieces. In brief, the inoculum (100  $\mu$ L) was taken from  
17 the overnight incubated *E. coli* culture at the concentration of  $1 \times 10^6$  CFU/mL and was spread on  
18 LB agar plates. Then, the bare Nylon/composite membrane was placed in the center of the plate  
19 and incubated for 24 h at  $37 \pm 1$  °C; the test was performed in the dark or in the presence of white  
20 LED lamp (100 W/m<sup>2</sup>). After 24 hours, the inhibition zone was observed in the culture plates [45].  
21  
22 The experiments were conducted in duplicate, and the zone of inhibition was calculated as  
23 suggested in the previously reported studies [46, 47]. Further, for the evaluation of liquid bacterial  
24 suspension, *E. coli* was inoculated in a 50 mL tube of LB broth (Oxoid, England) after overnight  
25 incubation at 37 °C and shaking at 120 rpm. Afterward, the culture broth was centrifuged at 5000  
26 rpm for 10 minutes, and the settled pellets were washed several times with a sterilized normal  
27 saline solution (0.85% of NaCl). Then, the bacterial biomass was diluted in 2 L of saline solution  
28 to reach a bacterial concentration around  $1 \times 10^6$  CFU/mL, by measuring an optical density (OD)  
29 of 0.01 at 600 nm. The prepared bacterial stock was tested in the CPMR for photocatalytic  
30 inactivation, at 25 mL/min. Initially, the dark conditions were maintained for 30 minutes, then the  
31 cylindrical tube was irradiated. A 100  $\mu$ L sample was collected in a predefined time sequence of  
32 photocatalytic treatment. The collected samples were serially diluted and plated on LB agar plates,  
33 incubated for 24 hours at 37 °C, and the numbers of bacterial colonies were counted.

60

To observe if the photocatalytic action was able to damage the *E. coli* cells, live/dead bacterial cell fluorescence staining was performed. For this, a 1 mL sample was collected at different time intervals, centrifuged at 10,000 rpm for 15 minutes, and then the bacterial biomass was washed with sterilized saline solution. Finally, the obtained bacterial biomass was resuspended in 1 mL of sterilized saline solution. Afterward, by following the protocol provided in the received live/dead fluorescence staining kit, a 1:1 mixed dye stock solution of SYTO-9 (3.34 mM, excitation 483 nm, emission 503 nm) and Propidium iodide (PI; 20 mM, excitation 535 nm, emission 617 nm) was prepared. For the fluorescence microscope imaging, 5  $\mu$ L of the mixed dye stock solution was added in the bacterial suspension and incubated in the dark for 30 minutes. After incubation, 5  $\mu$ L of the stained bacterial suspension was collected and pipetted over a glass slide and covered for fluorescence analysis. The fluorescence microscope (Zeiss Axio Scope.A1, Carl Zeiss, Germany) equipped with FITC and Texas RED filters, was used to acquire fluorescence images. The acquired images were analyzed via ImageJ 1.50d to assess the percentage of live (green-stained) and dead (red-stained) bacterial cells.

### 3. Results and discussions

#### 3.1 Characterization

The composite membranes containing the bismuth oxide-based nanomaterial were synthesized and characterized, as described in the experimental part. In the following, the physical-chemical characterization using XRD, UV-Vis, FT-IR, Raman spectroscopy, FESEM imaging, EDX analysis are reported.

##### 3.1.1 XRD analysis

The XRD patterns of bare Nylon, Bi<sub>2</sub>O<sub>3</sub>/Nylon, and synthesized  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> powder are shown in Fig. 2A. The bare Nylon, being semi-crystalline, does not show any peak, while in case of

Bi<sub>2</sub>O<sub>3</sub>/Nylon composite some peaks were observed at 27.06°, 31.7°, and 53.6° indicating the formation of monoclinic  $\alpha$ -Bi<sub>2</sub>O<sub>3</sub> phase [42]. These peaks match with standard XRD data (JCPDS 16-0654) [43]. Additional peaks were observed at  $2\theta = 27.96, 32.72^\circ$ , and  $46.22^\circ$ , corresponding to  $\beta$ -Bi<sub>2</sub>O<sub>3</sub> phase (JCPDS card no. 01-078-1793) [42]. As shown by the comparison in Fig. 2A, the pattern of the Bi<sub>2</sub>O<sub>3</sub>/Nylon composite retained the main peaks observed for the  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> powder after integration into Nylon by electrospinning. However, due to the dilution in the Nylon membrane, the weaker peaks of the XRD spectra of  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> could not be detected [48].

**Figure 2** A) XRD patterns of the sample holder, bare Nylon, Bi<sub>2</sub>O<sub>3</sub>/Nylon composite, and synthesized  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> powder, and B) UV-Vis DRS Spectra of bare Nylon, Bi<sub>2</sub>O<sub>3</sub>/Nylon composite; inset Tauc plot for the estimation of the bandgap.

### 3.1.2 Optical properties

Fig. 2B shows the DRS spectra of the bare and composite Nylon membranes. The bare Nylon displayed a slight absorption in the region 250 nm to 300 nm, typical of Nylon polymer [49]. Instead, the Bi<sub>2</sub>O<sub>3</sub>/Nylon composite membrane exhibited one absorbance stretch in the plateau between 375 nm and 450 nm, which is the characteristic optical transition range of  $\alpha$ -Bi<sub>2</sub>O<sub>3</sub>. Moreover, an extended absorbance stretch in the range of 450-530 nm represented the characteristic transition range of  $\beta$ -Bi<sub>2</sub>O<sub>3</sub> [42]. The observed adsorption edge in the visible

spectrum could facilitate the transition of the electrons from the valence to the conduction band and consequently allow the composite membrane to harvest the solar irradiation for photocatalytic activity [34]. The bandgap of the composite membrane estimated from the Tauc plot was around 2.78 eV i.e. shown in inset Fig. 2B. As per the XRD analysis, the  $\alpha$ -phase is dominant in the  $\alpha/\beta$ - $\text{Bi}_2\text{O}_3$  composite. Therefore, the two absorption edges in the visible region have a combined representation in the Tauc plot, and the predominant characteristics of  $\alpha$ - $\text{Bi}_2\text{O}_3$  were slightly narrowed due to the presence of  $\beta$ - $\text{Bi}_2\text{O}_3$ .

### 3.1.3 FESEM analysis

Fig. 3 shows the FESEM images of bare Nylon (Fig. 3A, 3B) and  $\text{Bi}_2\text{O}_3$ /Nylon composite (Fig. 3C, 3D) at different magnification. In the case of bare Nylon, the images exhibited both thick and thin electrospun nanofiber strands in the range of 20-60 nm diameter that form a net-like structure with overlaid multilayers [43, 50]. The obtained nanofibers displayed a uniform and bead-free formation. In the case of the  $\text{Bi}_2\text{O}_3$ /Nylon composite, the FESEM images in Fig. 3C shows the integration of nano-sized round  $\text{Bi}_2\text{O}_3$  particles over the Nylon fibers. Moreover, Fig. 3D suggests that this integration was achieved across each electrospun layer and in the whole thickness of the membrane.

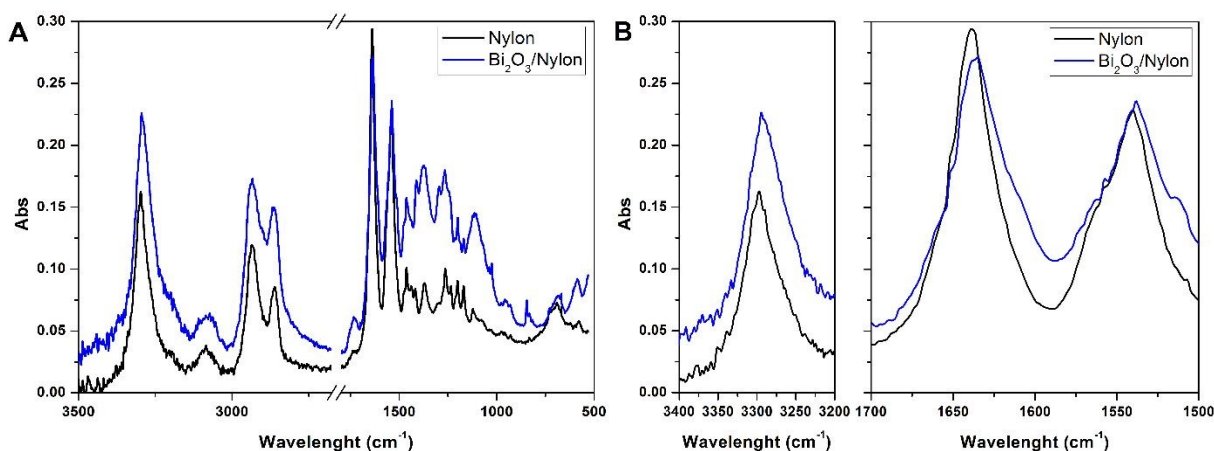

**Figure 3** FESEM images of bare Nylon and  $\text{Bi}_2\text{O}_3/\text{Nylon}$  membranes at different magnifications. (A) bare Nylon (25 kX), (B) (50 kX), (C)  $\text{Bi}_2\text{O}_3/\text{Nylon}$  (25 kX), and (D) (50 kX).

A further confirmation of the integration of the bismuth nanomaterial into the multilayered electrospun membrane was revealed by the EDX analysis, reported in Fig. S1. This evaluation clearly revealed the presence of Bi atoms in the  $\text{Bi}_2\text{O}_3/\text{Nylon}$  membranes.

### 3.1.4 FT-IR analysis

Fig. 4 shows the FT-IR spectra of the bare and composite membranes samples. Nylon-6 is a polyamide, therefore, its molecular structure is featured by the presence of amide groups as displayed by the amide I stretching at  $1638\text{ cm}^{-1}$  (C=O stretching), and amide II stretching at  $1540\text{ cm}^{-1}$  (as a combination of -CN stretching and -NH bending) [51]. At the same time, the intense band at  $3297\text{ cm}^{-1}$  indicates the N-H stretching vibration [52]. The peaks at about  $1367\text{ cm}^{-1}$ ,  $1263\text{ cm}^{-1}$ , and  $1200\text{ cm}^{-1}$  are due to amide III stretching and  $\text{CH}_2$  wagging, while the peaks at  $2860\text{ cm}^{-1}$

and  $2933\text{ cm}^{-1}$  are due to  $\text{CH}_2$  symmetric and asymmetric stretching, respectively [52]. All other peaks match with FT-IR assignments of Nylon-6 nanofibers reported previously and summarized in Table S1 [51, 52]. In the  $\text{Bi}_2\text{O}_3/\text{Nylon}$  composite, concerning  $\text{Bi}_2\text{O}_3$ , its leading bands are below  $500\text{ cm}^{-1}$ , but the ATR diamond crystal used to acquire the spectra cuts this region. The only clear signal of bismuth oxide is the peak at  $846\text{ cm}^{-1}$  due to the symmetric Bi-O stretching [53]. Nevertheless, some of the absorption bands of Nylon-6 are downshifted. In particular, the amide I and amide II bands are shifted to  $1635\text{ cm}^{-1}$  and  $1538\text{ cm}^{-1}$ , respectively, whereas the N-H stretching is moved to  $3294\text{ cm}^{-1}$ . This is probably the result of the interaction of the Nylon polymer with  $\text{Bi}_2\text{O}_3$ .

**Figure 4 FT-IR Patterns of Nylon and  $\text{Bi}_2\text{O}_3/\text{Nylon}$  membranes: A) whole FT-IR spectrum b) magnification of the N-H stretching (left) and amide I and amide II (right) regions.**

### 3.1.5 Raman analysis

Raman analysis of the bare Nylon and composite membranes was performed to further assess the incorporation of the  $\alpha/\beta\text{-Bi}_2\text{O}_3$  nanoparticles. As shown in Fig. 5 the Nylon fibers are featured by a weak Raman signal that matches the typical vibrational pattern of polyamides.

**Figure 5 Raman spectra of the bare (bottom black curve) and  $\alpha/\beta$ - $\text{Bi}_2\text{O}_3$  decorated (top blue curve) Nylon membrane.**

In detail, different bands assigned to CC stretching coupled to  $\text{CH}_2$  bending modes are observed around  $1100\text{ cm}^{-1}$  (CC stretching +  $\text{CH}_2$  twisting around  $1080$  and CC stretching +  $\text{CH}_2$  wagging at  $1120\text{ cm}^{-1}$ ), while two  $\text{CH}_2$  twisting and one  $\text{CH}_2$  bending-related bands are detected between  $1260$ - $1300\text{ cm}^{-1}$  and at  $1440\text{ cm}^{-1}$ , respectively [54]. Finally, amide I band appears at about  $1635\text{ cm}^{-1}$  [55]. The addition of the  $\text{Bi}_2\text{O}_3$  nanopowder results in significant changes in the low Raman shift range, while the vibrational pattern is almost unaffected over  $600\text{ cm}^{-1}$ , except for a narrow band at  $1040\text{ cm}^{-1}$  due to residual nitrates from the synthesis. The emergence of intense Raman modes in the  $120$ - $600\text{ cm}^{-1}$  range attributable to two different  $\text{Bi}_2\text{O}_3$  crystalline phases clearly witness the incorporation of the bismuth oxide in the membrane. The bands at  $278$ ,  $313$  and  $440\text{ cm}^{-1}$  were previously assigned to  $\alpha$ - $\text{Bi}_2\text{O}_3$  [56, 57]. Instead, the vibrational modes at  $142$  and  $335\text{ cm}^{-1}$  appear slightly up-shifted with respect to the main bands of the  $\beta$ - $\text{Bi}_2\text{O}_3$  ( $128\text{ cm}^{-1}$  and  $317\text{ cm}^{-1}$ ) [58], but can still be consistent with the presence of the tetragonal phase. Depending on the Raman shift region where they occur, the observed Raman bands can be attributed to Bi-dominated lattice movements ( $< 155\text{ cm}^{-1}$ ), modes with significant Bi and O contribution ( $155$ - $255\text{ cm}^{-1}$ ) and

oxygen related displacements ( $> 255 \text{ cm}^{-1}$ ), as derived previously for  $\alpha\text{-Bi}_2\text{O}_3$  [57]. Raman analysis thus confirms both the formation of the composite and the preservation of the crystalline phases of the nanopowder after electrospinning.

### 3.2 Photocatalytic dye discoloration/degradation

Once the composite membranes have been physico-chemically characterized, their photocatalytic efficiency was evaluated, employing photocatalytic tests against anionic IC and cationic RhB organic dyes. The selection of these dyes was made to compare the obtained results with the previously reported ones, in which both dyes were evaluated individually and in a mixed solution using the bulk  $\alpha/\beta\text{-Bi}_2\text{O}_3$  powder [42].

**Figure 6** Photocatalytic tests using bare Nylon and  $\text{Bi}_2\text{O}_3/\text{Nylon}$  composite membranes: **A)** Relative concentration ( $C/C_0$ ) of IC degradation vs time ( $C_0 = 5$  ppm); **B)**  $C/C_0$  of RhB degradation vs time ( $C_0 = 5$  ppm); **C)**  $C/C_0$  of different IC dye concentrations with  $\text{Bi}_2\text{O}_3/\text{Nylon}$  composite membrane, and **D)** Kinetic curve of IC and RhB dye solutions, and estimated apparent kinetic rates ( $K_{app}$ ).

Fig. 6A shows the relative concentration ( $C/C_0$ ) profile of IC dye at different times of photocatalytic exposure, using bare Nylon and  $\text{Bi}_2\text{O}_3/\text{Nylon}$  composite membranes. The absorption spectra of IC vs different treatment time using  $\text{Bi}_2\text{O}_3/\text{Nylon}$  is given in Fig. S2 of supplementary data. Initially, in the dark condition, the absorbance spectra of IC dye at 610 nm was reduced by 21.4% due to its charge interactions towards the Nylon multilayers [59]. Any

1  
2  
3 further decrease due to adsorption was not observed for a longer period in the dark. Instead, after  
4 the irradiation exposure, the absorbance peak of IC started to decrease further, due to the  
5 photocatalytic response of the  $\alpha/\beta$ -  $\text{Bi}_2\text{O}_3$ , until it completely disappeared after prolonged exposure  
6 of 180 minutes. The removal of IC is due to the oxidation and breaking of the indigoid group  
7 (NHC=CNH), as indicated by the observed isosbestic point at 250 nm and by the increase of  
8 absorbance of intermediate products (shown in Fig. S2) i.e. *Isatin sulfonic acid* and *2-amine-5-*  
9 *sulfo-benzoic acid*, in the UV absorbance region between 250 nm and 275 nm [5, 42]. The persisted  
10 appearance of these peaks was probably the indication of incomplete mineralization [44].

11  
12 Further, in Fig. 6A the photolysis of IC dye solution i.e. under irradiation exposure without the  
13 presence of any membrane showed no/less significant change in the IC concentration, while in the  
14 case of bare Nylon membrane, around 19% of IC dye was initially adsorbed in the dark conditions  
15 and, afterward, did not show any further activity in the light. This could be ascribed to a limited  
16 amount of adsorption sites of the Nylon fibrous membrane, which could not accommodate further  
17 dye molecules, resulting in a limited removal of the dye from the solution [26]. Instead, the  
18  $\text{Bi}_2\text{O}_3/\text{Nylon}$  composite membrane showed slightly higher adsorption (21.4%), compared to the  
19 bare Nylon membrane. This could be related to additional adsorption sites provided by the  
20 embedded nanoparticles [23]. Afterward, in the following first 45 min of irradiation, the improved  
21 removal of IC was observed due to the high concentration of adsorbed IC molecules over the  
22 membrane surface, which was rapidly oxidized by the generated ROS after irradiation. Further,  
23 after 180 min of irradiation, around 78% of mineralization was achieved, as analyzed by the TOC  
24 analysis. Afterward, the TOC reduction remained unchanged for a longer run of 360 min, due to  
25 the persistent nature of the resulted intermediates [42]. The kinetic curve for the degradation of IC  
26 (shown in Fig. 6D; at 5 ppm concentration) is plotted using the  $\ln(C_0/C)$  function vs time that

5  
6

### 7 8 3.2.2 Rhodamine B (RhB) dye 9

10 RhB is a cationic dye and has both diethylamine and carboxylic groups [42]. Fig. S3 in the  
11 supplementary data shows the UV-Vis absorbance spectra of RhB at different time intervals  
12 obtained with  $\text{Bi}_2\text{O}_3/\text{Nylon}$  composite membrane. The RhB shows the maximum absorbance peak  
13 at 555 nm [40], which was followed to relate its removal via simultaneous adsorption and  
14 photocatalytic oxidation. In Fig. 6B,  $C/C_0$  profiles of RhB dye at different times of photocatalytic  
15 exposure, using bare Nylon and  $\text{Bi}_2\text{O}_3/\text{Nylon}$  composite membranes are compared. Initially, 21%  
16 of the RhB intensity was reduced due to its interaction with the multilayers and integrated  $\text{Bi}_2\text{O}_3$   
17 particles i.e. under dark conditions, and the adsorption-desorption equilibrium was attained with  
18 the saturation of the composite membrane by RhB dye molecules as no further adsorption noted  
19 up to 60 min in dark conditions. The interaction of cationic dyes with Nylon is assumed to be  
20 weaker than that of anionic dyes. However, an improved interaction of RhB dye with the composite  
21 membrane was observed. This could be associated with the anionic carboxylic group of RhB and  
22 good protonation of  $\alpha/\beta\text{-Bi}_2\text{O}_3$  particles that could have allowed amphoteric sites of RhB to  
23 interact with the composite membrane [42]. After the irradiation, the adsorbed and highly  
24 interacting RhB dye was removed and oxidized by the reactive species generated by the composite  
25  $\alpha/\beta\text{-Bi}_2\text{O}_3$  particles after 90 minutes, and reached a degradation and mineralization degree up to  
26 68% after 180 min exposure, as observed through TOC analysis. The mineralization of RhB was  
27 unchanged after that due to the formation of persistent intermediates [44]. Compared to IC dye,  
28 the removal of RhB was found faster with the calculated  $K_{app}$  of  $1.57 \times 10^{-2} \text{ min}^{-1}$  i.e. shown in  
29 Fig. 6D. The improved kinetics of RhB could be due to its high affinity towards the membrane and

9

### 10 3.2.3 Varied dye concentrations

11  
12 To evaluate the membrane performance at high loading of the IC dye, the photocatalytic tests were  
13  
14 conducted at varied IC concentrations using the Bi<sub>2</sub>O<sub>3</sub>/Nylon composite. Fig. 6C and 6D show the  
15  
16 C/C<sub>0</sub> and removal kinetics of IC at the concentrations of 5, 10 and 20 ppm, and reveal that the  
17  
18 removal efficiency of the Bi<sub>2</sub>O<sub>3</sub>/Nylon composite membrane decreased to 75.11%, and 61.45% at  
19  
20 the concentrations of 10 and 20 ppm, respectively, during 180 minutes irradiation exposure. This  
21  
22 behavior could be related to the low availability/generation of ROS due to the attachment of the  
23  
24 dye molecules on active sites of  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub>. Secondly, the resulting increase in solution opacity and  
25  
26 consequently the decreased irradiation transmission subsequently lowered the removal efficiency  
27  
28 of IC [60, 61]. Moreover, the high organic load could reduce the water flux and increase the mass  
29  
30 transfer resistance of the membrane and could decrease the membrane efficiency [62]. This trend  
31  
32 was observed during the TOC analysis, which revealed a decrease in the degradation and  
33  
34 mineralization efficiency of the composite membrane, i.e. after 180 min irradiation, the analyzed  
35  
36 TOC reduction was 63% and 37% for 10 and 20 ppm concentrations of IC dye, respectively,  
37  
38 compared to 78% reduction in case of 5 ppm solution. The resultant decrease in mineralization  
39  
40 efficiency could be due to the saturation of the composite membrane with intermediate species that  
41  
42 affected the semiconductor activation to support the generation of reactive species and induce  
43  
44 oxidation. The Fig. 6D, shows calculated  $K_{app}$  values as  $0.63 \times 10^{-2} \text{ min}^{-1}$  and  $0.43 \times 10^{-2} \text{ min}^{-1}$  for  
45  
46 10 and 20 ppm IC dye concentrations, significantly reduced compared to  $0.83 \times 10^{-2} \text{ min}^{-1}$  in the  
47  
48 case of 5 ppm concentration.

### 3.2.4 Mixed dyes degradation

Since colored wastewater contains the mixture of several dyes, interfering with each other in the mixed effluent, their removal behavior and mechanism of interaction for any potential treatment (including the case of membrane assisted photocatalysis) could be different. Therefore, the evaluation of a mixed solution of both IC and RhB dyes was performed using the composite membrane. The recorded absorbance spectrum of the mixed solution vs irradiation time given in Fig. 7A showed two main peaks corresponding to the contribution of both IC and RhB dyes at 610 and 555 nm, respectively. In Fig. 7B,  $C/C_0$  profile of mixed solution at different times of photocatalytic exposure are reported i.e. using bare Nylon and  $\text{Bi}_2\text{O}_3/\text{Nylon}$  composite membranes.

In dark conditions, both IC and RhB dyes preferentially adsorbed on the membrane at 23% and 22%, respectively. After irradiation, the absorbance of the IC dye was significantly reduced in the first 90 min (Fig. 7B), with originated intermediate products absorbing in the UV region i.e. from 200 nm to 250 nm. Due to an intense peak (Fig. 7A), the RhB dye depletion followed the IC removal, but at slightly lower kinetics. Actually, the calculated  $K_{app}$  was  $1.05 \times 10^{-2} \text{ min}^{-1}$  and  $1.21 \times 10^{-2} \text{ min}^{-1}$  in case of RhB and IC, respectively. The degradation kinetics of RhB was also found lower compared to when it was tested alone ( $K_{app} 1.57 \times 10^{-2} \text{ min}^{-1}$ ) (Fig. 7C). This decrease in RhB removal kinetics probably was due to the limited ROS availability for the attack and degradation of both dyes. The investigation revealed that both dyes underwent simultaneous degradation with the formation of IC dye intermediates products probably because of the good interaction of both dyes enabled by the membrane, in contrast to our previously reported observation with the dispersed  $\alpha/\beta\text{-Bi}_2\text{O}_3$  nanoparticles, where the IC was preferentially degraded, and after its complete degradation, the activity was directed against RhB [42].

**Figure 7** A) Absorbance spectra vs irradiation time of the mixed solution B) relative concentration ( $C/C_0$ ) of combined dyes degradation using  $\text{Bi}_2\text{O}_3/\text{Nylon}$  composite, C) Kinetic curves of removal of IC and RhB dyes in the mixed solution, and estimated  $K_{app}$ . D) Cyclic stability of  $\text{Bi}_2\text{O}_3/\text{Nylon}$  composite membrane up to three cycles;  $C/C_0$  profiles at 5 ppm IC dye concentration.

Here the equal and concurrent interaction of both dyes with the originated ROS is supported by the membrane. The overall obtained results suggested no/less interfering behavior among the tested dyes, as the removal kinetics of both dyes was almost similar i.e. from  $1.21 \times 10^{-2} \text{ min}^{-1}$  and  $1.05 \times 10^{-2} \text{ min}^{-1}$ , for IC and RhB, respectively.

### 3.2.5 Cyclic stability

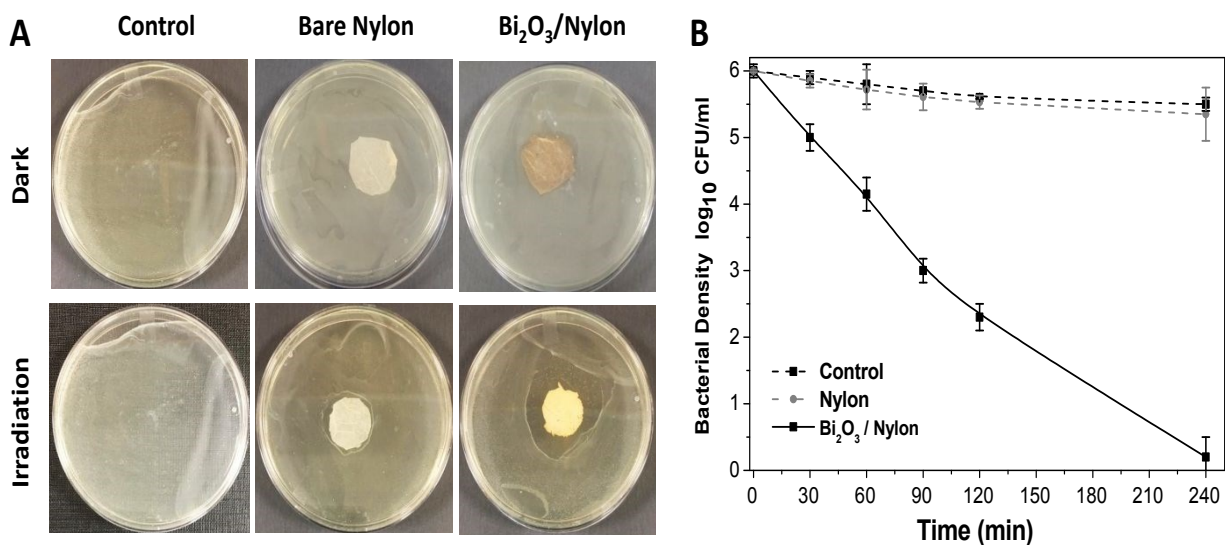

1  
2  
3 For the cyclic stability of the Bi<sub>2</sub>O<sub>3</sub>/Nylon nanocomposite membrane, the photocatalytic tests were  
4 carried out up to three cycles i.e. after the composite membrane was recovered and rinsed and  
5 configured again in the CPMR. Fig. 7D shows the relative concentration (C/C<sub>0</sub>) decrease of the IC  
6 dye at 5 ppm concentration up to three cycles. The composite membrane showed good stability  
7 and performance in the first two cycles; however, the removal efficiency significantly decreased  
8 in the third cycle. This reduction could be associated with membrane exhaustion due to an altered  
9 porosity or to the affected active sites of the Nylon fibers, and integrated  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> particles that  
10 previously had sustained the capture of dye molecules and intense interaction with the originated  
11 radical species.  
12  
13  
14

### 3.3 Antibacterial Activity

#### 3.3.1 Bacterial inhibition on solid media

15  
16  
17 The main aim of this study was to evaluate the potential of the composite membrane for the  
18 photocatalytic inactivation of waterborne pathogens i.e. *E. coli*. Therefore, initially, the inhibition  
19 tests were performed on *E. coli* cultured on solid media. The obtained results, showed in Fig. 8A,  
20 confirmed a growth inhibition halo against *E. coli* in the case of the composite membrane  
21 compared to the bare Nylon membrane and control samples (biotic control). The calculated zone  
22 of inhibition was around 14 mm. Moreover, under dark conditions, no significant inhibition zone  
23 was observed in the case of the composite membrane, revealing that the integrated  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub>  
24 particles remained inactive and did not generate ROS against the growth of *E. coli*. Only a little  
25 zone of inhibition was recorded in some replicates, highlighting that probably the integrated  $\alpha/\beta$ -  
26 Bi<sub>2</sub>O<sub>3</sub> particles at high concentration can be a little bit toxic against the bacterial growth, too. While  
27 in the case of bare Nylon and control samples (without membranes), a high growth of *E. coli* was  
28

observed in the whole petri dish, both under dark and irradiated conditions, resulting in no significant effect on the bacterial growth.

**Figure 8** A) Bacterial inhibition on solid media of control, bare Nylon, and Bi<sub>2</sub>O<sub>3</sub>/Nylon after incubation in the dark or under LED irradiance; B) *E. coli* density reduction in a liquid suspension treated with the photocatalytic Bi<sub>2</sub>O<sub>3</sub>/Nylon membrane.

### 3.3.2 Bacterial inhibition in liquid suspension

Once the antibacterial activity of the composite membrane was assessed on solid agar media, the photocatalytic response against a liquid stock solution of *E. coli* at a concentration of  $1 \times 10^6$  CFU/mL was evaluated by using the CPMR. The obtained results revealed a continuous *E. coli* reduction during the photocatalytic exposure i.e. as shown in Fig. 8B. The number of bacterial cells assessed by the plate count method of serially diluted samples collected from the CPMR at specified times confirmed the reduction of the cell density. It revealed a 50% of log reduction of *E. coli* after 90 min, and their complete removal after 240 min of treatment (as observed in Fig. 8B). To further confirm that the composite membrane has a biocidal effect on the microorganisms, the fluorescence live/dead cell staining and imaging were applied i.e. using fluorescence microscopy. The samples were taken from the CPMR and stained, resulting in green-stained cells

1  
2  
3 that represent living bacteria, whereas the red-stained cells are dead. The acquired fluorescence  
4 microscopy images of *E. coli* are shown in Fig. 9. In the beginning, plenty of live green-stained  
5 cells were observed, while at continued photocatalytic exposure, the red-stained cell increased  
6 their number. The obtained fluorescence images revealed that the bacterial cells were attacked by  
7 the  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> in the composite membrane, resulting in the rupture of their cell membranes and  
8 allowing the PI dye to stain the DNA inside the nucleus, as indicated from the observed red-stained  
9 cells. After treatment of 240 min, a higher proportion of red-stained cells over green-stained cells  
10 revealed that the Bi<sub>2</sub>O<sub>3</sub>/Nylon composite membrane has not only a biostatic effect (growth  
11 inhibition) on the treated *E. coli* cells, but it acts as a biocidal material, able to kill this bacterial  
12 strain. During the photocatalytic reaction, the catalytic material integrated into the membranes  
13 could produce ROS that could attack the bacterial cell, lead to cell damage, and increase the  
14 permeability of the cell membrane towards PI staining dye [63]. Compared to these results, the  
15 bare Nylon and control samples showed no significant red stained (dead) cells after prolonged  
16 exposure; the acquired fluorescence images for bare Nylon treatment and control (without any  
17 membrane) samples are given in supplementary data Fig. S4.

46 **Figure 9** Fluorescence stained images of live and dead *E. coli* cells at different treatment time

### 47 48 49 **3.4 Photocatalytic mechanism**

50  
51 The photocatalytic particles partially embedded in polymeric/ceramic membranes remained active  
52 under irradiation and released reactive oxidative species (ROS) in water media and across the  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 adsorbed/retained pollutants [61, 64]. The dispersion of ROS across the membrane could get  
4 affected by mass-transfer limitations. However, due to the large surface created by the multi-  
5 layered nylon membrane and the exposed appearance of  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> particles on these layers, the  
6 large release of ROS could have been enough to reach the nearest adsorbed/retained pollutants,  
7 resulting in the dyes degradation and bacterial inactivation, compared to bare nylon. Indeed, the  
8 obtained results suggest that the  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> nanocomposite membranes have good adsorption  
9 assisted photocatalytic properties against the removal of both anionic and cationic dyes as well as  
10 bacteria. Some of the reported studies suggested the ROS generation around the surface of  
11 heterojunctioned  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> [42] and nanocomposite materials i.e. Sb<sub>2</sub>WO<sub>6</sub>/BiOBr and  
12 BiSbO<sub>4</sub>/BiOBr [38, 39]. In the case of dyes, there could be various possibilities of their interaction  
13 with the generated ROS on the  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> active sites of composite membrane. Either the dye  
14 molecules of IC and RhB could have been adsorbed through ionic interaction i.e., in case of IC  
15 dye via sulphonic branched groups, while for RhB dye via the carboxylic group, or the dye  
16 molecules of IC and RhB were captured within the membrane pores of the multilayered Nylon  
17 fibers. However, the good affinity of both dyes towards the composite membrane could be driven  
18 by both mechanisms i.e. through simultaneous ionic interaction and capture of dye molecules.  
19 After irradiation with visible light, the  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> particles in the composite membranes originated  
20 reactive species that attacked the captured/adsorbed dye molecules, performing the adsorption-  
21 assisted photocatalysis. During the photo discoloration of IC, the reactive species attacked the  
22 sulfonic groups, partially mineralized, and degraded into intermediate compounds identified as  
23 *Isatin sulfonic acid* and *2-amine-5-sulfo-benzoic acid* [65]. Instead, the degradation of RhB  
24 followed carboxylic path oxidation and reduction, resulting partly mineralized without any  
25 apparent shift of the absorbance in the UV-Vis spectrum, typical of a de-ethylation (see Fig. S3 in  
26

1  
2  
3 supplementary data) [42]. In the case of the mixed solution, both dyes showed a good interaction  
4 and removal kinetics without any ionic inhibition/interference because of the equivalent interface  
5 provided by the membrane multilayers. Further, under prolonged exposure, the simultaneous  
6 degradation of both dyes occurred, due to the attack of ROS towards the IC and RhB dye  
7 molecules.  
8

9  
10 Concerning bacteria, the results obtained with *E. coli* revealed that probably the bacterial cells  
11 interacted with the composited  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> particles through multilayered channels, and were  
12 subsequently attacked by the originated ROS with resulting damage of cell wall/membrane and  
13 their constituents. It is well-known that ROS can oxidise proteins, lipids and phospholipids [66],  
14 damaging the membrane itself or simply its lipid bilayer organization, eventually leading to efflux  
15 of cytosolic contents or to cell lysis. These effects are particularly efficient on bacteria, fungi, and  
16 viruses, including multidrug-resistant strains, and due to their quick action, ROS are considered  
17 potent antimicrobial agents [67]. Similar mechanisms have been suggested for other antimicrobial  
18 metal and metal oxides, such as silver or copper, and are consistent with previous works that report  
19 the efficacy of  $\beta$ -Bi<sub>2</sub>O<sub>3</sub> on *E. coli* and *S. aureus* [68, 69]. The adsorption of the bacterial cells in  
20 the porous structure of the composite membranes combined with the action of the bismuth-based  
21 nanomaterial irradiated with the LED visible light, allowed a complete degradation of the  
22 pathogens. Indeed, the ROS generated by the photocatalytic action of the  $\alpha/\beta$ -Bi<sub>2</sub>O<sub>3</sub> activated  
23 particles are more effective in the close vicinity, due to their extremely low half-life. The increased  
24 number of red-stained (dead) cells at increased photocatalytic exposure showed that live cells  
25 interacted and were attacked continuously by the photo-originated ROS. All of these results proved  
26 the potential applicability of the bismuth-based composite membranes for water treatment and  
27 sanitation.

#### 4. Conclusion

The  $\alpha/\beta$ - $\text{Bi}_2\text{O}_3$  powder semiconductor was synthesized by the thermal annealing of  $\text{Bi}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}$  salt. The synthesized powder was integrated into the Nylon-6 multilayered fibrous membrane via electrospraying, and characterized by XRD, FESEM, EDX, UV-Vis, FT-IR and Raman analyses. The  $\text{Bi}_2\text{O}_3/\text{Nylon}$  nanocomposite membrane showed a photocatalytic response against the separate solution of IC and RhB dyes, with a complete discoloration. The TOC analyses revealed the partial mineralization and degradation of IC and RhB treated solutions with the formation of stable and persistent intermediates. Further, in the case of the mixed solution of IC and RhB dyes, the composite membrane showed simultaneous degradation response to anionic IC dye and cationic RhB dye, due to their equal interaction with the reactive species, originated by  $\alpha/\beta$ - $\text{Bi}_2\text{O}_3$ . Moreover, dealing with a higher concentration of IC, the degradation kinetics was reduced by 3-fold, mainly due to the high saturation of the membrane layers by the dye-intermediates.

Furthermore, the composite membrane showed an antibacterial response against *E. coli* solid and liquid cultures. In the case of solid *E. coli* media, the formation of a 14 mm inhibition zone was obtained, whereas, for liquid *E. coli* suspension ( $1 \times 10^6$  CFU/mL), the complete inhibition of bacterial growth was attained after 240 min of photocatalytic exposure. The induced bactericidal effect on *E. coli* was observed by fluorescence microscopy that confirmed the high proportion of dead over live cells. Further, the successive recycle tests employing the used membrane suggested the suitable applications and efficacy of the  $\text{Bi}_2\text{O}_3/\text{Nylon}$  nanocomposite membrane for the removal of organic dyes and inactivation of waterborne pathogens.
