Abstract: Zonal velocity and temperature daily global reanalysis data of 30 years are used to search seasonally steady planetary disturbances in the middle troposphere (400 hPa) and middle stratosphere (10 hPa). Significant wavenumber 1, 2 and 3 modes are found. Constant phase lines of zonal velocity 1 modes exhibit significant inclination angles with respect to the meridians. The winter hemisphere generally shows a more significant presence of structures. The Northern Hemisphere (NH) exhibits all over the year a larger amount of structures and more intense amplitudes than the Southern Hemisphere (SH). Middle latitudes exhibit the most significant cases and low latitudes the least significant ones. Longitudinally oriented land-sea transitions at +- 65 deg and -35 deg latitudes appear to play a significant role for the presence of steady planetary modes. The stratosphere exhibits a much simpler picture than the troposphere. Large scale structures with respectively NE-SW (NH) and NW-SE (SH) tilts in the observed temperature and zonal velocity constant phase lines recall the quasi-stationary Rossby wave trains that favor the poleward transport of angular momentum.

Highlights

- Steady planetary disturbances show significant wavenumber 1, 2 and 3 modes.
- Middle and low latitudes exhibit respectively the most and least significant steady structures.
- Longitudinally oriented land-sea transitions at + - 65 deg and - 35 deg latitudes appear to play a significant role for the presence of steady planetary modes.
- The stratosphere exhibits a much simpler picture than the troposphere.

10 **Abstract**

11 Zonal velocity and temperature daily global reanalysis data of 30 years are used
12 to search seasonally steady planetary disturbances in the middle troposphere
13 (400 hPa) and middle stratosphere (10 hPa). Significant wavenumber 1, 2 and
14 3 modes are found. Constant phase lines of zonal velocity 1 modes exhibit
15 significant inclination angles with respect to the meridians. The winter hemi-
16 sphere generally shows a more significant presence of structures. The Northern
17 Hemisphere (NH) exhibits all over the year a larger amount of structures and
18 more intense amplitudes than the Southern Hemisphere (SH). Middle latitudes
19 exhibit the most significant cases and low latitudes the least significant ones.
20 Longitudinally oriented land-sea transitions at $\pm 65^\circ$ and -35° latitudes ap-
21 pear to play a significant role for the presence of steady planetary modes. The
22 stratosphere exhibits a much simpler picture than the troposphere. Large scale
23 structures with respectively NE-SW (NH) and NW-SE (SH) tilts in the observed
24 temperature and zonal velocity constant phase lines recall the quasi-stationary
25 Rossby wave trains that favor the poleward transport of angular momentum.

12 **1. Introduction**

13 A large fraction of the spatial variability of the atmosphere is produced by
14 modes of global scales and temporal intervals on the order of seasons. They are
15 mainly forced by airflow over topography and large-scale thermal factors. Lau
16 (1979) indicated that this quasi-steady component plays a dominant role in the
17 local balances of momentum and energy, whereas the transient contributions
18 have a secondary importance. This showed that a better knowledge of these
19 nearly stationary structures was very relevant to an adequate description of the
20 general circulation.

21 Planetary scale disturbances like Kelvin and Rossby waves have a significant
22 role in the winter or spring stratosphere, but they are also important in the tro-
23 posphere in relation to meteorological phenomena (see e.g. Hansen and SUTERA,
24 1986). Stationary planetary waves largely contribute to the middle and upper
25 atmosphere dynamics and are related to the sudden stratospheric warmings.
26 There is a strong seasonal variation of stationary planetary waves in the strato-
27 sphere (see e.g. Randel, 1988). Charney and Eliassen (1949) and Smagorinsky
28 (1953) in the troposphere and Charney and Drazin (1961), Matsuno (1970) and
29 Schoeberl and Geller (1977) in the stratosphere were probably among the first
30 ones to develop a framework trying to explain some of the features of planetary

31 waves. Diverse observational works contributed later on to the description of
32 these waves (Hartmann, 1977; Smith, 1983; Barnett and Labitzke, 1990; Li et
33 al, 2006; Shepherd and Tsuda, 2008; Xiao et al, 2009; Mukhtarov et al, 2010).
34 However, many aspects of the planetary disturbances are presently not com-
35 pletely understood, so further studies of them should be performed. As a large
36 fraction of planetary disturbances generated in the troposphere propagate into
37 the stratosphere, knowledge of their presence and seasonal evolution throughout
38 both layers may be important. Analyzes in both hemispheres may yield clarifica-
39 tions because forcing mechanisms and climatologies are different in both areas.
40 Notable differences in the features between the two geographical halves have
41 become apparent (see e.g. Hio and Hirota, 2002): in the Northern Hemisphere
42 (NH), the forcing during winter of stratospheric stationary planetary waves is
43 considered to be due mainly to the large-scale topography, whereas in the South-
44 ern Hemisphere (SH) stratosphere forcing from the Indian Ocean region as well
45 as orographic and thermal forcing from the Antarctic continent have been sug-
46 gested. The surface topographies are also quite different in the two hemispheres.
47 All these studies may provide validations for numerical global model solutions.
48 The present study takes advantage of a long dataset, which provides robust
49 estimates of seasonal characteristics of stationary planetary structures in the

8
9 troposphere and stratosphere all over the globe.

10 11 12 **2. Data** 13 14

15 Apparent climate changes resulted from modifications introduced in the op-
16
17 erational global data assimilation system to improve forecasts about 20 years
18
19 ago. This motivated the National Centers for Environmental Prediction (NCEP)
20
21 / National Center for Atmospheric Research (NCAR) reanalysis project. The
22
23 basic idea is to use a frozen state-of-the-art analysis/forecast system and perform
24
25 data assimilation using information from the past up to the present to produce
26
27 a retroactive record of more than 50 years of atmospheric fields (Kistler et al.,
28
29 2001). Data from rawinsondes, balloons, aircraft, ships, surface stations, and
30
31 satellites are first scrutinized through a quality check, then they are fed into the
32
33 assimilation model that includes parameterizations for all major physical pro-
34
35 cesses, and finally they become analyzed again for self-consistency. All data are
36
37 given on a 144 x 73 global grid at constant pressure levels. The NCEP reanaly-
38
39 ses now cover the years from 1948 to the present. In 1979 the satellite-observing
40
41 system was established, which partially affected reanalysis results. For example,
42
43 some phenomena as depicted in the NCEP reanalysis data exhibit a discontinu-
44
45 ous behavior around 1978 in diverse variables (Huesmann and Hitchman, 2001,
46
47 2003; Kistler et al., 2001). The emergence of satellite data resulted in a sig-
48
49
50
51
52
53
54
55
56
57
58

61
62
63
64
65

1
2
3
4
5
6
7
8
9 69 nificant change, indicating that the results from 1979 to present day are the
10
11 70 most reliable and coherent ones. The global features before that year are rather
12
13
14 71 governed by the model outcome in data-sparse areas, leading to the possible
15
16 72 generation of some spurious results in those regions.
17
18

19 73 Different outputs of the reanalyses are not equally reliable. The NCEP/NCAR
20
21 74 fields have been graded according to the relative influence of the observed data
22
23
24 75 and the assimilation model on the output field. Atmospheric temperature (T)
25
26 76 and zonal wind (U) are significantly affected by the observations, and the nu-
27
28
29 77 merical model does not have a strong influence. Therefore they are among the
30
31 78 variables with the highest grade, which are considered to provide an estimate
32
33
34 79 of the state of the atmosphere better than would be obtained just with mea-
35
36 80 surements. In this work we analyzed global zonal oscillations of seasonal means
37
38
39 81 of daily air temperature and zonal wind reanalysis data over 30 years (1979-
40
41 82 2008). We grouped data into seasons DJF (December, January, February),
42
43
44 83 MAM (March, April, May), JJA (June, July, August), SON (September, Octo-
45
46 84 ber, November). We have chosen levels in the middle troposphere at 400 hPa
47
48
49 85 and in the middle stratosphere at 10 hPa. We performed Fourier analysis on
50
51 86 the 144 data at each of the 73 latitudes. Zonal averages were initially removed
52
53
54 87 in each dataset. In order to keep the most relevant fluctuations of the anal-
55
56
57

62
63
64
65

1
2
3
4
5
6
7
8
9 88 ysis, the following procedure was followed in each dataset. Typical planetary
10
11 89 waves exhibit an amplitude of 1 K in temperature and 2 m/s in zonal velocity
12
13
14 90 (Andrews et al, 1987; Mohanakumar, 2008). We used these values as the lower
15
16 91 limits in order to keep the modes coming out from the Fourier analysis. We
17
18
19 92 set a priori no upper constraint on the wavenumber w representing planetary
20
21 93 scales and the shortest mode that emerged from all our analyzes with a relevant
22
23
24 94 structure (amplitude above the lower limits) was $w = 3$.

25 26 27 95 **3. Results**

28
29
30 96 Significant features that differ from the well-known behavior of a wave have
31
32
33 97 been found below in several cases and therefore these patterns are called here
34
35
36 98 structures. For example significant perturbations in one variable have not been
37
38 99 always accompanied by the other variable or clear phase differences between
39
40 100 them (polarization relations) did not clearly come out. However, we cannot
41
42
43 101 discard that the wave relations are present, but are small or obscure enough
44
45
46 102 to avoid detection. The amplitude limit selection criterium outlined above was
47
48 103 partially arbitrary (but necessary) and therefore the latitude ranges of modes
49
50 104 exhibited below should be considered of an indicative rather than of an accurate
51
52
53 105 nature. In particular, temperature and zonal wind oscillations exhibit similar
54
55
56 106 features at some given altitudes and seasons but the latitude bands of occurrence
57
58
59
60
61
62
63
64
65

1
2
3
4
5
6
7
8
9 107 exhibit moderate differences among them in some cases. In order to represent
10
11 108 the detected structures we used amplitude and phase from the Fourier analysis to
12
13
14 109 plot the location of maxima and minima of modes $w = 1, 2$ and 3 on topographic
15
16 110 maps.

17
18
19 111 Regarding the use of any possible spectral representation tool of quasiperi-
20
21 112 odic structures, every particular choice gives more visibility to certain patterns
22
23
24 113 of the data and obscures other characteristics. The way information is processed
25
26 114 ultimately affects the results and their corresponding interpretations. Applying
27
28
29 115 a Fourier decomposition to given atmospheric data and interpreting the com-
30
31 116 ponents as waves implies that we assume that nature has building blocks with
32
33
34 117 a certain shape. In addition, we should check if observations reproduce the
35
36 118 physical laws or equations of waves or their consequences (conservation of given
37
38
39 119 quantities, polarization relations between certain variables, spectral shapes, etc).

40 41 120 *3.1. The troposphere*

42
43
44 121 In Figure 1 DJF shows a rich deployment of structures in the NH for $w = 1,$
45
46 122 2 and $3,$ with the strongest values at middle latitudes. The SH exhibits a more
47
48
49 123 limited activity at high and middle latitudes. The Antarctica land-sea interface
50
51 124 at about -65° latitude produces changes in the observable patterns. A similar
52
53
54 125 behavior (mainly in zonal wind U the features disappear northwards) is observed
55
56 126 close to the latitude of the Southern border of Africa and Australia, at about

1
2
3
4
5
6
7
8
9 127 -35°. Figure 2 shows that in MAM there are structures in the NH for $w = 1, 2$
10
11 128 and 3, with the strongest values at middle latitudes. The SH exhibits a more
12
13 129 limited activity at high and middle latitudes. The Antarctica land-sea interface
14
15 130 produces changes in the constant phase lines. Figure 3 shows that in JJA the
16
17 131 NH exhibits structures at low and middle latitudes. The whole SH shows a
18
19 132 variability of the structures with latitude. During SON Figure 4 shows that
20
21 133 there is activity in the NH for $w = 1, 2$ and, 3, mainly at the middle latitudes.
22
23 134 The SH exhibits structures at high and middle latitudes. Again, close to the
24
25 135 latitude of the Southern border of Africa and Australia, there are noticeable
26
27 136 changes of patterns. Along all seasons U structures are generally more oblique
28
29 137 than temperature T ones, particularly for $w=1$. The inclinations in SH and NH
30
31 138 are always respectively NW-SE and NE-SW.

32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63 64 65

139 *3.2. The stratosphere*

140 In Figure 5 for DJF only the NH exhibits structures. The activity is domi-
141 nated by $w = 1$, where $w = 2$ has a secondary role, both modes mainly at large
142 and middle latitudes. The $w = 1$ features have the largest values of all studied
143 heights and seasons. The U structures undergo a significant longitudinal shift
144 at the land-sea interface at about 65° latitude. In Figure 6 during the MAM
145 season only $w = 1$ features appear in SH and NH at large and middle latitudes.
146 In the NH, U again undergoes a longitudinal shift at 65° latitude. In the SH the

147 U patterns are rather oblique, as in the troposphere. The T features in the SH
148 change angle close to the Antarctic land-sea interface at about -65° latitude, as
149 in the troposphere. As shown in Figure 7, in JJA there are patterns only in the
150 SH. Again the T features change angle close to the Antarctica land-sea interface
151 and U structures are rather oblique, both characteristics as in the troposphere.
152 The former variable covers low and middle latitudes and the latter one the whole
153 hemisphere. As in MAM, both hemispheres of SON in Figure 8 exhibit activity,
154 but somewhat stronger. The lower halves look similar to JJA (but stronger) and
155 the upper halves to DJF (but weaker). No structures are seen at low latitudes.
156 The $w = 1$ U features are rather oblique, as in the troposphere.

157 **4. Discussion**

158 The weaker planetary wave activity observed in the SH compared to the
159 NH is generally believed to be mainly due to the lower amount of land-sea
160 contrast. We recall that we refer here to seasonally steady planetary structures
161 and that the same holds true. The features observed in this work tend to
162 be predominant in the winter hemisphere and at middle or high latitudes. In
163 particular, the stratosphere exhibits in no season the most intense values at low
164 latitudes and it shows no patterns during the summer. In the troposphere, the
165 largest amount of intense cases may be found at middle latitudes, but in the SH

166 strong activity may also be found close to the Antarctic rim. In addition the
167 latter is the only broad (at least 20° latitude) permanent pattern in T and U all
168 over the globe. There are no structures at the highest latitudes for U at DJF,
169 but recall that our thresholds for the representation of the modes are partially
170 arbitrary. Significant activity may be found in the troposphere during winter at
171 about the latitudes of the highest mountains (Himalayas in the NH and Andes
172 in the SH) mainly for U, not for T. Some structures seem to have been filtered
173 out at the stratosphere and the picture looks simpler than at the troposphere.
174 In particular, there are no $w = 3$ patterns in any season neither in U nor in T.
175 Wallace and Hsu (1983) provided a theoretical framework in terms of stationary
176 Rossby waves that leads to more restrictive constraints for the development of
177 structures in the stratosphere. However, it could also happen that the numerical
178 model generating reanalysis is not able to reproduce a similar complexity due
179 to its lower reliability and the fact that there are much less observations to be
180 assimilated at these altitudes. The phase lines in T that appear nearly in the
181 same geographical location in the troposphere and stratosphere are about half
182 a cycle out of phase. This relation holds only in some cases for U, where in
183 addition the association between features in the troposphere and stratosphere
184 is more difficult due to the significant inclination of the phase lines.

185 The tilt in the phase lines, mainly in U, recalls the quasi-stationary Rossby
186 train waves that favor the meridional transport of angular momentum in the
187 global atmosphere. The poleward transfer from low latitudes becomes efficient
188 when the structures have a preferential NE-SW orientation in the NH and op-
189 posite in the SH (Starr, 1948; Peixoto and Oort, 1992). The collective effect
190 of this phenomenon all over the globe may be leading to the observed global
191 imprint.

192 In the troposphere the persistent more oblique nature of the U phase lines
193 as compared to the T ones did not allow any calculation of presumable wave
194 phase differences. This would have been possible only in the stratosphere at
195 about latitude 50° during DJF and SON, but the bands would have been rather
196 narrow (around 10°). In addition, the $w = 1$ structures of U in the troposphere
197 have large inclination angles with respect to the meridians, which obscure the
198 visualization of the diverse structures. The general inclination of the phase lines
199 is opposite in both hemispheres and the relation holds for the troposphere and
200 stratosphere.

201 Zonal structures detected near polar latitudes deserve a particular warning.
202 The convergence of meridians there typically leads to synoptic scale phenomena,
203 so any planetary labeling at large latitudes above is abusive. In addition, the

204 modes detected close to those areas could rather be due to numerical artifacts
205 generated by the large land-sea zonal interfaces rather than true nearly periodic
206 structures.

207 We now recall previous works that are relevant in relation to our results.
208 Traveling modes detected by some of the earlier investigations on planetary sig-
209 natures (see e.g. Salby, 1984; Salby and Callaghan, 2001) are out of our scope
210 due to our focus on steady features. Lindzen et al (1982) analyzed with a prim-
211 itive equation numerical model the stationary planetary waves generated by
212 orographic or thermal forcing. It was found that the response to the latter was
213 sensitive to small changes in the distribution of wind and temperature, which im-
214 plies that variability in stationary modes can occur even without changes in the
215 forcing itself. Later, Jacqmin and Lindzen (1985) found that at mid-latitudes
216 orographic forcing predominates over the thermal component in the response.
217 They stated that the stratospheric outcome is dominated by topographic sources
218 and its sensivity is much greater than in the troposphere. Steady patterns of $w =$
219 5 with broad latitudinal extent have been observed in early global analysis data
220 by Salby (1982) in the summer season of the Southern Hemisphere in the mid-
221 latitude troposphere and lower stratosphere. Murgatroyd and O'Neill (1980)
222 made a sound review on the interactions between troposphere and stratosphere.

223 They outlined that the circulation looks simpler in the stratosphere than in the
224 troposphere and stated that the winter extratropical stratosphere has significant
225 quasi-stationary planetary waves of $w = 1$ and 2. In the Southern Hemisphere
226 stratosphere the perturbations are far less pronounced. The characteristics of
227 the equatorial stratosphere benefit the absorption of the quasi-stationary plane-
228 tary waves. Tropospheric waves of $w = 1$ and 2 with smaller amplitude than in
229 the upper layer exhibit the same seasonal behavior and may be a determinant
230 factor for the observed stratospheric modes. The degree of vertical penetration
231 of the waves from the troposphere depends on their zonal wavelength, whereby
232 shorter waves find less favorable conditions for propagation. In the Northern
233 Hemisphere, the large-scale mountain ranges are considered the main drivers
234 of the the tropospheric nearly steady waves. Stationary waves of $w > 2$ are of
235 progressively smaller amplitude in the stratosphere. Transient planetary com-
236 ponents possess much smaller amplitude than their stationary counterparts in
237 the Northern Hemisphere, but have comparable intensity in the Southern Hemi-
238 sphere, which could favor a masking effect on the stationary structures in this
239 terrestrial half. Roughly, the overall characteristics of this work are quite well
240 reproduced in our results. The main difference relies in the fact that we have
241 detected some relevant role for $w = 3$ modes. Moreover, in some cases we find

242 that they are comparable to $w = 1$ and 2 structures.

243 Finally, although waves are often alluded in studies, compliance of observa-
244 tions with wave criteria is often not verifiable or dubious or nonexistent. Our
245 results imply signs of steady structures at planetary scales but no clear indica-
246 tion that they can be called waves. Structures all along the scales that do not
247 definitely meet wave criteria have been found by Lovejoy and Schertzer (2011) in
248 a study of the scaling and cascade properties of diverse meteorological fields and
249 fluxes from European Centre for Medium-Range Weather Forecasts (ECMWF)
250 interim reanalyses. In general, planetary signatures may be better conceptual-
251 ized as disturbances about the zonal mean circulation, which are not necessarily
252 a wave. These perturbations can be mainly produced by two mechanisms: oro-
253 graphic forcing or differential heating (Salby, 1984). Stationary structures may
254 be forced by mechanical or thermal sources anchored to the surface of the Earth.
255 Topography can produce disturbances either by flow forcing or as elevated heat
256 sources. Thermal forcing may be also associated with land-sea transitions or
257 sea surface temperature gradients. The planetary distribution of these sources
258 may ultimately determine the typical space scales of the disturbances.

9 259 **5. Conclusions**

10
11
12 260 Significant wavenumber 1 and 2 seasonally steady structures in zonal ve-
13
14
15 261 locity and temperature have been found in 30 years of reanalysis data at the
16
17 262 middle troposphere (400 hPa) and middle stratosphere (10 hPa) respectively.
18
19
20 263 Wavenumber 3 structures also appear at 400 hPa. The zonal wind 1 modes
21
22 264 exhibit significant inclination angles with respect to the meridians. The winter
23
24
25 265 hemisphere shows stronger activity, whereby the NH exhibits a larger amount of
26
27 266 structures and more intense amplitudes than the SH. Middle latitudes exhibit
28
29
30 267 the most significant cases and low latitudes the least significant ones. Longitu-
31
32 268 dinally oriented land-sea transitions at $\pm 65^\circ$ and -35° latitudes appear to play a
33
34
35 269 significant role for the presence of steady planetary structures. The stratosphere
36
37 270 exhibits a much simpler picture than the troposphere. There are possible theo-
38
39
40 271 retical explanations for this characteristic, but this fact may also be due to the
41
42 272 lower reliability of the numerical model of reanalysis in describing the strato-
43
44
45 273 sphere and to the smaller amount of data being assimilated at these altitudes.
46
47 274 Large scale structures with respectively NE-SW (NH) and NW-SE (SH) tilts in
48
49
50 275 the observed T and U phase lines recall the quasi-stationary Rossby wave trains
51
52 276 that favor the poleward transport of angular momentum. It must be finally
53
54
55 277 stated that the observed planetary structures do not exhibit fulfillment of wave

*Detailed Response to Reviewers

Reviewer 1

Paragraph 1: please see page 7 (middle paragraph), the paragraph on page 14 and the last sentence of Conclusions in the new version of the manuscript.

Paragraph 2: please see the paragraph spanning the pages 12-14 of the new version of the manuscript.

Paragraph 3: please see the last paragraph on page 11 of the new version of the manuscript.

Reviewer 3

> 1. I do not understand the sentence on line 159 "There are only no
> symbols at the highest latitudes.". Would you like to say "There are
no
> structure sat the highest latitudes ." or what do you mean?

We followed your suggestion, please see line 168 of the new version of the manuscript.

> 2. Lines 193-195: This statement is not correct. Significant wavenumber
> 3 does not appear at 10 hPa.

We reformulated the sentence, please see lines 260-263 of the new version of the manuscript.

> 3. Wording and misprints:

> - Lines 114, 120 and 125: "large" should be "high".

> - Line 116: write "in zonal wind (U) the features".

> - Line 128: write "than temperature (T) ones".

Please see lines 123, 129, 134, 125 and 137 of the new version of the manuscript.
