A method using ion chromatography coupled to high-resolution Orbitrap mass spectrometry was developed to quantify highly-polar organic compounds in aqueous filter extracts of atmospheric particles. In total, 43 compounds, including short-chain carboxylic acids, terpene-derived acids, organosulfates, and inorganic anions were separated within 33 min by a KOH gradient. Ionization by electrospray was maximized by adding 100  $\mu\text{L min}^{-1}$  isopropanol as post-column solvent and optimizing the ion source settings. Detection limits ( $S/N \geq 3$ ) were in the range of 0.075–25  $\mu\text{g L}^{-1}$  and better than previously reported for 22 compounds. Recoveries of extraction typically range from 85 to 117%. The developed method was applied to three ambient samples, including two arctic flight samples, and one sample from Melpitz, a continental background research site. A total of 32 different compounds were identified for all samples. From the arctic flight samples, organic tracers could be quantified for the first time with concentrations ranging from 0.1 to 17.8  $\text{ng m}^{-3}$ . Due to the minimal sample preparation, the beneficial figures of merit, and the broad range of accessible compounds, including very polar ones, the new method offers advantages over existing ones and enables a detailed analysis of organic marker compounds in atmospheric aerosol particles.

## 1 | INTRODUCTION

Aerosol particles in the atmosphere consist of inorganic substances and a large number of organic compounds. In contrast to the well-characterized inorganic fraction, much less is known about concentrations and sources of organic constituents. A significant fraction of the organic aerosol consists of small polar compounds, including low molecular weight mono- and dicarboxylic acids (MCAs and DCAs, respectively), terpene-derived acids, and organosulfates [1, 2]. These compounds originate from a variety of primary and secondary sources and are important tracers for the source assignment of aerosol particles. Small MCAs are emitted by the combustion of fossil fuels and biomass [3], or in a biogenic way by fungi, bacteria, pollen, and algae [4]. Small DCAs originate from cigarette smoke, the pyrolysis of vegetation, or fossil fuel combustion [5,6]. In general, organic acids are mainly formed secondarily from precursor gases. Plant-emitted isoprene is an important precursor for pyruvic acid, glyoxylic acid and glycolic acid [7], which can be subsequently oxidized to form oxalic acid [8,9]. In particular, pinonic, pinic, and norpinonic acid are a result of the photochemical oxidation of terpenes emitted by vegetation [10]. Similar to carboxylic acids, organosulfates are ubiquitously present in aerosol particles [2]. They can be formed by the reaction of organic precursor compounds with gaseous  $\text{SO}_2$  [11] or by acid-catalyzed multiphase reactions with acid sulfate aerosol [12–15]. Due to the lack of authentic standards, there are still uncertainties regarding concentrations in the ambient aerosol and the presence of unknown or unidentified organosulfates. Compared to ground measurements, relatively little is known about the composition of aerosol particles from high altitudes, as flights are expensive and measurements are difficult to perform. For polar latitudes and particularly the arctic region, only few flights have been performed until today, mostly focusing on inorganic tracers such as  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ , and metals [16–18]. The significance of organic components in this environment is still largely unclear. To enable the determination and quantification of organic tracers following in-flight sampling especially for high altitudes and polar latitudes, a highly sensitive method is needed that allows simultaneous determination of a large number of compounds with low sample consumption. So far in atmospheric aerosol samples, organic markers are determined with GC/MS [19], LC/MS [20], Ion chromatography-conductivity detection (IC-CD) [21] and CE [22]. GC/MS [23, 24] is characterized by high sensitivity and efficient analyte separation. For its application, carboxylic acids need to be derivatized to volatile compounds. They are usually concentrated by volume reduction in a vacuum, which makes sample preparation time-consuming and

potentially an error-prone working step [25]. IC-CD allows a simple, reliable, and inexpensive separation and quantification of water-soluble organic acids. The analysis is limited to ionic or ionizable and hydrophilic species and may suffer from peak overlap of individual compounds [21, 26] when a large number of species is present in the sample. Alternatively, CE is used for small carboxylic acids due to its fast separation and good separation efficiency [27]. The detection is mostly carried out by UV [28, 29], or via ESI coupled to MS [25, 27, 30]. Organosulfate analysis is performed by reversed-phase LC [12, 31] or hydrophilic interaction liquid chromatography (HILIC) coupled to MS [32, 33]. However, it is often challenging to separate these small polar compounds using reversed-phase LC [34], whereby HILIC separations are associated with reproducibility issues [35, 36]. Coupling advanced ion chromatography separation techniques to an Orbitrap mass spectrometer (IC-MS) is a promising alternative to overcome these separation issues and would allow for determining organic acids and organosulfates with a single method. In addition, the sample preparation could be uniformed to save time and sample volume. At the same time, MS detection allows a highly sensitive identification and quantification of low concentrated tracers from complex substance mixtures. Up until today, IC-MS has been used for surface-water [37], food samples [38], forensics samples [39], urine samples [40], and pesticides [41]. In the field of atmospheric science, only a few IC-MS applications are known, focusing on inorganic anions and carboxylic acids [42, 43]. The objective of the present study was the development of an IC-MS method, enabling the separation and sensitive detection of a large number of anionic compounds in aqueous aerosol particle extracts from arctic flight and continental ground measurements. Therefore, IC was coupled with an Orbitrap-MS and a standard mixture containing inorganic ions, organosulfates, mono-, di-, and tricarboxylic acids, and terpene-derived acids was used for method development. In order to optimize the LODs, various organic post-column solvents as well as basic and acidic additives and ESI source parameters were varied and tested. The final method was validated and used to quantify the analytes in aqueous extracts of aerosol particles from different sites.

## 2 | MATERIALS AND METHODS

### 2.1 | Chemicals

Standard compounds were obtained from Sigma Aldrich (St. Louis, USA), and Santa Cruz Biotechnology

(Huston, USA) in purity >95% or synthesized (Supporting Information Table S1). Stock solutions of all analytes were prepared by dissolution in ultrapure water (>18.20 M $\Omega$ /cm). From the stock solutions, a standard mixture was prepared, which included the MCAs glyoxylic acid, glycolic acid, pyruvic acid, the homologous series of DCAs from oxalic acid up to azelaic acid, the substituted DCAs methylsuccinic, methylmalonic, dimethylmalonic, fumaric, mesaconic, maleic, malic, citraconic, tartaric and tartronic acid, as well as the tricarboxylic acid citric acid. In addition, the terpene-derived acids pinic acid, cis-pinonic acid, 3-methyl-1,2,3-butanetricarboxylic acid (MBTCA), diaterpenylic acid acetate (DTAA), norpinonic acid, trans-norpinic acid, terebic acid, camphoric acid, a series of organosulfonates and -sulfates including hydroxyacetone sulfate (HAS), limonaketone organosulfate (limonaketoneOS), 2-hydroxy- $\alpha$ -pinene organosulfate ( $\alpha$ -pineneOS), 2-hydroxy-carene organosulfate (careneOS), mannose-6-sulfate, methylsulfate, methansulfonate (MSA), the organosulfate surrogates camphorsulphonate (CSA), and octylsulfate, and the inorganic ions sulfate, sulfite and bromide were included. To stabilize sulfite, a small volume of formaldehyde solution (37 %, Merck, Darmstadt, Germany) was added as an oxidation inhibitor. The KOH eluent cartridge for the IC was purchased from Thermo Fisher Scientific, Waltham, USA. Organic post-column solvents acetonitrile (ACN) and methanol (MeOH) were obtained in LC-MS grade from Fisher Scientific (Loughborough, UK). LC-MS Chromasolv™ isopropanol (IPA) was purchased from Honeywell. LiChropur® ammonium hydroxide solution (25 %), LiChropur® formic acid (puriss.  $\geq$  98 %), and LiChropur® acetic acid (puriss.  $\geq$  98%) were purchased from Merck as acidic and basic additives.

## 2.2 | Setup of the ion chromatography Orbitrap MS system and used software

For separation, a Dionex Integrion High Pressure Ion Chromatography (Thermo Fisher Scientific, Waltham, USA) system consisting of a pump, an eluent generator, a continuously regenerated anion trap column, an autosampler, a suppressor, and a conductivity detector was used. After separation, a defined flow of an organic post-column solvent was added via T-piece into the aqueous eluent stream through an external Vanquish pump (Thermo Fisher Scientific, Waltham, USA). The flow was then led into the ESI source of a Q Exactive Plus mass spectrometer (Thermo Fisher Scientific, Waltham, USA). For instrument control and data recording, Chromeleon 7.2 and the Xcalibur software bundle (4.0.27.19) were used.

## 2.3 | Separation and ionization conditions

For separation, the AS19-4  $\mu$ m separation- and an AG19-4  $\mu$ m guard column, were used at 30°C. A volume of 5  $\mu$ L was injected in partial loop mode. The method runtime was 42 min utilizing a multi-step KOH gradient. The initial KOH concentration was set to 10 mM, held for 6 min, and increased linearly with different slopes to 45 mM, 60 mM, and 100 mM after 21, 23, and 25 min, respectively. After reaching the maximum KOH-concentration, the mobile phase composition was held for 6 min and then set back to 10 mM for 11 min of equilibration. The eluent flow rate was set to 0.25 mL min<sup>-1</sup>, while a flow of 0.10 mL min<sup>-1</sup> IPA was added post-column. The solvent mixture, including the analytes, was led into the ESI source and ionized according to the following parameter settings: capillary temperature of 253°C, spray voltage of 3.25 kV, aux gas flow rate of 5 arbitrary unit (A.U.), sheath gas flow rate of 46 A.U., and the aux gas heater temperature of 406°C. The probe was set to position D while the Orbitrap was operated in full-MS-negative mode with a resolution of 35 000 in the range of 50–300 *m/z*.

## 2.4 | Optimization and validation of the ion chromatography Orbitrap MS coupling

To improve the signal intensity of the method and thus its LOD, the influence of the flow rate of organic post-column solvents, the volume fraction of acidic and basic additives, and the ESI source parameters were investigated in the order mentioned above. For this purpose, a standard mixture containing all compounds at a concentration of 50  $\mu$ g L<sup>-1</sup> was used, and the influence of each investigated parameter on the cumulative peak area was determined. After each optimization step, the largest cumulative peak area was selected as starting point for further investigations. For method validation, the final optimized IC-MS method LODs (*S/N*  $\geq$  3) were determined by analyzing dilution series of standard mixtures. If an *m/z* trace showed no noise, the lowest detectable concentration was set as the LOD. The calibration function was determined from a series of 15 standard mixtures ranging from 0.025 to 500  $\mu$ g L<sup>-1</sup>. The RSD of peak area (PA) was used to characterize interday- and intraday repeatability. Intraday repeatability was determined by nine and interday repeatability by three injections of the same standard mixture on the same and on three different days, respectively. The recoveries of aqueous sample extraction were determined from spiked filters, as appropriate reference materials for these analytes in ambient particles are not available. Therefore, 47 mm polycarbonate filter

(Whatman, Little Chalfont, UK) and 13 mm quartz fiber filter (MK 360, 180 Munktell, Sweden) were spiked with a defined volume of a 1000  $\mu\text{g L}^{-1}$  standard solution. The filters were dried and transferred to a pre-cleaned 5 mL syringe (Omnifix, Braun, Melsungen, Germany). To simulate the different extraction protocols applied for real samples, either 3 mL or 0.25 mL of ultrapure water was added to a 47 mm polycarbonate filter, while 0.25 mL was added to a quartz fiber filter. Afterwards, the solutions were shaken for 2 h at 420 rpm. The resulting extracts were filtered through a 0.2  $\mu\text{m}$  syringe filter (Acrodisc 13, Pall, Dreieich, Germany), transferred into a vial, and measured with the developed method. Mean recoveries were determined from five replicate experiments. In parallel, three non-spiked filters were used as a reference.

## 2.5 | Sampling and sample extraction

For testing the method, three ambient samples were analyzed (I) from a flight of the ACLOUD campaign (Arctic CLOUD Observations Using airborne measurements during polar Day) [44], (II) from the rural background station Melpitz in Germany (12° 56' E, 51° 32' N) and (III) from a flight of the PAMARCMiP 2018 (Polar Airborne Measurements and Arctic Regional Climate Model Simulation Project 2018). During ACLOUD, the research aircraft POLAR 6 started on June 8th and 9th 2017 from Longyearbyen, Svalbard (15° 38' E, 78° 13' N) and flew over the arctic ocean towards the pack ice above 80° N and back. By means of a Counterflow Virtual Impactor Inlet [45] which was operated to sample ambient aerosol particles, 1.12 m<sup>3</sup> ambient air was accumulated on a 13 mm fiber filter (MK 360, Munktell, Sweden). Furthermore, a sample was taken with the in-house developed High-Volume Aerosol Sampler (HERA) on 26<sup>th</sup> January 2018 at the Melpitz research station in Germany. The HERA sampler was operated in a measurement container and connected via stainless steel tubing to an existing inlet. With a pump, atmospheric particulate matter with an upper aerodynamic diameter of 10  $\mu\text{m}$  (PM<sub>10</sub>) was accumulated with a flow rate of 0.0167 m<sup>3</sup> min<sup>-1</sup> for 24 h on a 47 mm polycarbonate filter (Whatman, Little Chalfont, UK). After first tests at the ground station of Melpitz, the prototype of HERA was also used during the PAMARCMiP 2018 campaign at the research aircraft Polar 5. On 2nd April 2018, the aircraft took off from Villum research station in Greenland (81° 36' N, 16° 40' W) into direction of Svalbard. Halfway along the route, the aircraft turned back and made targeted flights over the Arctic Ocean and along the pack ice border. During the flight, the HERA sampler was connected over a ~6 m long, horizontal stainless-steel tube with a shrouded inlet diffuser mounted at the outside of the aircraft [46]. Thus, aerosol particles of 2.32 m<sup>3</sup>

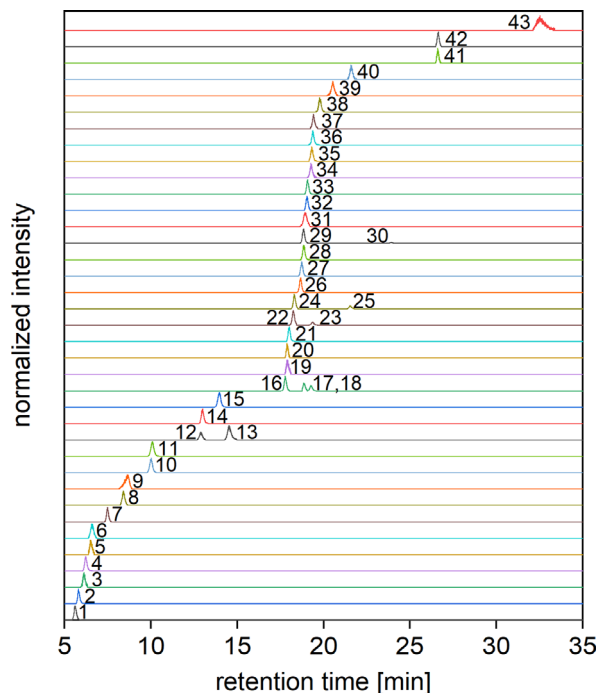

ambient air were accumulated on a 47 mm polycarbonate filter. After sampling, all filters were stored at a temperature < 0°C. For extraction, the ACLOUD filter was shaken in 0.25 mL ultrapure water at 420 rpm for 2 hours. The filters of the Melpitz- and PAMARCMiP-campaign were part of an interdisciplinary analysis protocol, in which in addition to their chemical composition other sample properties were investigated. Therefore, their extraction protocol differed as follows: The filters were shaken in 3 mL ultrapure water and 2.9 mL of the resulting extract was diluted with 3.1 mL ultrapure water. To protect the column from remaining particles, all extracts were filtered with a pre-cleaned 5 mL syringe (Omnifix, Braun, Melsungen, Germany) through a 0.2  $\mu\text{m}$  syringe filter (Acrodisc 13, Pall, Dreieich, Germany), transferred into the vial, and measured with the developed IC-MS-method.

## 3 | RESULTS AND DISCUSSION

### 3.1 | Method optimization

#### 3.1.1 | Separation conditions

Even with an MS detector, the choice of the IC-column has to be made carefully in order to elute as many compounds as possible with good separation, peak shapes, and S/N. Although anion exchange is the dominating separation mechanism, the hydrophobicity of the column stationary phase also affects the retention of the analytes. The Virtual Column Separation software implemented in Chromeleon 7.2 uses a data set of known retention times of compounds to suggest appropriate columns. For bromide, nitrate, sulfite, sulfate, glycolate, pyruvate, malonate, maleate, glutarate, malate, tartrate, oxalate, fumarate, and citrate, the software proposed to use the AS11-HC-4  $\mu\text{m}$  or AS19-4  $\mu\text{m}$  separation column. Due to its medium-low hydrophobicity, the AS11-HC-4  $\mu\text{m}$  typically is the column of choice for the separation of small polar organic acids, but is unsuitable for the separation of larger organosulfates. Therefore, the AS19-4  $\mu\text{m}$  column with low hydrophobicity was chosen for further investigations. For separation, the standard flow rate of 0.25 mL min<sup>-1</sup>, the column temperature of 30°C and the KOH gradient were adopted from the AS19-4  $\mu\text{m}$  column manual. Then a last 100 mM step was added to the KOH gradient to elute highly retained species and free the column from possible matrices of the sample extracts. Figure 1 shows the chromatogram for a 50  $\mu\text{g L}^{-1}$  standard, where all compounds are separated within 33 min. Shorter polar MCAs in the form of glycolate, pyruvate, and glyoxylate, as well as the organosulfonate MSA and the monoterpene-derived norpinonate, terebate, and

**FIGURE 1** Chromatogram of the multi-standard (concentration  $50 \mu\text{g L}^{-1}$ ) using an ASI9-4  $\mu\text{m}$  column. (1) Glycolate, (2) Norpinonate, (3) Terebate, (4) cis-Pinonate, (5) Pyruvate, (6) MSA, (7) Glyoxylate, (8) CSA, (9) LimonaketonOS, (10) Methylsulfate, (11) HAS, (12)  $\alpha$ -PineneOS, (13) CareneOS, (14) Bromide, (15) Nitrate, (16) Dimethylmalonate, (17) Glutarate, (18) Methylsuccinate, (19) Mannose-6-sulfate, (20) Sulfate, (21) Sulfite, (22) Methylmalonate, (23) Succinate, (24) Citraconate, (25) Mesaconate, (26) Malonate (27) DTAA, (28) Malate, (29) Maleate, (30) Fumarate, (31) trans-Norpinate, (32) L-Tartrate, (33) Tartronate, (34) Pinate, (35) CA, (36) Adipate, (37) Oxalate, (38) Pimelate, (39) Suberate, (40) Azelate, (41) Citrate, (42) MBTCA, (43) Octylsulfate

cis-pinonate elute earliest between 5.62 and 7.51 min. All inorganic ions and organosulfates, except octylsulfate, can be detected between 8.39 and 18.03 min. The dicarboxylic, the tricarboxylic and the remaining terpene-derived acids elute in a time window of 17.78–26.66 min. Octylsulfate elutes last from the column after 32.52 min. Coelution is observed for (I) methylsulfate and hydroxyacetonesulfate at 10.01 min, (II) dimethylmalonate, sulfate, and mannose-6-sulfate at 17.89 min, (III) methylmalonate and citraconate at 18.25 min, (IV) malonate and DTAA at approximately 18.68 min, (V) maleate, malate, and glutarate at 18.85 min, (VI) L-tartrate and tartronate at 19.04 min, (VII) methylsuccinate, pinnate, and camphorate at 19.27 min, (VIII) succinate, adipate, and oxalate at 19.40 min, and (IX) mesaconate and azelate at 21.53 min. However, all isomeric analytes are completely baseline separated. The organosulfates limonaketonOS, careneOS, and octylsulfate showed peak widths up to 0.7 min because of peak fronting and tailing. The remaining compounds elute in excellent peak shapes.

### 3.1.2 | Optimization of the post-column solvent

To enhance ESI and to optimize sensitivity, organic solvents comprising MeOH, ACN, and IPA were added post-column to the IC effluent. The influence of this post-column addition on single analyte peak areas, as well as their cumulative peak areas, was investigated. For each organic post-column solvent, the flow rate was varied in  $50 \mu\text{L min}^{-1}$  increments from 50 to  $450 \mu\text{L min}^{-1}$  (Figure 2). For MeOH and ACN (Figure 2A and B), the normalized peak areas of almost all analytes increase with higher flow rates of up to 250–350  $\mu\text{L min}^{-1}$  and 300–400  $\mu\text{L min}^{-1}$ , respectively. Above these ranges, signals mostly remain constant or start to decrease. For IPA (Figure 2C), a flow rate of up to 100  $\mu\text{L min}^{-1}$  led to a small increase in peak areas for the majority of analytes, whereas higher flow rates yielded lower signal intensities for most compounds instead. In general, ESI response was increased when adding organic solvents due to their low surface tensions, low dielectric constants [47], low boiling points [48], and high gas-phase proton affinities [49]. On the other hand, since ESI-MS is a concentration-sensitive technique [50], the addition of post-column solvents dilutes the IC effluent, leading to a decreasing cumulative peak area at higher flow rates [48]. Furthermore, excessive flow rates were previously shown to lower ionization efficiency due to the formation of larger droplets at the ESI emitter [51, 52]. From the cumulative peak areas in Figure 2D, it can be seen that on average for flow rates up to 300  $\mu\text{L min}^{-1}$ , the MS response is strongest for IPA among the three different solvents. At higher flow rates, MeOH exhibits slightly stronger signal intensities, whereas ACN always gives the weakest average response. A possible explanation could be the formation of a more stable spray when using MeOH and IPA compared to ACN. According to Straub and Voyksner [53], this is due to the higher onset voltage (the lowest voltage, at which electric discharge takes place) of both solvents, preventing the formation of an electrical discharge that can interfere with the spray formation. Since the use of a flow rate of 100  $\mu\text{L min}^{-1}$  IPA leads to the largest growth of the cumulative peak area, it is used as post-column solvent for further optimization steps.

### 3.1.3 | Influence of post-column solvent additives

To test for possible further increases of detection sensitivity, acidic and basic additives, i.e., formic acid (FA), acetic acid (AA), and ammonium hydroxide ( $\text{NH}_4\text{OH}$ ), were added to the post-column injection of IPA in volumetric proportions of 0.1–0.5 vol%. As can be seen from Figure 3,

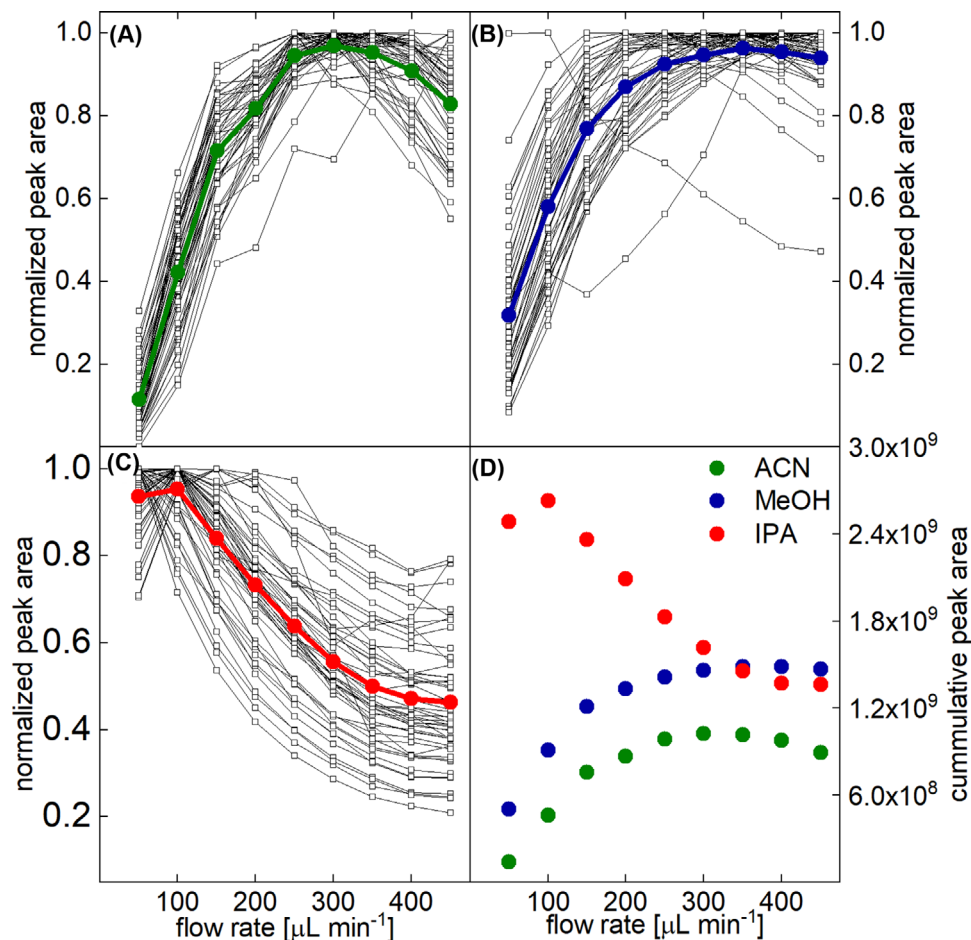

FIGURE 2 Dependence of the normalized peak area on the flow rate of added (A) ACN (green), (B) MeOH (blue), and (C) IPA (red). Black lines indicate individual analytes, and colored lines correspond to the mean values determined from all compounds. Panel (D) shows cumulative peak areas of all components

all additives led to a decrease in signal intensities, thus giving the highest cumulative peak areas for pure IPA. For  $\text{NH}_4\text{OH}$ , a continuous decrease in the cumulative peak area was observed with increasing additive fractions. For both acids, the determined cumulative peak areas remain at approximately the same level, which was lower for FA than for AA. Additional protons from the acids could lead to a neutralization of the analyte ions and thus to a decrease of the cumulative peak areas. Considering the lower  $\text{p}K_a$  value of FA (3.75) compared to AA ( $\text{p}K_a$  4.75), more protons are formed when using FA, explaining the lower cumulative peak area. Also, signals of formate dimers ( $m/z = 91.00$ ) and acetate ( $m/z = 59.01$ ) were observed in the mass spectra and could cause suppression effects in the ESI [54] that decrease the signal intensity. Suppression effects could also explain the continuous decrease in signal intensity for the use of  $\text{NH}_4\text{OH}$ , since in the mass spectra the formation of intensive background signals at  $m/z$  57.03 and 60.01 are detectable. Overall, regardless of the nature and quantity of additive added, no increase in the cumulative peak area could be achieved.

Therefore, the optimization was continued with pure IPA at a flow rate of  $100 \mu\text{L min}^{-1}$ .

### 3.1.4 | Optimization of the ESI source parameters

In the last step, the ESI source parameters were optimized. Starting points were suggested by the Tune software (Thermo Fisher Scientific, Waltham, USA) for a flow rate of  $250 \mu\text{L min}^{-1}$  as follows: capillary temperature of  $253^\circ\text{C}$ , spray voltage of 2.5 kV, auxiliary gas flow rate of 11 A.U., sheath gas flow rate of 46 A.U., auxiliary gas heater temperature of  $406^\circ\text{C}$ . For the optimization, the parameters were systematically changed in the order mentioned above, keeping all other settings constant at the value leading to maximum cumulative peak areas. If no change in response could be observed, the initial value was used. As shown in Figure 4A, the capillary temperature did not lead to significant changes in the cumulative peak area, hence the suggested temperature of  $253^\circ\text{C}$  was used. In

**FIGURE 3** Influence of the post-column solvent additive on the cumulative peak area from IPA (red) at a flow rate of  $100 \mu\text{L min}^{-1}$  and added portions of AA (black), FA (orange), or  $\text{NH}_4\text{OH}$  (blue)

contrast, the spray voltage had a strong influence on signal intensities giving a maximum at 3.25 kV (Figure 4B). The optimum spray voltages provide a stable Taylor cone at the tip of the ESI-needle, where ion-containing droplets of a certain size are formed [55]. At lower and higher voltages, unfavorable effects on the Taylor cone likely led to the observed lower signal intensities. The auxiliary gas flow rate, sheath gas flow rate, and auxiliary gas heater temperature assist the desolvation by adjusting the amount and temperature of introduced  $\text{N}_2$ -drying gas. In addition to this, the auxiliary gas flow rate and sheath gas flow rate focus the spray into the direction of the MS-entrance [56]. Best results were found for an auxiliary gas flow rate of 5 A.U. and a sheath gas flow rate of 46 A.U. The mean values of the cumulative peak areas of the aux gas heater temperatures of 356, 406, and  $456^\circ\text{C}$  were within the uncertainty range of the measurements, with a maximum of  $4.96 \times 10^9$  at  $406^\circ\text{C}$ , which was chosen for further measurements. As can be seen in Figure 4F, the spray voltage and the auxiliary gas flow rate have the greatest influence on the cumulative peak area. As mentioned above, the spray voltage determines the stability of the spray and the size of the ion-carrying droplets and thus significantly affects the number of formed ions [55]. Similarly, the auxiliary gas flow rate, sheath gas flow rate, and aux gas heater temperature influence the efficiency of the ESI process [56, 57], which explains the observed impact of

these parameters on signal intensities. Since the aux gas flow rate was optimized first, the corresponding influence is the greatest. For method validation, the following final ESI settings were used: capillary temperature of  $253^\circ\text{C}$ , spray voltage of 3.25 kV, auxiliary gas flow rate of 5 A.U., sheath gas flow rate of 46 A.U. and the auxiliary gas heater temperature of  $406^\circ\text{C}$ .

### 3.2 | Method validation

The optimized method was validated by analyzing a series of standard mixtures with 43 compounds. The resulting figures of merit and LODs from other methods are summarized in Table 1. For the 47 mm polycarbonate filters extracted with 0.25 mL ultrapure water, determined recoveries were in the range of 85–117% and are thus considered sufficiently close to a complete extraction of the analytes from the filter material. Similar results for the extraction of the polycarbonate filter with 3.00 mL and the extraction of the quartz fiber filter with 0.25 mL are listed in Table S2. With regards to the measured peak area, intraday and interday repeatability were below 3.0 % for all compounds except for nitrate, fumarate, and citrate. Both, linear and quadratic regression lines were applied in the calibration ranges from 0.25 to  $500 \mu\text{g L}^{-1}$ . To reduce the error of the calibration function a  $1/X$  or  $1/X^2$  weighting was applied. The obtained coefficients of determination  $R^2$  ranging from 0.9659 to 0.9996 and can be considered as satisfactory. The LODs of all analytes are between 0.075 and  $25 \mu\text{g L}^{-1}$  and are compared to most sensitive reported ones from the literature. For inorganic anions, best available LODs from the literature tend to show a factor of 11–3116 higher LODs, except for nitrate, where the LOD of the IC-MS method is a factor of 5 lower than the literature reference. In the case of MCAs, the LODs are equal or lower by up to a factor of 16. Among the 18 di- and tri-carboxylic acids, the LODs of oxalate, glutarate, dimethylmalonate, methylsuccinate and L-tartrate could be improved by a factor of up to 130. The LODs of methylmalonate, citraconate, malonate, malate and adipate were about a factor of 2 lower or higher. Reference studies with lower LODs could be found for succinate, pimelate, suberate, azelate, fumarate, maleate, and citrate. For the remaining DCAs, no corresponding literature reference could be found. The same applies to the terpene-derived compounds DTAA, terebate, trans-norpinate, and camphorate, except for pinate with LODs of the developed IC-MS method being nearly equal or greater by a factor of 10 than the best available literature LOD. Among the organosulfates, similar to the literature references LODs could be found for all compounds except the surrogate mannose-6-sulfate. For HAS and methylsulfate, the LODs of the IC-MS are lower by a factor of 35. For

the remaining compounds, LODs are nearly equal to the literature references. Even with low injection volumes of 5  $\mu\text{L}$ , compared to previously published methods the IC-MS could improve the detection for 22 compounds. Due to the low LODs, the filtered aqueous sample extraction can directly be injected. An error-prone and time-consuming further enrichment of the samples, e.g., with solid-phase extraction or the evaporation of excess solvent, is avoided. Accordingly, the method benefits from a minimal sample preparation before the measurement. Furthermore, the methods listed in Table 1 focus only on a few numbers of compounds and have difficulties especially with the analysis of organosulfates. Since LC-MS is used for the separation of larger organosulfates like limonaketoneOS,  $\alpha$ -pineneOS, and careneOS as well as the surrogates octylsulfate and CSA [68, 69], LC cannot properly separate small polar compounds. In contrast, organosulfates contained in samples with  $m/z > 200$  have difficulties to be baseline-resolved with HILIC-MS [33] and suffer under poor peak shape. Smaller compounds elute within the first minute near the dead volume and therefore can be suppressed by coeluting of a large number of other compounds. The method presented in this study is able to

baseline separate and detect all organosulfates and avoids suppression effects by early elution.

### 3.3 | Method application

With the developed IC-MS method three ambient particle samples from Melpitz and the arctic flight campaigns ACLOUD and PAMARCMiP 2018 were investigated. The corresponding chromatograms are shown in Supporting Information Figures S1–S3. The atmospheric concentrations of the observed analytes are listed in Table 2 and were calculated including a correction for field blank values. Typically, nitrate and sulfate are the main components of particle mass and showed the highest concentration in all samples. In addition, the samples from the rural background station in Melpitz show 2.7  $\text{ng m}^{-3}$  and the ACLOUD sample 0.2  $\text{ng m}^{-3}$  sulfite. Bromide was determined in all three samples with an average concentration of 0.9  $\text{ng m}^{-3}$ . In previous studies, bromide has been identified as an important component of sea salt aerosol [70, 71], arctic snow [72, 73], and cloud and fog samples of polluted air [74]. Besides the inorganic anions,

several organic tracers were identified and quantified. For the MCAs glycolate, pyruvate and glyoxylate, the concentrations of the Melpitz sample ranged from 10.5 to 23.1  $\text{ng m}^{-3}$ . Anthropogenic sources like the combustion of fossil fuels and the burning of biomass could be relevant sources for these compounds [3]. According to the authors' knowledge, MCAs, DCAs, MSA, and terpene-derived compounds could be determined for the first time from filter-based flight measurements in the arctic atmosphere. Pyruvic acid and glycolic acid were also determined in the sample from the ACLOUD campaign. Due to the flight path above Svalbard and the arctic ocean both compounds, as well as the detected DCAs oxalic, succinic, glutaric, suberic, and azelaic acid could be of rural and marine origin. Also hydroxylated diacids tartronic and tartaric acid were found in marine samples before [75] and might therefore be attributed to oceanic sources. Longer chain DCAs ( $C_5$ - $C_{12}$ ) are known to result from the photochemical oxidation of fatty acids found in the sea surface and can be oxidized to short chain DCAs ( $C_2$ - $C_4$ ) [76, 77]. Marine emission would also explain the determination of adipic acid, pimelic acid, and azelaic acid in the sample from the PAMARCMiP 2018 campaign. Besides, for the research station in Melpitz anthropogenic emissions and subsequent photochemical oxidations seem to be a possible explanation for the high variety of detected diacids [1], including low molecular weight DCAs ( $C_2$ - $C_4$ ), hydroxylated DCAs such as tartronic, tartaric and malic acid, as well as the unsaturated DCAs maleic and fumaric acid and branched DCAs such as methylmalonic, dimethylmalonic, and methylsuccinic acid, which are known to be formed by the oxidation of aromatic hydrocarbons [6, 42, 76] and methylcycloalkenes [78]. Citraconic acid has, to the best of the author's knowledge not yet been detected in atmospheric particles. The detection of the terpene derived acids MBTCA, terebic acid, pinic acid, and DTAA indicates a certain vegetative activity [10] and the emission of terpenes also during wintertime. Terebic acid, MBTCA, and cis-pinonic acid were also determined from the filter of the ACLOUD campaign. According to the literature [79], terpenoid compounds can correlate moderately with other tracers of biological activity in the ocean like MSA, that could also be quantified with 17.8  $\text{ng m}^{-3}$ . In

lower concentrations of  $4.6 \text{ ng m}^{-3}$  MSA was also found in the Melpitz sample. Further organosulfates were detected in the form of  $0.6 \text{ ng m}^{-3}$  HAS and  $0.3 \text{ ng m}^{-3}$  methylsulfate, which were both reported in urban areas before [33, 80]. Further organosulfates could not be detected or were below the field blank values of the samples.

## 4 | CONCLUSIONS

An IC-MS method was developed to determine organic acids, organosulfates, and inorganic anions in aqueous extracts of aerosol particles with high sensitivity. All compounds were separated within 33 min using an AS19-4  $\mu\text{m}$  column with a multi-step KOH gradient. To optimize sensitivity, the influence of organic post-column solvents, acidic as well as basic additives, and the ESI source parameters were investigated. The resulting method is characterized by a good inter- and intraday reproducibility below 3 %, recoveries in the range of 85–117 %, minimal sample preparation and was successfully applied to real samples. Compared to other methods that focus on specific tracers, a broad range of 43 compounds can be determined in a single run. LODs were improved for 22 compounds. In all samples both inorganic anions and MCAs could be detected. The sample from the ground station in Melpitz showed signals for all compound classes. In addition, it was also possible to identify aliphatic long-chain DCAs in the pure arctic air of the PAMARCMiP flight sample. Also, short-chain aliphatic and hydroxylated DCAs as well as terpene-derived acids and MSA could be observed in the sample from the ALOUD campaign. Thus, for the first time, a variety of organic tracers could be determined on arctic flight filters. In future studies, the new method will be applied to a larger set of ambient field samples to quantify concentrations of the described organic tracers and possibly also identify new compounds based on the high-resolution orbitrap MS capabilities.

## ACKNOWLEDGMENTS

We gratefully acknowledge the funding of S. Mertes by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – Project Number 268020496 – TRR 172, within the Transregional Collaborative Research Center “Arctic Amplification: Climate Relevant Atmospheric and Surface Processes, and Feedback Mechanisms (AC)<sup>3</sup>. Furthermore, we thank the DFG for funding the joint development of the HERA sampler under project Hera4HALO (FK HE 3086/31-1 and STR 453/10-1) supporting C. Kwiezinski and C. Jentsch and the subsequent funding of the projects HE 3086/44-1 and STR 453/13-1, which are both part of the DFG priority program HALO SPP 1294.

## CONFLICT OF INTEREST

The authors have declared no conflict of interest.
