HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Regional identification of mechanical properties in arteries

S. Avril^{a*}, M.R. Bersi^b, C. Bellini^b, K. Genovese^c and J.D. Humphrey^b

Keywords: Arteries, mechanobiology, identification, hyperelasticity, mechanical behavior.

1. Introduction

Aortic aneurysms are often characterized by localized changes in aortic wall composition and structure that result from the degradation of elastin, loss of smooth muscle cell function, and remodeling of collagen. Correlations between wall composition and local mechanical properties can potentially provide insight into conditions that render a vessel susceptible to failure. Previous work has shown that chronic angiotensin-II infusion in ApoE^{-/-} mice often results in dissecting aneurysms (Bersi et al. 2012). The objective of this work is to establish a new protocol able to characterize *in vitro* the local mechanical properties of arteries on the murine model.

2. Methods

The constitutive behaviour of the aorta is modeled using a microstructurally motivated constrained mixture bilayer model (Bellini et al. 2014). The media is modeled as a hyperelastic membrane having a strain energy function per unit mass of the form: $W^i = \phi^e W^e + \phi^m W^m$ where ϕ^e is the local mass fraction of elastin for each position (averaged over the thickness) and ϕ^m is the total mass fraction of collagen fibers and smooth muscle cells in the media for each position. In particular, relations for the elastin and smooth muscle are:

$$W^e = \frac{c^e}{2} \left[\left([\lambda_{e1}^m]^2 + [\lambda_{e2}^m]^2 + \left[\frac{1}{\lambda_{e1}^m \lambda_{e2}^m} \right]^2 \right) - 3 \right]$$

$$W^m = \frac{c^m}{4\kappa^m} \left[\left[e^{\kappa^m |[\lambda_{e1}^m]^2 - 1|_+^2} - 1 \right] + \alpha^m \left[e^{\kappa^m |[\lambda_{e2}^m]^2 - 1|_-^2} - 1 \right] \right]$$

where c^e , c^m , κ^m and α^m are material parameters, α^m accounts for the lower contribution of fibers to compression than to tension. Moreover, λ_{e1}^m and λ_{e2}^m are elastic stretches of the elastin in the media. They are defined such as: $\lambda_{e1}^m = \lambda_1^m G^{e1}$, $\lambda_{e2}^m = \lambda_2^m G^{e2}$, where G^{e1} and G^{e2} are the circumferential and axial

deposition stretches, respectively, for elastin. Finally, λ_c^m is the elastic stretch of the collagen fibers and smooth muscle cells in the media, defined as: $\lambda_c^m = \lambda_1^m G^m$, where G^m is the average deposition stretch of collagen and smooth muscle cells in the media.

The adventitia was similarly modeled as hyperelastic membrane having a strain energy function per unit mass of the form: $W^o = 0.05\phi^e W^{e0} + \phi^c W^c + \phi^a W^a$ where $0.05\phi^e W^{e0}$ accounts for the small, but non-negligible, response of elastin in the adventitia. It is assumed that the mass fraction of elastin is 5% that of the media. Additionally, ϕ^c is the local mass fraction of diagonal collagen fibers (oriented respectively and on average at an angle $\mp\beta$ towards the axial direction), ϕ^a is the local mass fraction of axial collagen fibers, W^c is the local strain energy of diagonal collagen fibers, and W^a is the local strain energy of the axial fibers. Hence,

$$W^{e0} = \frac{c^{e0}}{2} \left[\text{tr}(\underline{\underline{C}}_{2D}^{e0}) + \frac{1}{\det(\underline{\underline{C}}_{2D}^{e0})} - 3 \right]$$

where $\underline{\underline{C}}_{2D}^{e0} = \left(\underline{\underline{F}}_{2D}^a \underline{\underline{G}}_{2D}^e \right)^T \underline{\underline{F}}_{2D}^a \underline{\underline{G}}_{2D}^e$ and $\underline{\underline{G}}_{2D}^e$ is the deposition stretch tensor of elastin. Finally,

$$W^c = \frac{c^c}{2\kappa^c} \left[\left[e^{\kappa^c |[\lambda_{c1}^a]^2 - 1|_+^2} - 1 \right] + \alpha^c \left[e^{\kappa^c |[\lambda_{c1}^a]^2 - 1|_-^2} - 1 \right] \right]$$

$$W^a = \frac{c^a}{4\kappa^a} \left[\left[e^{\kappa^a |[\lambda_{c2}^a]^2 - 1|_+^2} - 1 \right] + \alpha^a \left[e^{\kappa^a |[\lambda_{c2}^a]^2 - 1|_-^2} - 1 \right] \right]$$

where c^c , κ^c , c^a , κ^a , α^c and α^a are parameters to be determined and α^c and α^a account for the lower contribution of fibers to compression than to tension. Note, too, that λ_{c1}^a is the average elastic stretch of axial collagen fibers in the adventitia.

It is: $\lambda_a^a = G^a \sqrt{\underline{C}_{2D}^a : (\underline{G}_2 \otimes \underline{G}_2)}$ where G^a is the average deposition stretch of axial collagen fibers in the adventitia. Also, $\underline{C}_{2D}^a = (\underline{F}_{2D}^a)^T \underline{F}_{2D}^a$. λ_{c1}^a and λ_{c2}^a are the average elastic stretches of diagonal collagen fibers in the adventitia (1 and 2 represent 2 symmetric directions in the reference configuration). They are defined as: $\lambda_{ci}^a = G^c \sqrt{\underline{C}_{2D}^c : (\underline{A}_i \otimes \underline{A}_i)}$ where G^c is the average deposition stretch of diagonal collagen fibers in the adventitia and:

$$\underline{A}_i = \cos(\beta) \underline{G}_1 - (-1)^i \sin(\beta) \underline{G}_2$$

Identification. Local mechanical properties are quantified in site-specific aortic segments (Figure 1) by combining, for the first time, a computer-controlled biaxial testing system (cyclic pressure loading at different axial stretches (Gleason et al. 2004), a panoramic-Digital-Image-Correlation measurement system (Genovese et al. 2013), an Optical Coherence Tomographic scanning system, and a regional inverse analysis.

The regional inverse analysis is based on the virtual fields method (Avril et al. 2010) applied at the different stages of the biaxial loading protocol. Eventually, the identified regional mechanical properties are compared to constituent area fractions obtained using quantitative histological analyses.

3. Results and discussion

Two mice aortas were tested: an untreated control aorta and an ANG-II induced dissecting aneurysm. The control aorta showed a gentle cylindrical shape whereas the dissecting aneurysm showed a complex geometry and extensive intramural thrombosis (Figure 1). The average material properties identified on the control aorta showed a good agreement with a traditional identification approach.

When looking at the local properties reported in Tab. 1, important regional variations were identified. These regional variations are related to heterogeneities in the composition of the tissue. Combining such findings with advances in growth and remodeling simulations promises to improve our ability to predict rupture risk in aortic aneurysms.

4. Conclusions

Results highlight the necessity to better understand the mechanobiological processes governing the balance between extracellular matrix production and degradation in health and disease, as ultimately it is alterations to this homeostatic balance that can render vessels susceptible to vascular disorders.
