24 **Abstract**

25 **Background**

26 Bacterivores, mostly represented by protists and nematodes, are a key component of soil
27 biodiversity involved in soil fertility and plant productivity. In the current context of global
28 change and soil biodiversity erosion, it becomes urgent to suitably recognize and quantify
29 their ecological importance in the maintenance of ecosystem functions.

30 **Scope**

31 Using meta-analysis tools, we aimed at providing a quantitative synthesis of the ecological
32 importance of soil bacterivores on ecosystem functions. We also intended to produce an
33 overview of the ecological factors that are expected to drive the magnitude of bacterivore
34 effects on ecosystem functions.

35 **Conclusions**

36 Bacterivores in soil contributed significantly to numerous key ecosystem functions. We
37 propose a new theoretical framework based on ecological stoichiometry stressing the role of
38 C:N:P ratios in soil, microbial and plant biomass as important parameters driving bacterivore-
39 effects on soil N and P availability for plants, immobilization of N and P in the bacterial
40 biomass, and plant responses in nutrition and growth.

45

46 **1. Introduction**

47

48 Soils are some of the most biologically diverse environments, encompassing about 25% of
49 global biodiversity in terms of species (Coleman and Wall 2015; Decaëns 2010). One gram of
50 soil can host 6000 different bacterial genomes, several hundred meters of fungal hyphae and a
51 wide range of protists, nematodes, enchytraeids or mites (Jones et al. 2009; Lavelle and Spain
52 2001; Wall et al. 2010). Through their activities, soil organisms ensure key soil functions
53 (Barrios 2007; Brussaard et al. 2007; Wagg et al. 2014) and contribute to many ecosystem
54 services (de Vries et al. 2013; Kibblewhite et al. 2008).

55 Unfortunately, soils are also among the most threatened environments in terms of biodiversity
56 loss (Kibblewhite 2012). Many pressures (soil erosion, land use change, overexploitation,
57 pollution, biological invasion, etc.) have been identified as directly disturbing soil organism
58 abundance, distribution and activity (Bossio et al. 2005; Dupouey et al. 2002; Foley et al.
59 2005; Gardi et al. 2013; Pimentel 2006; Schlaghamersky et al. 2014). A thorough
60 understanding of the many roles of soil biodiversity is required in order to predict how these
61 threats could damage ecosystem services accomplished by soil organisms.

62 A key component of soil biodiversity involved in soil fertility and plant productivity are
63 bacterivores (Bardgett et al. 1999; Bonkowski 2004; Bonkowski et al. 2009; Brussaard 1997).

64 These bacterivores are mostly represented by protists and nematodes (Ronn et al. 2012).

65 Bacterivorous soil protists are generally unicellular heterotrophic eukaryotes, that were
66 traditionally grouped into ciliates, flagellates, naked amoebae and testate amoebae
67 (Darbyshire 1994). However, molecular studies reveal an enormous taxonomic diversity in
68 soils (Geisen et al. 2014; Geisen et al. 2015), and only the ciliated protists are monophyletic,
69 while flagellated, and naked, and testate amoeboid morphotypes repeatedly originated during
70 protist evolution (Adl et al. 2005; Adl et al. 2012).

71 Despite their small size (average size 2-50 μm), protists can largely contribute to total soil
72 faunal biomass (Bonkowski 2004). Nematodes are small multicellular eukaryotes (0.03-1 mm
73 size range) and form a highly diverse monophyletic group including about one million of
74 species (Lambshhead 1993), making this phylum one of the most diverse animal taxa on Earth
75 (Lambshhead et al. 2004). Both bacterial-feeding protists and nematodes are widely distributed
76 in terrestrial ecosystems and successful colonizers of soil niches (Cowling 1994; Geisen et al.
77 2014). It has been estimated than tens of millions of protists and hundreds of thousands of
78 nematode individuals co-exist in only one forest square meter (Cowling 1994; Foissner 1999;
79 Yeates 2007; Yeates 2003). Still, they remain poorly studied in comparison to other soil taxa
80 (Coleman and Wall 2015; Couteaux and Darbyshire 1998). Only a fraction of protist and
81 nematode species have been described yet, and their biology and ecology remain poorly
82 known (Brussaard et al. 2007). It thus becomes urgent, in the current context of global change
83 that is expected to alter soil bacterivore communities, to suitably recognize the species and to
84 quantify their ecological importance in the maintenance of ecosystems.

85 Here, as a complement to detailed reviews published in the past (Bonkowski 2004;
86 Bonkowski and Clarholm 2012; Bonkowski et al. 2009; Chen et al. 2007), we aimed at
87 providing a quantitative synthesis of the ecological importance of bacterivores in soil on
88 ecosystem functions using meta-analysis tools. We also intended to produce an overview of
89 the ecological (biotic and abiotic) factors that are expected to drive the magnitude of their
90 effects on ecosystem functions.

91

92 **2. Meta-analysis - Data sources, extraction and analysis**

93

94 We investigated the literature published in peer-reviewed journals before December 2014
95 through computer searches in available databases (Google Scholar and ISI Web of

96 Knowledge), with no restriction on the year of publication, that investigate bacterivore-
97 induced effects. We used the following key-words (alone or in combination): soil,
98 biodiversity, bacteria, bacterivore, bacterial-feeders/grazers, protozoa, protists, nematodes,
99 predators, mycorrhiza, earthworms, nodules, nutrient, nitrogen, phosphorus, microbial loop.
100 We also searched studies in the reference lists of relevant articles and reviews. We selected
101 studies that (i) tested the effects of bacterivores on ecosystem functions by successfully
102 manipulating soil bacterivores in controlled experimental conditions, (ii) measured at least
103 one function of interest, and (iii) reported means of treatment and control. We excluded field
104 studies that monitored soil bacterivore population changes after perturbation or during
105 seasonal cycles, or eliminated soil bacterivores by adding biocides in the soil, freezing or
106 sieving the soil without measuring the success of the elimination. We also excluded studies
107 comparing low *versus* high soil bacterivore densities and modelling studies.

108 We analyzed the effects of bacterivores on 18 microbial and plant functions: soil microbial
109 biomass (measured by fumigation or substrate-induced respiration), soil bacterial number
110 (measured by plate counting), soil microbial basal respiration, microbial metabolic quotient
111 (microbial respiration divided by microbial biomass carbon), soil phosphatase activity, soil
112 net N mineralization, soil net P mineralization, plant growth (shoot and root biomass,
113 shoot:root ratio) and plant nutrition (total N and P amounts expressed in mg-N or mg-P plant⁻¹
114 and concentrations in shoot and root expressed in mg-N or mg-P g⁻¹). For each study, we
115 recorded the mean values of these functions in presence/absence of bacterivores as well as
116 experimental information (soil parameters, species, protocols, etc.). These data were extracted
117 directly from tables, the text or figures using PlotDigitizer 2.6.4 software.

118 For each observation, we calculated the individual effect size (ES_i) from the natural log of the
119 response ratio using Equation 1 (Hedges et al. 1999).

120

121 (1) $ES_i = \ln(T_i / C_i)$; where “T” was the treatment mean (presence of bacterivores) and
122 “C” the control mean (absence of bacterivores) for the observation *i*.

123
124 This metric reflects a relative change in a function due to the presence of bacterivores.
125 Positive and negative ES_i indicated respectively a positive and a negative effect of
126 bacterivores on the function of interest. We then calculated the mean effect size (ES_m) using
127 the equation 2 and estimated the 95% confidence interval around the ES_m using bootstrapping
128 (999 iterations).

129
130 (2) $ES_m = (\sum ES_i) / n$; with “n” the total number of observations

131
132 ES_m was considered significant ($P < 0.05$) if its 95% confidence intervals did not overlap with
133 zero. For a more intuitive understanding of the effects of bacterivores on functions, we also
134 calculated the percentage of change from control (%CC) from the ES_m . We also tested the
135 effect of the medium used by the experimenters in their studies. To do so, we split the
136 database into 4 groups according to the medium: “agar” (or agarose), “humus”, “sand” (mixed
137 with organic matter or with nutrient solution) and “soil” (alone or amended with sand, organic
138 matter and/or nutrient solution). We then calculated ES_m for each group and tested for
139 significance among groups using the Kruskal-Wallis test at the $P < 0.05$ level.

140 We also determined whether the presence of mycorrhizal fungi altered bacterivore-effects on
141 plant nutrition and growth. We collected data from studies comparing the effects of
142 bacterivores in the rhizosphere of plants infected or not by mycorrhizal fungi (7 studies, 14
143 observations). We did not include studies where the control (non mycorrhizal plant) was
144 lacking. For each observation, we calculated the ES_i for mycorrhizal and non-mycorrhizal

145 plants and tested for significant difference in ES_m using the Kruskal-Wallis test at the $P < 0.05$
146 level.

147 Linear meta-regressions were performed to tested the relationships between the bacterivore-
148 induced effect size on total N (or P) amount in shoot (or root) (responses variables) and the
149 bacterivore-induced effect sizes on shoot (or root) N (or P) concentration and shoot (root)
150 biomass (explanatory variables). 95% confidence intervals were calculated for each
151 regression. The normal distribution of residuals was tested using Shapiro test. Finally, we
152 searched for publication bias using funnel plots. We tested the significance (P -value < 0.05)
153 of regression between the bacterivore-induced ES *versus* the inverse sample size of the study
154 for each function (Peters et al. 2006). A significant regression indicated that the funnel plot
155 was asymmetric, corresponding to possible publication bias, which was the case only for
156 respiration (P -value: 0.02). We also tested the relationships between experiment duration,
157 which ranged from 3 to 561 days, and ES_m values using regression. Except for the
158 concentration of N in roots, we did not find any effect of experiment duration on ES_m .

159

160 **3. Quantitative synthesis of soil bacterial-bacterivore literature**

161

162 We collected 41 experimental studies published since 1977 investigating the effects of soil
163 bacterivores on ecosystem functions (Appendix 1). Among them, 38 and 17 studies
164 investigated effects of bacterivores on N and P concentrations (either in soil or plant tissues),
165 corresponding to ~93% and ~41% of reported studies, respectively (Figure 1). Around 66% of
166 experimental studies co-inoculated bacteria and bacterivores in the rhizosphere of plants,
167 using either herbaceous (73%) or woody (27%) species. According to our literature survey, in
168 a period of 37 years, only 1.1 papers per year on average focused on the ecological functions
169 accomplished by these organisms (without taking into account reviews and books). We

170 believe that the number of studies (and observations) is large enough to conduct a meta-
171 analysis but remains critically limited regarding the significant roles of these organisms on
172 ecosystem functioning (Bonkowski 2004; Chen et al. 2007).

173 This apparent lack of interest in soil bacterivores can be explained by the difficulties involved
174 in observing, characterizing (extraction, enumeration and description) and manipulating these
175 small-sized organisms in comparison to larger soil fauna (e.g. arthropods or earthworms)
176 (Cowling 1994; Ekelund and Ronn 1994; Griffiths and Ritz 1988). This is particularly true for
177 protists because the majority of taxa cannot be extracted from soils, and our taxonomic
178 knowledge is mostly restricted to few cultivable species (Ekelund and Ronn 1994; Foissner
179 1999). Furthermore, this practical difficulty is enhanced by the heterogeneous and opaque
180 nature of soils at the micro-spatial scale in contrast to aquatic environments. Soil
181 protozoology and nematology thus require specific taxonomic skills and time-consuming
182 microscopy in addition to expensive equipment (high-quality light-, or electron-microscopy).

183 These methodological drawbacks together with the difficulties working under strictly sterile
184 conditions have certainly constituted the main obstacles in the establishment of soil micro-
185 food web experiments.

186 We also noted that contrasting experimental protocols have been used in these studies. For
187 instance, experimenters used various types of medium (agar, sand, humus or soil) or
188 experimental devices (Petri dishes, glass tubes, rhizoboxes or pots) for the growth of
189 organisms (Table 1). The amount and composition (C:N:P ratio) of organic amendments and
190 nutrient solutions were also highly different among studies as well as the choice of model
191 species and the duration of the experiment (from 2 to 561 days). This high diversity in
192 protocols made the identification of ecological factors that are likely to drive bacterivore-
193 effects on ecosystem functions more difficult. On the other hand, it also allowed us to

194 estimate an overall bacterivore-effect representative of a wide range of environmental
195 conditions.

196

197 **4. Bacterivore-effects on the soil microbial community and nutrient availability**

198 *4.1. Microbial biomass*

199

200 Because protists and nematodes feed on bacteria, the presence of these organisms usually
201 induced a reduction in soil microbial biomass or bacterial abundance (Anderson et al. 1978;
202 Coleman et al. 1977; Darbyshire et al. 1994; Elliott et al. 1979; Zwart and Darbyshire 1992).

203 However, a number of studies showed that the presence of bacterivores can lead to higher
204 bacterial abundance (and biomass) due to a strong reduction of senescent cells (Elliott et al.
205 1980; Ingham et al. 1985; Sundin et al. 1990). The global effect of grazing on the soil
206 microbial biomass and bacterial abundance estimated by the meta-analysis was -16% and -
207 17% of control, respectively (Figure 2).

208 The effect of bacterivores on bacterial abundance has been shown to vary according to
209 bacterivore species (Ingham et al. 1985; Postma-Blaauw et al. 2005), soil texture (Elliott et al.
210 1980), incubation time (Elliott et al. 1980), supply and availability of labile carbon (Anderson
211 et al. 1978; Elliott et al. 1980) or nitrogen (Baath et al. 1981) and identity of bacterial taxa
212 (Glücksman et al. 2010; Griffiths et al. 1999; Ronn et al. 2002; Xiao et al. 2010), showing that
213 differences in bacterivore-effects on bacterial abundance are multifactorial. Certainly the long
214 co-evolution between bacteria and protists had a major influence on the evolution of prey-
215 capture mechanisms (Parry 2004) and bacterial defense strategies (Jousset 2011; Matz and
216 Kjelleberg 2005). In consequence, predicting bacterivore-effect on soil bacterial community
217 in a particular environment (or experimental set up) remains difficult.

218

219 4.2. Microbial composition

220

221 The whole composition of the soil microbial community drastically changed in the presence
222 of protists (Bonkowski et al. 2011; Ekelund et al. 2009; Griffiths et al. 1999; Koller et al.
223 2013c; Ronn et al. 2002; Rosenberg et al. 2009) and bacterial-feeding nematodes (Blanc et al.
224 2006; Djigal et al. 2010; Djigal et al. 2004; Postma-Blaauw et al. 2005). Unfortunately, most
225 published studies have a coarse taxonomic resolution limiting our ability to assess accurately
226 grazing effects on microbial composition. Usually, the presence of bacterivores changed the
227 relative abundance of dominant bacterial populations (Djigal et al. 2004), often increasing the
228 proportions of bacteria that are grazing protected, either by physical means, such as gram-
229 positive bacteria (Griffiths et al. 1999; Ronn et al. 2002; Weekers et al. 1993) and those that
230 make filaments such as actinomycetes (Rosenberg et al. 2009), or by chemical means (Jousset
231 et al. 2009; Jousset et al. 2010; Jousset et al. 2008; Mazzola et al. 2009). The ability of
232 bacterivores to alter the composition of the microbial biomass can feed back on microbial
233 function, such as nitrification (Djigal et al. 2010; Jousset et al. 2006) or phosphatase activity
234 (Djigal et al. 2004; Gould et al. 1979). For instance, using a DGGE technique based on PCR
235 amplification of the *amoA* gene, Xiao et al. (2010) found a significant shift in the community
236 composition of ammonia-oxidizing bacteria (AOB) from *Nitrosospira* sp. to *Nitrosomonas* sp.
237 in presence of nematodes bacterivores.

238 Selective grazing of cells has been proposed as the main mechanism causing a shift in
239 microbial composition in the presence of protists (Bonkowski et al. 2009). Bacteria evolved
240 different means to become grazing-resistant, which can be grouped in physical protections
241 such as bacterial shape and size (Bjornlund et al. 2012), cell wall resistance, and the ability of
242 cells to form micro-colonies, filaments or biofilms (Bonkowski et al. 2009; Jousset 2011); and
243 chemical protections, such as the production of pigments (Weekers et al. 1993) or of specific

244 toxins (Jousset et al. 2006; Jousset et al. 2009; Mazzola et al. 2009). In particular, the latter
245 have been identified as main drivers of changes in bacterial community composition, since
246 bacterivores have been shown to consume preferentially the competitors of the grazing-
247 resistant taxa (Jousset et al. 2008). The differences in growth rates of bacterivorous protist
248 (Ekelund 1996; Weekers et al. 1993) and nematode populations (Anderson and Coleman
249 1981; Blanc et al. 2006; Venette and Ferris 1998) according to bacterial species suggest that
250 also the digestibility and nutritional values of preys constitute an important trait involved in
251 bacteria-bacterivore interactions (Pussard et al. 1994).

252 On the other hand, bacterivores have developed different forms of feeding (direct
253 interception, grasping, filter-, diffusion- or raptorial feeding); this appears as an important
254 trait involved in selective grazing aptitude (Parry 2004; Ronn et al. 2012; Weisse 2002).

255 While ciliates move out of toxic biofilms, amoebae graze directly within biofilms and
256 grasping and raptorial feeders rather rely on bacteria they can dislocate from biofilm surfaces,
257 while diffusion and filter feeders rely on the free-swimming bacteria (Ronn et al. 2012). In
258 addition, certain bacterivore nematode taxa evolved a grinder in the terminal bulb which
259 serves for crushing trapped bacteria (Fürst von Lieven 2003), thus providing a physical means
260 to consume bacteria with thick cell walls that are largely undigestible for other bacterivores,
261 like gram-positive bacteria.

262 Because bacterial-feeding nematodes can ingest around 20 cells during each suction of their
263 continuously pumping pharynx (Ferris et al. (1997), it appears unlikely that nematodes
264 actively select for specific prey taxa such as protists. Jousset et al. (2009), using mixed
265 populations of mildly toxic wild-type and non-toxic *gacS*-deficient mutants of *Pseudomonas*
266 *fluorescens* CHA0 in batch and rhizosphere systems, showed that the diet composition of the
267 nematode *Caenorhabditis elegans* did not vary with changes in the frequency of the two
268 bacterial strains, confirming its lack in selective compared to *Acanthamoeba castellanii* that

269 clearly preferred the non-toxic bacterial mutants. Accordingly, bacterial-feeding nematodes
270 are more likely to alter bacterial community composition through passive mechanisms. The
271 high variations in the head shape of Cephalobidae species recorded by De Ley (1992)
272 supports this hypothesis. He investigated in detail how the shape of the labial probolae and the
273 development of cephalic probolae at the nematode head allow passive food specialization,
274 thereby optimizing niche partitioning among co-occurring bacterivore nematode species.
275 Lastly, bacterivores have been suggested to modify the amount and composition of
276 rhizodeposits (Sundin et al. 1990), which can in turn feed back on the composition of the
277 bacterial community (Benizri et al. 2002; Puglisi et al. 2013).

278

279 *4.3 Microbial activity and nutrient availability*

280

281 The presence of bacterivores generally enhanced the overall microbial activity and turnover
282 (Alphei et al. 1996; Coleman et al. 1978; Djigal et al. 2004; Kuikman et al. 1990). The meta-
283 analysis revealed that the presence of bacterivores significantly increased soil microbial basal
284 respiration and microbial turnover, measured as microbial metabolic quotient (respired-carbon
285 relative to microbial biomass carbon) by +29% and 35% of control, respectively (Figure 2),
286 indicating that the microbial carbon-use efficiency (CUE) strongly decreases in presence of
287 bacterivores (Manzoni et al. 2012; Sinsabaugh et al. 2013). The main mechanisms are that (i)
288 bacterivores can ingest senescent bacteria and contribute to maintain younger bacteria cells
289 with higher metabolic activity (see discussion in Bonkowski (2004)) and (ii) they release
290 undigested food particles, labile carbon and nutrients making the medium more favorable for
291 bacterial re-growth (Griffiths 1994a; Pussard et al. 1994).

292 The effects of bacterivores on microbial communities have strong consequences for soil

293 nutrient availability (Clarholm 1985a; Koller et al. 2013b; Kuikman and Vanveen 1989; Xiao

294 et al. 2010). We found that the presence of bacterivores almost doubled soil N (N_{\min})
295 mineralization (x 1.8 in absence of plants) (Figure 2). Two main pathways of bacterivore-
296 effects on soil nutrient availability do exist simultaneously: excretion of nutrients (direct way)
297 according to the consumer-driven nutrient recycling (CNR) theory (Elser and Urabe 1999)
298 and stimulation of the microbial activity and turnover as quoted earlier (indirect way).
299 Using stable isotopes, Crotty et al. (2013) found that soil protists only have a production
300 efficiency of 37%. Ferris (1997) found higher production efficiencies (ranging from 58% to
301 86%) for eight bacterivore nematodes species. Because bacterivores have to maintain
302 stoichiometric homeostasis relative to their food, and loose carbon due to respiration, a great
303 part of the ingested N will be ultimately released by bacterivores (Anderson et al. 1983;
304 Darbyshire et al. 1994; Ferris et al. 1997; Ferris et al. 1998; Griffiths 1994b). Borkott (1989)
305 found mass C:N ratios of 3.5:1, 4.7:1 and 5.6:1 for *Naegleria gruberi* (amoeba), *Colpoda*
306 *steinii* (ciliate) and *Rhabditis* sp. (bacterivore nematode), respectively. Using recent values of
307 global soil microbial stoichiometry (mass C:N ratios ranging from 5.5:1 to 7.4:1) (Cleveland
308 and Liptzin 2007; Xu et al. 2013) and production efficiencies from Crotty et al. (2013) and
309 Ferris et al. (1997), we calculated that theoretical ranges of N excretion would be 23-32%, 43-
310 49% and 9-20% of assimilated-N for amoebae, ciliates and nematodes, respectively. The C:N
311 ratios of both bacteria and bacterivores will thus directly influence the amount of assimilated-
312 N excreted by the bacterivores (Elser and Urabe 1999).
313 Furthermore, the presence of bacterivores will increase microbial respiration and turnover
314 (Coleman et al. 1978; Levrat et al. 1992), leading to lower microbial CUE and a decreased
315 microbial C:N ratio. In addition, the C:N ratio of bacteria determines the respiration rates in
316 presence of bacterivores, with C-losses increasing at decreasing C:N ratios (De
317 Telegdy-Kovats 1932) leading to higher N release by bacterivores at narrow C:N ratios of the
318 prey. However, the soil microbial biomass C:N:P has been shown to be relatively stable

319 compared to its resource (Cleveland and Liptzin 2007; Xu et al. 2013); and microbes keep
320 strict homeostasis in respect to nutrient availability in soils (Griffiths et al. 2012). To maintain
321 their stoichiometry, microbes can regulate their nitrogen-use efficiencies by releasing
322 elements in excess depending on their CUE (Mooshammer et al. 2014a). The excess N may
323 then become available for roots in presence of bacterivores (Kuzyakov and Xu 2013).
324 However, small changes of microbial biomass stoichiometry can occur after shifts in the
325 microbial community structure (Fanin et al. 2013). For instance, fast-growing bacteria
326 (copiotrophs) have been suggested to exhibit lower biomass C:N:P ratios (higher nutrient
327 requirements) than slow-growing ones (oligotrophs) (Elser et al. 2003; Hodge et al. 2000).
328 Indeed, in line of the growth rate hypothesis (GRH) (Elser et al. 2003), N:P ratios in organism
329 decrease with increasing growth rates due to elevated demands for P for the synthesis of P-
330 rich ribosomes. Therefore, shifts in the dominance of fast- or slow-growing bacteria induced
331 in presence of bacterivores can transfer to shifts in microbial biomass stoichiometry, with
332 important consequences on the content of N and P available for plant growth.
333 Ferris et al. (1998) calculated that bacterial-feeding nematodes excreted $\text{NH}_4\text{-N}$ with rates
334 ranging between 0.0012 and 0.0058 $\mu\text{g-N ind.}^{-1} \text{ day}^{-1}$ according to species, but in addition,
335 considerable amounts of organic N (Norg) can be released by nematodes (Anderson et al.
336 1983). Wright (1975) found that that 3-14%, 15-34% and 35-45% of the total N (mean 13.7
337 $\mu\text{moles N g}^{-1} \text{ nematode fresh wt hour}^{-1}$) liberated in Ringer solution by the nematode
338 *Panagrelus redivivus* were composed of urea, amino acids and proteins, respectively, while
339 ammonium contributed 23-35% of total N-release. Large releases of organic N (in total and in
340 proportion of total N) by nematodes may occur when nematodes exhibit high nitrogen-use
341 efficiency (NUE) in order to balance their stoichiometry to bacterial biomass C:N:P ratios,
342 explaining why Anderson et al. (1983) observed declines in excretion of Norg with decreasing
343 resource availability (i.e. when nematode populations became older). Knowing that dissolved

344 Norg (especially low molecular weight N compounds) can be re-used by soil bacteria or taken
345 up by plants (Gallet-Budynek et al. 2009; Nasholm et al. 2009; Neff et al. 2003), bacterivore-
346 effects on soil N availability likely have been under-estimated because experimenters
347 generally focused only on NH_4 .

348 Interestingly, we found a great variability in ES_i for N_{\min} as shown by the 95% confidence
349 interval. In parallel, we found that when the substrate used in experiments was soil, the ES_m
350 was very high in comparison to humus, while in sand it exhibited intermediate values (Figure
351 3.A). Humus had the highest mass C:N ratios (mean $\sim 39:1$) while soils had the lowest ones
352 (mean $\sim 15:1$) and sand exhibited intermediate values (mean $\sim 20:1$). We therefore suggest that
353 bacterial growth in substrates with high C:N ratios (humus), and in absence of living roots,
354 will be mostly limited by N, leading to rapid immobilization of N released by bacterivores. In
355 contrast, in substrate with low C:N ratios (soil), bacterial growth will be limited by C and
356 bacterial N immobilization should decrease (Ferris et al. 1998).

357 We also found that protists exhibited significant higher effects than nematodes on N_{\min} but the
358 highest values were found when both bacterivore groups were present in the microcosms
359 (Figure 4.A). Accordingly, the choice in bacterivore species appears as an important
360 experimental parameter explaining the magnitude of bacterivore-effects on N_{\min} . The broad
361 classification of bacterivores is by far not accurate enough to predict how bacterivores impact
362 soil N cycling. For instance, Ferris et al. (1998) found high variation of different nematodes
363 species to net N mineralization. Predicting bacterivore-effects on nutrient availability
364 therefore remains difficult, especially when a mixture of bacterivore species is used.

365 Applying the same stoichiometric reasoning as for N (Borkott 1989; Cleveland and Liptzin
366 2007; Crotty et al. 2013; Ferris et al. 1997; Xu et al. 2013), theoretical ranges of excess-P
367 excretion would be 27-48%, 73-81% and 66-76% of assimilated-P for amoebae, ciliates and
368 nematodes, respectively. These estimates are higher than for N (except for nematodes) while,

369 in the meta-analysis, we found lower bacterivore-effects on P mineralization (P_{\min}) (22% of
370 control) in comparison to N (Figure 2). *Why did these theoretical differences in N and P*
371 *excretion rates of bacterivores not match with N_{\min} and P_{\min} data provided by the meta-*
372 *analysis?*

373 The theoretical liberations of N and P by bacterivores did not take into account biotic
374 (microbial immobilization, microbial CUE, resource stoichiometry, etc.) and abiotic processes
375 (adsorption of P, leaching of N, etc.) occurring after nutrient excretion by bacterivores, thus
376 differentiating *gross* from *net* effects of bacterivores on nutrient availability. In humus (where
377 the C:P ratio is high), the bacterivore-effect on P_{\min} was negative, while in soil (where the C:P
378 ratio is low) we found a positive effect of bacterivores on P_{\min} (Figure 3.B). Hence, in a high
379 C:P ratio environment, bacterial growth may be mostly limited by P and rapid immobilization
380 of excreted P from bacterivores may have occurred. However, in contrast to N, P is poorly
381 mobile in the soil solution and can be rapidly adsorbed by soil colloids (Hinsinger et al.
382 2011), reinforcing rapid immobilization of P in the microbial biomass and hampering the
383 overall positive net effect of bacterivores on P_{\min} .

384

385 **5. Bacterivore-effects on plant performance**

386 *5.1. Plant growth and root architecture*

387

388 Positive effect of bacterivores on plant growth have been observed for both herbaceous
389 (Alpei et al. 1996; Djigal et al. 2004; Krome et al. 2009a) and woody (Bonkowski et al.
390 2001b; Irshad et al. 2011; Jentschke et al. 1995) plant species (see Table 1 for details). Our
391 meta-analysis revealed a significant effect of bacterivores on shoot (+27% of control) and root
392 biomass (+21% of control) without affecting the shoot:root ratio (Figure 2). Interestingly, the
393 95% confidence interval did not exhibit huge variation though many ecological factors have

394 been suggested in the literature to affect bacterivore-effects on plant growth. Both, protists
395 and nematodes induced root growth of similar magnitude, but when both were present, their
396 effects were significantly larger (Figure 4.C). We did not find such an additive effect for
397 shoot biomass (Figure 4.B; P -value = 0.109).

398 Besides biomass, the presence of protists in the rhizosphere of plants has been shown to alter
399 profoundly root architecture by promoting lateral root production (Jentschke et al. 1995;
400 Kreuzer et al. 2006) (Table 1). Based on 11 studies, we found that bacterivores increased the
401 number of root tips by 96% of control. However, this positive effect was greatly variable
402 among studies (Table 1). Shifts in root architecture were also observed for bacterial-feeding
403 nematodes but to a lesser extent than for protists (Cheng et al. 2011; Irshad et al. 2012; Irshad
404 et al. 2011). For instance, while protists increased the number of root tips on average by a
405 factor of 2.5, nematodes only increased the number of tips by a factor of 1.2 (Table 1). The
406 presence of mycorrhizal fungi usually reduced the bacterivore effect on root length, specific
407 root length, root area and number of root tips.

409 5.2. Plant nutrition

410
411 The positive effects of bacterivores on plant biomass could be mostly related to increased
412 plant nutrient acquisition when protozoa and nematodes were inoculated in the soil
413 (Bonkowski et al. 2009). Generally, we found substantial bacterivore-effects on the total
414 amount of N in shoots and roots, *i.e.* +59% and +28% of control (Figure 2). Although the
415 increase of plant N concentration in shoots by bacterivores was large (+25% of control) it was
416 highly variable and not different from 0 (non-significant effect on this variable). By
417 conducting linear meta-regressions, we found that ~34% ($P < 0.001$) and ~65% ($P < 0.001$) of
418 the total variance of ES_m on total N amount in shoot (response variable) was explained by

419 bacterivore-effect on shoot biomass and shoot N concentration (explanatory variables),
420 respectively, without significant interaction between the two explanatory variables (Figure
421 5.A). These results imply that in some experimental conditions, bacterivores enhanced the
422 total shoot N amount by increasing the shoot N concentration while in others, bacterivores
423 increased the shoot N amount by increasing shoot biomass, explaining why we found high
424 variance in ES_m for shoot N concentration. Exceptions are the studies by Kuikman et al.
425 (1991) and Alpehi et al. (1996) where increased plant biomass production in presence of
426 protists or nematodes was neither paralleled by an increased total uptake of plant N, nor by
427 increased concentrations of N.

428 Interestingly, we found higher shoot N concentrations in experiments with bacterial-feeding
429 nematodes than with protists (Figure 4.C). These results suggested that the increase in total
430 shoot N amount was mostly caused by higher N concentrations in plant tissue when
431 nematodes were inoculated. Together with the lower effects of nematodes on root
432 architecture, the data suggest different mechanisms of plant responses to bacterivore
433 nematodes or protists, and might explain why the combined effects of both bacterivore groups
434 were generally larger than the effects of either group alone.

435 In respect to P, we found that bacterivores increased the total amount of P in shoots and roots
436 by 38% and 55% of control, respectively (Figure 2). The data suggest differences in the
437 internal plant cycling of newly-acquired N and P: the bacterivore-induced gain of N in plant
438 tissues was mostly allocated to shoots (probably for the maintenance of high carbon fixation
439 rates via photosynthesis) while the gain of P was more allocated to roots. Krome et al. (2009a)
440 and Koller et al. (2013c) showed that the effects of protozoa on plant performance were more
441 related to enhanced plant carbon fixation rather than nitrogen uptake. Compared to N, the
442 effects of bacterivores on shoot P concentration (+30% of control) were less variable and
443 different from 0, suggesting that surplus P made available by bacterivores was commonly

444 concentrated in plant tissues. Although the presence of bacterivores led to an important
445 increase in root P concentration (+23% of control), this effect was highly variable. The meta-
446 regression showed that ~16% ($P<0.001$) and ~75% ($P<0.001$) of the total variance of ES_m on
447 total P amount in roots (response variable) was explained by bacterivore-effects on root
448 biomass and root P concentration (explanatory variables), respectively without significant
449 interaction between these two explanatory variables (Figure 5.B). Some experimental
450 conditions, which remain to be known, may thus favor bacterivore-effects on nutrient
451 concentration in plant tissues (without affecting plant biomass) and others may promote
452 bacterivore-effects on plant biomass (and increase total N and P amount in plants).

453

454 5.3. Plant reproduction & defense

455

456 It is not surprising that positive effects of bacterivores on nutrient uptake and biomass of
457 plants will lead to increased plant reproduction. For instance, the presence of protozoa
458 increased the number of ears (+60%), seeds (24%) and the individual seed weight (+32%) of
459 barley plants, and the crop was even more tolerant to aphid herbivores (Bonkowski et al.
460 2001a). More recently, Krome et al. (2009a) showed that *A. castellanii* enhanced the seed
461 production of *Arabidopsis thaliana* (Brassicaceae) more than 3- and 7-fold compared to
462 treatments with bacteria and sterile grown plants, respectively. These results imply that gains
463 in plant fitness might be much more profound than increases of plant biomass and/or nutrient
464 contents in tissues indicate. Unfortunately, only these two papers investigated bacterivores
465 effects on plant reproduction. More studies are certainly needed to investigate bacterivore
466 effects on plant fitness and on interactions with herbivores and plant pathogens.

467

468 6. Relationships between bacterivores and root-infecting symbionts

469 6.1. Bacterivores & Mycorrhizal fungi

470

471 The effects of bacterivores on plant functions have been mostly investigated in the
472 rhizosphere of non-mycorrhizal plants (84% of reported studies) (Figure 1). This is a severe
473 shortcoming knowing that, in natural conditions, more than 80% of herbaceous and woody
474 plants are infected by soil fungi, mostly forming arbuscular mycorrhizal (Smith and Read
475 2008) and ectomycorrhizal symbioses (Marmeisse et al. 2004).

476 The formation of mycorrhizal roots is considered as the most widespread response of plants to
477 low soil nutrient availability (Plassard et al. 2011). By prospecting a large volume of soil
478 away from plant roots, and by releasing carboxylates (Finlay 2008) and enzymes (Courty et
479 al. 2006; Louche et al. 2010), mycorrhizal fungi have been often shown to significantly
480 enhance plant N and P acquisition (Plassard and Dell 2010; Tibbett and Sanders 2002;
481 Wallenda and Read 1999). The presence of mycorrhizal fungi can alter the positive effects of
482 bacterivores on plant performance through two main pathways: at a first glance, the presence
483 of mycorrhizal fungi is *a priori* likely to reduce the positive effect of bacterivores. The growth
484 of bacteria and bacterivores clearly depend on plant carbon allocation to roots. It has been
485 estimated that ca. 7-30% of net carbon fixation will be directly allocated to the root-infecting
486 fungal symbionts by the host plant (Jones et al. 2009; Leake et al. 2004). It is likely that the
487 amount of carbon released by root exudation will decrease in the presence of a mycorrhizal
488 partner (Meier et al. 2013; Olsson et al. 1996) with indirect detrimental effects on bacterivore
489 populations. Secondly, mycorrhizal fungi are known to profoundly change root biomass and
490 architecture (Brown et al. 2013). Usually, the presence of the mycorrhizal symbiont reduced
491 the stimulating effect of bacterivores on lateral root production (Table 1). Bacterivore effects
492 on plant nutrition through more complex root architecture can thus be altered by mycorrhizal
493 fungi.

494 However, this *a priori* hypothesis could not be confirmed by the meta-analysis. We did not
495 find any negative effect of mycorrhizal fungi on bacterivore effects on N and P concentrations
496 or total amount in plant tissues. In contrast, the ES_m of bacterivores on shoot and root biomass
497 were significantly reduced when the plants were in association with mycorrhizal fungi (Figure
498 6). This negative effect of mycorrhizal fungi on ES_m was very low for shoot biomass (-5%)
499 but substantial for root biomass (-104%), showing that even when mycorrhizal fungi reduced
500 the positive effect of bacterivores on root growth, the positive effects of bacterivores on plant
501 nutrition were still maintained. The few existing studies support this hypothesis for both
502 plants infected by arbuscular (Koller et al. 2013b; Koller et al. 2013c) and ectomycorrhizal
503 fungi (Bonkowski et al. 2001b; Irshad et al. 2012). These results also support the hypothesis
504 formulated by Bonkowski et al. (2001b) assuming that the mycorrhizal and the bacteria-
505 bacterivore mutualisms complement each other and plant resources are allocated to optimize
506 simultaneous exploitation of both mutualistic relationships. Because studies are lacking, it
507 was not possible to distinguish the effect of each mycorrhizal fungi type (arbuscular-, or ecto-
508 mycorrhiza) on bacterivore-effect sizes. Knowing that both fungal symbionts are
509 phylogenetically and physiologically distinct, this constitutes a serious shortcoming. More
510 studies are required, especially those focusing on different types of mycorrhizal fungi in
511 interaction with bacterivores.

512 It is well known that the ability of plants to take up organic N as source of N is greater in
513 presence of mycorrhizal fungi (Cappellazzo et al. 2008; Nasholm et al. 2009; Neff et al. 2003;
514 Plassard et al. 2000; Wallenda and Read 1999). Because significant amounts of dissolved
515 organic N (amino acids) are released by bacterial-feeding nematodes (Anderson et al. 1983;
516 Sundin et al. 1990; Wright 1975), we expect that the presence of mycorrhizal fungi will favor
517 the acquisition of some organic N- (and maybe P-) forms released by bacterivores, before
518 nutrients can be re-used by rhizosphere bacteria. Mycorrhizal plants could thus gain a

519 competitive advantage over microorganisms for soil N released by bacterivores. We did not
520 find experimental study testing this hypothesis, but we believe that this organic N circuit
521 should not be overlooked, and may constitute an important mechanism by which bacterivores
522 improve mycorrhizal plant N nutrition.

523

524 6.2. Bacterivores & N₂-fixing plants

525

526 Because N usually limits plant productivity, biological N fixation is one of the most important
527 functions of terrestrial ecosystems. Yet, little attention has been given to the potential role of
528 bacterivores on symbiotic N fixation and legume growth (Appendix 1). Ramirez and
529 Alexander (1980) showed that protists decreased the abundance of root-nodule bacteria in the
530 rhizosphere of *Phaseolus vulgaris*. Lennox and Alexander (1981) found higher numbers of
531 root nodules and growth of *P. vulgaris* when they used a biocide to suppress protists, but we
532 can not judge the side-effects of the biocide, since no protist-specific biocides exist. High
533 symbiotic N fixation efficiency usually requires high levels of available P because high rates
534 of energy transfer take place in the symbiotic nodule (Drevon and Hartwig 1997; Vitousek et
535 al. 2002). The meta-analysis showed that bacterial bacterivores increased soil P availability on
536 average by 22% of control. We can hypothesize that protists and nematodes, by increasing
537 soil P availability and subsequent plant P acquisition, might promote higher N fixation
538 efficiency once the nodules are formed. The N:P ratio of nodules would then be an important
539 proxy to predict how bacterivores in the vicinity of nodules may affect plant N uptake.

540

541 7. A 'stoichiometric' perspective on bacteria-bacterivore-plant interactions

542 7.1. Stoichiometric controls on bacterivore-effects on soil nutrient availability

543

544 Comparing the data of bacterivore effects on N- and P-availability point to an important role
545 of stoichiometry if we want to predict how bacterivores impact ecosystem functions.

546 (1) Bacterivores have to maintain stoichiometric homeostasis, but especially protists have
547 been shown to exhibit low production efficiency (Crotty et al. 2013). Accordingly
548 bacterivores release a great part of ingested N and P in mineral form (Elser and Urabe 1999).
549 The amounts of N- and P-release are expected to vary according to bacteria and bacterivores
550 C:N:P ratios. For example, Cole et al. (1978) showed that amoebae were highly efficient at
551 recycling microbially immobilized P to soil in comparison to bacterivore nematodes.

552 (2) Bacterivores often increase microbial turnover and further decrease microbial CUE.
553 Microbes are strongly homeostatic in terms of their biomass C:N:P at the community scale
554 (Cleveland and Liptzin 2007) and can regulate their nutrient-use efficiency by releasing
555 elements in excess depending on their CUE (Mooshammer et al. 2014a) leading to a strict
556 homeostasis with the available N- and P-levels in soil (Griffiths et al. 2012).

557 (3) Bacterivores can alter the soil microbial community structure. According to GRH (Elser et
558 al. 2003), C:N:P ratios in organism vary with growth rates. Therefore, small changes in
559 microbial stoichiometry can occur after shifts in the microbial community structure (Fanin et
560 al. 2013) caused by bacterivores.

561 (4) Soils with high C:N or C:P ratios may be nutrient deficient for bacterial growth, favoring
562 rapid immobilization of newly-mineralized N or P from bacterivores (Ferris et al. 1998). Soils
563 with low C:N or C:P ratios may induce energetic starvation for bacterial growth, reducing
564 bacterial N and P immobilization. The net effects of bacterivores on soil N and P
565 mineralization therefore depend on energy available in terms of labile plant C, either provided
566 by plant roots, or derived during initial phases of litter decomposition (Bonkowski and
567 Clarholm 2012).

568

569 *7.2. Stoichiometric controls on bacterivore-effects on plant nutrition and growth*

570

571 Clarholm (1985b) and Bonkowski (2004) proposed theoretical frameworks describing how
572 bacterivores impact plant functions. The ‘soil microbial loop’ hypothesis (Clarholm 1985a)
573 described nutritional mechanisms, quoted earlier, by which bacterivores may increase plant
574 nutrition and growth. Because bacterivores can enhance root growth without increasing plant
575 nutrient concentrations (Alphei et al. 1996; Jentschke et al. 1995; Kuikman et al. 1991),
576 Bonkowski (2004) proposed a ‘hormonal’ hypothesis based on non-nutritional mechanisms
577 where protists increase lateral root branching by altering microbe-root communication, with
578 strong consequences on plant internal auxin metabolism (Krome et al. 2009b). Both
579 nutritional and non-nutritional mechanisms will occur concurrently in the rhizosphere of
580 plants and are not exclusive of each other. However, it is unlikely that they contribute to the
581 same magnitude to bacterivore-effects under different experimental conditions. For instance,
582 we showed that the increase in total N amount in shoots induced by bacterivores was either
583 explained by higher shoot N concentration or higher shoot biomass. We found similar
584 partitioning in explanatory variables for bacterivore-effects on total P amount in roots. We
585 believed that ecological stoichiometry can help to understand these patterns.
586 Ecological stoichiometry describes the importance of the relative proportions between
587 elements for the growth of organisms (Elser et al. 2000; Gusewell 2004; Sardans et al. 2012;
588 Zechmeister-Boltenstern et al. 2015). Plant C:nutrient ratios are assumed to decrease with
589 increasing plant relative growth rate (Ågren 2004; Elser et al. 2000). This was conceptually
590 presented by Ågren (2008) as a linear relationship between these two plant traits (Figure 7.A).
591 From this graph, we defined the “critical ratio” (R_{crit}) which designates the C:nutrient ratio
592 above which plant growth is null (nutrient limitation).

593 For a certain plant species, the major cause of natural high C:nutrient ratios in plant tissues is
594 assumed to be nutrient availability in soil (Ågren 2008). Nutritional mechanisms by
595 bacterivore activity rely on a relatively high release of nutrients from consumed microbial
596 biomass. Such conditions are experimentally met when detritus of narrow C:nutrient ratio is
597 added to soil, supporting high levels of microbial growth and a subsequent substantial release
598 of nutrients by bacterivores (Bonkowski et al. 2000). When the readily available organic C
599 from the amendments is depleted, microbial biomass turnover will release nutrients for plant
600 uptake, and nutrient release will be further enhanced in presence of bacterivores.

601 Under more natural soil conditions the nutritional mechanisms should prevail when nutrients
602 are poorly available for plants, *i.e.* when competition for N and P between microbes and
603 plants is strong. For example, Koller et al. (2013a) added litter of high C:N ratio (*i.e.* low
604 quality, LQ) or low C:N ratio (high quality, HQ) to soil inoculated with bacteria or with
605 bacteria and the amoeba *A. castellanii*, and planted with *Plantago lanceolata*. By ¹³C-labeling
606 of the plants, they showed that plants in presence of high C:N ratio substrates allocated 12%
607 more recently fixed photosynthates to roots in presence of protists compared to controls.
608 Subsequently, ¹³CO₂ respiration losses from the soil more than doubled, because the excess
609 release of root C could not be fixed in microbial biomass due to nutrient deficiency. Here the
610 presence of bacterivores caused a 17% decrease in plant C:N ratio which was likely due to
611 two parallel processes, an increased nitrogen uptake and an excess energy expenditure
612 towards rhizosphere C-allocation.

613 The non-nutritional mechanisms suggest that bacterivores stimulate higher root production
614 and relatively more C-fixation before or without an increase in plant nutrient concentration.

615 The formation of lateral roots and the resulting root branching requires substantial plant
616 investment of photosynthates and nutrients: N for proteins, P for ribosomes and energy
617 synthesis. Manipulating nutrient availability to plants through the addition of HQ litter to soil,

618 Koller et al. (2013a) found a substantially higher increase of root biomass (x1.8) (and
619 increased root surface area) compared to shoot biomass (x1.3) in treatments with bacterivores
620 compared to control. In contrast to the LQ treatment, the plant C:N ratio increased by 14%,
621 *i.e.* plant biomass increased while the nutrient concentration decreased. This relatively wider
622 plant C:N ratio might have been a result of a more efficient photosynthesis. At the same time,
623 due to greater nutrient availability in low C:N substrates, microbial biomass in the plant
624 rhizosphere incorporated substantially more ¹³C from recent photosynthates. This may be
625 observed when nutrients are highly available for plants, *i.e.* when competition for N and P
626 between microbes and plants is low.

627 The relative dominance of nutritional and non-nutritional mechanisms induced by presence of
628 bacterivores can be plotted along a soil C:N and C:P co-gradient likely to drive (i) plant-
629 microbe competition towards N and P and (ii) plant stoichiometry status at the beginning or
630 during co-inoculation experiments (Figure 7.B). The term *dominance* refers to the relative
631 importance of mechanisms to initiate and drive bacterivore-effects on plants. We
632 distinguished four contrasting cases. In case 1, plants exhibit C:N and C:P ratios above their
633 respective critical ratios, and are strongly limited by N and P (the relative growth rate is
634 therefore null). This case may happen when plants grow in soils with high C:N and C:P ratios.
635 Under such soil conditions, microbes are strongly limited by N and P and expected to exhibit
636 high NUE and PUE (Mooshammer et al. 2014b), and consequently the competition for N and
637 P will be shifted in favour of microbes (Kuznyakov and Xu 2013). The experiment of Koller et
638 al. (2013a) cited above, demonstrates that plants under nutrient limitation will allocate
639 relatively more photosynthates belowground, thus providing energy for potential root
640 symbionts or priming effects on soil organic matter. Under these circumstances the
641 consumption of microbes by bacterivores will lead to increased microbial turnover and a
642 decreased microbial CUE. Plants will primarily benefit from the released N and P by

643 bacterivores. In cases 2a and 2b, plants have C:N or C:P ratios just below their respective
644 critical ratios; they are thus strongly limited by N or P according to soil C:N:P ratios. Similar
645 mechanisms as described above may occur for other plant limiting nutrient concentrations,
646 but according to plant species stoichiometric behavior, an excess uptake of the non-limiting
647 nutrient may also occur (Ågren 2008). In cases 3a and 3b, plants grow in soils with
648 intermediate C:N or C:P ratios, respectively. Microbes become limited by carbon and their
649 NUE and PUE may decrease, while plants are limited by N or P but their C:nutrient ratios are
650 below the critical ratios. The presence of bacterivores, and the subsequent changes in nutrient
651 availability and root architecture, may result in both nutrient storage and biomass production,
652 according to species stoichiometric behavior (co-dominance of mechanisms). In case 4,
653 microbes are strongly limited by carbon (NUE and PUE are expected to be low) and plants
654 exhibit low C:N and C:P ratios. This may happen in substrates with low C:N and C:P ratios
655 (or soils with low availability of labile C). Plant nutrient concentrations are high enough to
656 cause an increase of plant biomass (dilution of plant nutrient concentration can occur), but
657 also lateral root production (*i.e.* root surface area) for more efficient nutrient uptake in
658 response to bacterivores (dominance of non-nutritional mechanisms). This case is expected to
659 happen when plants grow in a relatively nutrient-rich environment (Jentschke et al. 1995), or
660 when plants experience nutrient imbalances which is critical, especially at early life stages
661 (Fenner and Lee 1989; Hanley and Fenner 1997).

662

663 **8. Conclusion & Perspectives**

664

665 In this meta-analysis, we showed that bacterivores in soil contributed significantly to
666 numerous key ecosystem functions. We suggest a theoretical framework based on ecological
667 stoichiometry stressing the role of C:N:P ratios in soil, microbial and plant biomass as

668 important parameters driving bacterivore-effects on soil N and P availability for plants,
669 immobilization of N and P in the bacterial biomass, and plant responses in nutrition and
670 growth. Unfortunately, it has not yet been possible to test this ‘stoichiometric’ hypothesis
671 using meta-analysis tools because of insufficient data on soil and plant C:N:P ratios. More co-
672 inoculation experiments focusing on bacterivore-effects on plant nutrient acquisition in
673 various environmental conditions are therefore needed. In addition, we propose three outlooks
674 to contribute to our understanding of bacterivore functions in terrestrial ecosystems.

675 *From population to community-level experiments* – Studies investigating the effects of
676 bacterivores on ecosystem functions usually used one model species. In this meta-analysis, we
677 found that 57% of studies focusing on protists effects selected the *A. castellanii* species as a
678 model, corresponding to 28% of all studies reported in the meta-analysis. This species was
679 frequently used because it has a ubiquitous worldwide distribution (Geisen et al. 2014) and
680 has strong effects on the activity and composition of the soil microbial community (Griffiths
681 et al. 1999; Kreuzer et al. 2006; Rosenberg et al. 2009) and on root architecture (Bonkowski
682 and Clarholm 2012). Concerning bacterial-feeding nematodes, the genera *Mesodiplogaster*,
683 *Rhabditis*, *Acrobeloides* (and several other *Cephalobidae* genera), were frequently used. On
684 average, we found that 38% of studies used a mixture of different protists or nematodes
685 species. Only 6 studies (15%) investigated soil protists and nematodes together and only 2 of
686 them did it in the rhizosphere of a plant (Figure 1).

687 It is recognized that the effects of bacterivores on microbial community composition (Djigal
688 et al. 2004; Ronn et al. 2002), soil N mineralization (Ferris et al. 1998) or plant performance
689 (Bonkowski and Clarholm 2012; Cheng et al. 2011; Irshad et al. 2011) are species-specific.
690 Also, biological interactions among bacterivores are diverse and often antagonistic (Ronn et
691 al. 2012). Recent studies indicate that intraguild-predation between ‘bacterivores’, especially
692 antagonistic interactions between protists and nematodes are quite common and not

693 unidirectional. Bacterivore nematodes are known to prey on protists (Anderson et al. 1978;
694 Bonkowski et al. 2000; Neidig et al. 2010; Ronn et al. 2012) and vice-versa (Bjornlund and
695 Ronn 2008; Neidig et al. 2010). The population density of one bacterivore taxon can thus
696 increase on the cost of other another bacterivore (Anderson and Coleman 1981).
697 Unfortunately, the effect of within-trophic group diversity of the soil bacterivore community
698 on ecosystem function has rarely been investigated (Postma-Blaauw et al. 2005; Saleem et al.
699 2012). As a consequence, we are still far from predicting which bacterivore community
700 attribute(s) drive(s) the overall effect of the bacterivore community on ecosystem functions. A
701 number of community attributes might potentially drive the bacterivore community effects,
702 such as (i) species richness, (ii) keystone groups with specific ecology (*e.g.* amoebae), (iii)
703 keystone species (*e.g.* *Acanthamoeba castellanii*), (iv) particular trait dissimilarity (head
704 morphology, feeding types, body size, demographic parameters; etc.) or (v) multi-trait
705 dissimilarity (Rao's dissimilarity coefficient). Identifying the most relevant attributes of soil
706 bacterivore communities driving ecosystem functions should help us to get closer to
707 predicting the actual effects of bacterial bacterivores in the fields.

708 *Kinetic experiments to monitor bacterivore-induced effects on plant performance* – Most
709 studies investigated the effect of bacterivores on plant performance after a specific period of
710 growth. Kinetic experiments are scarce because monitoring bacterivore-effects on plant
711 growth or nutrition requires a high number of replicates, which is difficult from a technical
712 point of view. However, this type of studies might provide crucial information on the
713 sequence of plant and microbial responses in the presence of bacterivores, and the dynamic
714 and persistence of bacterivore-effects on ecosystem functions (Krome et al. 2009a). For
715 instance, Ingham et al. (1985) observed a temporary effect of nematodes (*Pelodera* sp. and
716 *Acrobeloides* sp.) on plant (*Bouteloua gracilis*) growth. Kinetic experiments conducted under
717 contrasting soil N and P availability would be optimal to test the *stoichiometric* hypothesis.

718 *Emphasize on P and ecological factors* – P is essential for plant growth and may be limiting
719 in many environments. In contrast to N, P is characterized by its relative immobility in soil
720 and the very low concentration of its available form in the soil solution (Hinsinger 2001;
721 Hinsinger et al. 2011). Here, we found that N was 2.3-times more studied than P in both soil
722 and plant tissues. This is a serious deficiency given that plant P acquisition efficiency is often
723 based on biological interactions between plant roots and rhizosphere organisms. Using P
724 radio-isotopes is probably the best way to better understand how bacterivores affect P cycling
725 at the soil-plant interface. Also, the literature indicates that a large number of other ecological
726 factors are likely to impact bacterivore-effects on ecosystem functions: bacterivore species
727 (Cheng et al. 2011; Ferris et al. 1997), soil properties (Ekelund and Ronn 1994), plant species,
728 or cultivars (Somasundaram et al. 2008), the presence of symbiotic mutualists (Herdler et al.
729 2008; Irshad et al. 2012) or other free fauna (Bonkowski and Schaefer 1997; Tao et al. 2009),
730 time after inoculation (Krome et al. 2009a), etc. Unfortunately, the number of observations
731 for each factor was too low or difficult to aggregate to perform a meta-analysis. For instance,
732 it was impossible to test the effect of initial bacterivore biomass (or density), soil properties
733 (pH, texture, carbon content, water content; etc.), plant species or cultivar, or the presence of
734 rhizosphere organisms (*e.g.* mycorrhizal fungi or rhizobia) on bacterivore-induced effects on
735 ecosystem functions. Conducting more detailed studies on bacteria/root/bacterivore
736 interactions should deeply improve our understanding of soil food web roles in ecosystems
737 functions, and ultimately help us to predict how the erosion of soil biodiversity will affect
738 ecosystem services in the future.

Trap, J., Bonkowski, M., Plassard, C., Villenave, C., Blanchart, E. (2015). Ecological importance of soil bacterivores for ecosystem functions. *Plant and Soil*, 1-24. DOI : [10.1007/s11104-015-2671-6](https://doi.org/10.1007/s11104-015-2671-6)

Figure 1. Number of studies included in the meta-analysis (total and per criteria).

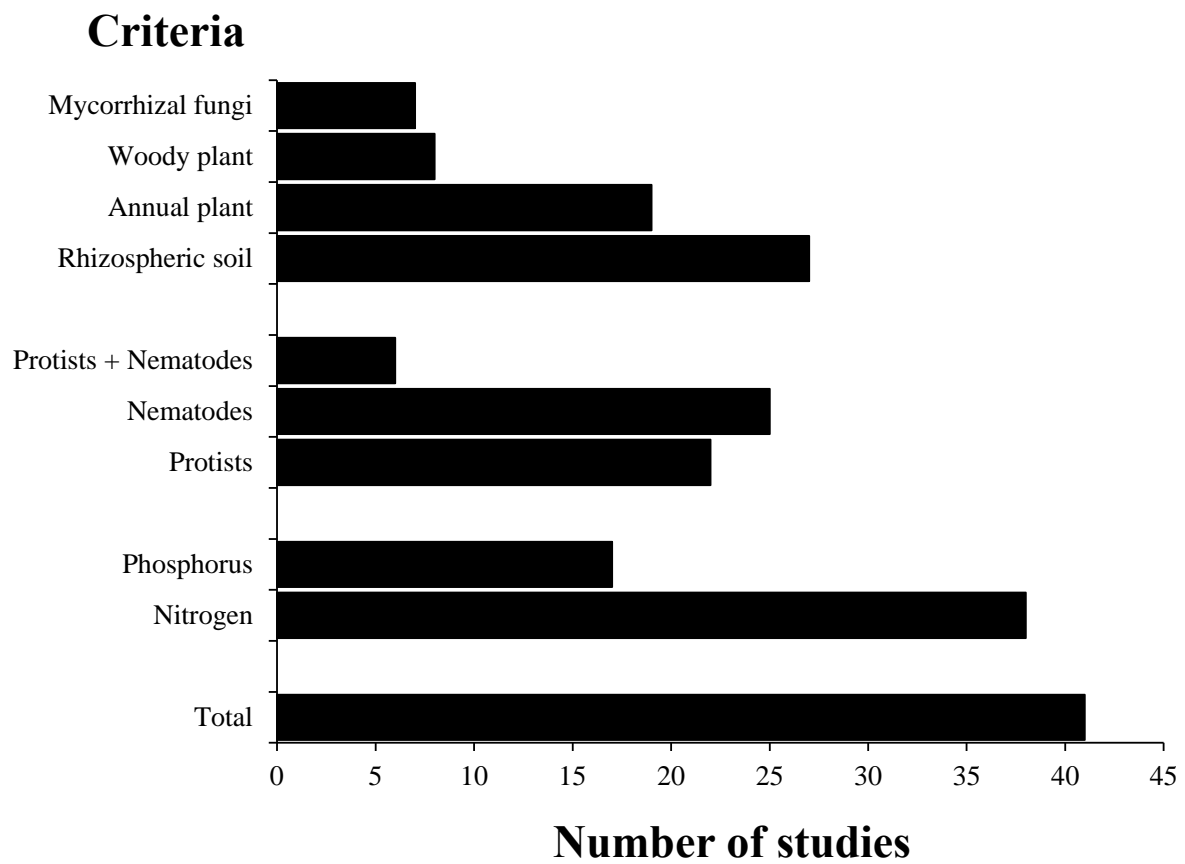

Figure 2. Mean effect sizes (ES_m) of bacterivores on ecosystem functions. White and black circles indicate significant (different from zero) and non-significant ES_m , respectively.

Horizontal bars correspond to 95% confidence intervals. Bold numbers above circles specify the ES_m expressed as % of control (%CC). Italic numbers between brackets specify the total number of observations for each function. M_{mic} : microbial biomass; B_{num} : bacterial number; Q_{mic} : microbial metabolic quotient; N_{min} : net N mineralization; P_{min} : net P mineralization; S:R : shoot:root ratio.

Figure 3. Changes in bacterivore-induced effect size (mean) on soil net N (A) and P (B) mineralization according to media types used in experimental studies. Letters (a and b) indicate significant differences in ES_m between media types according to a Kruskal-Wallis test at $P < 0.05$.

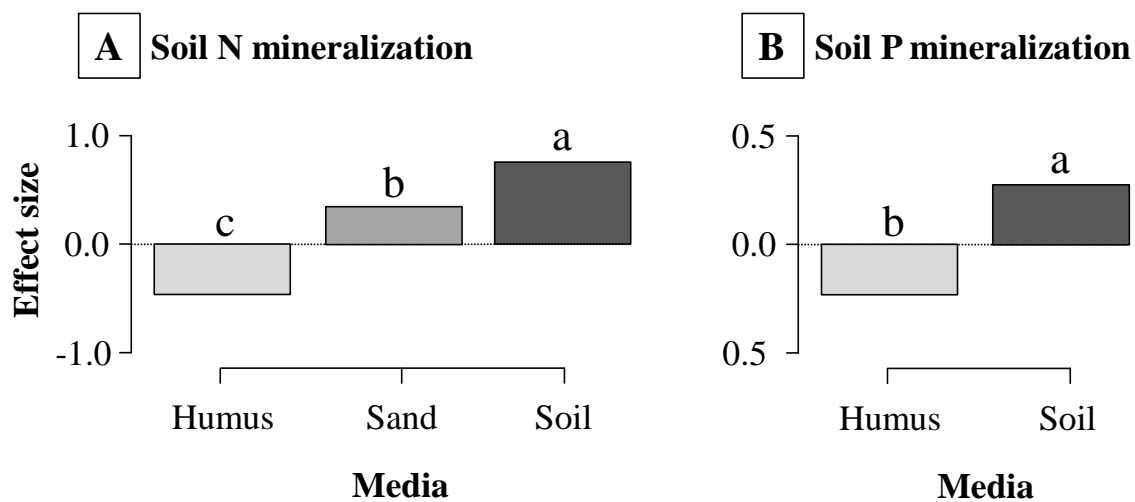

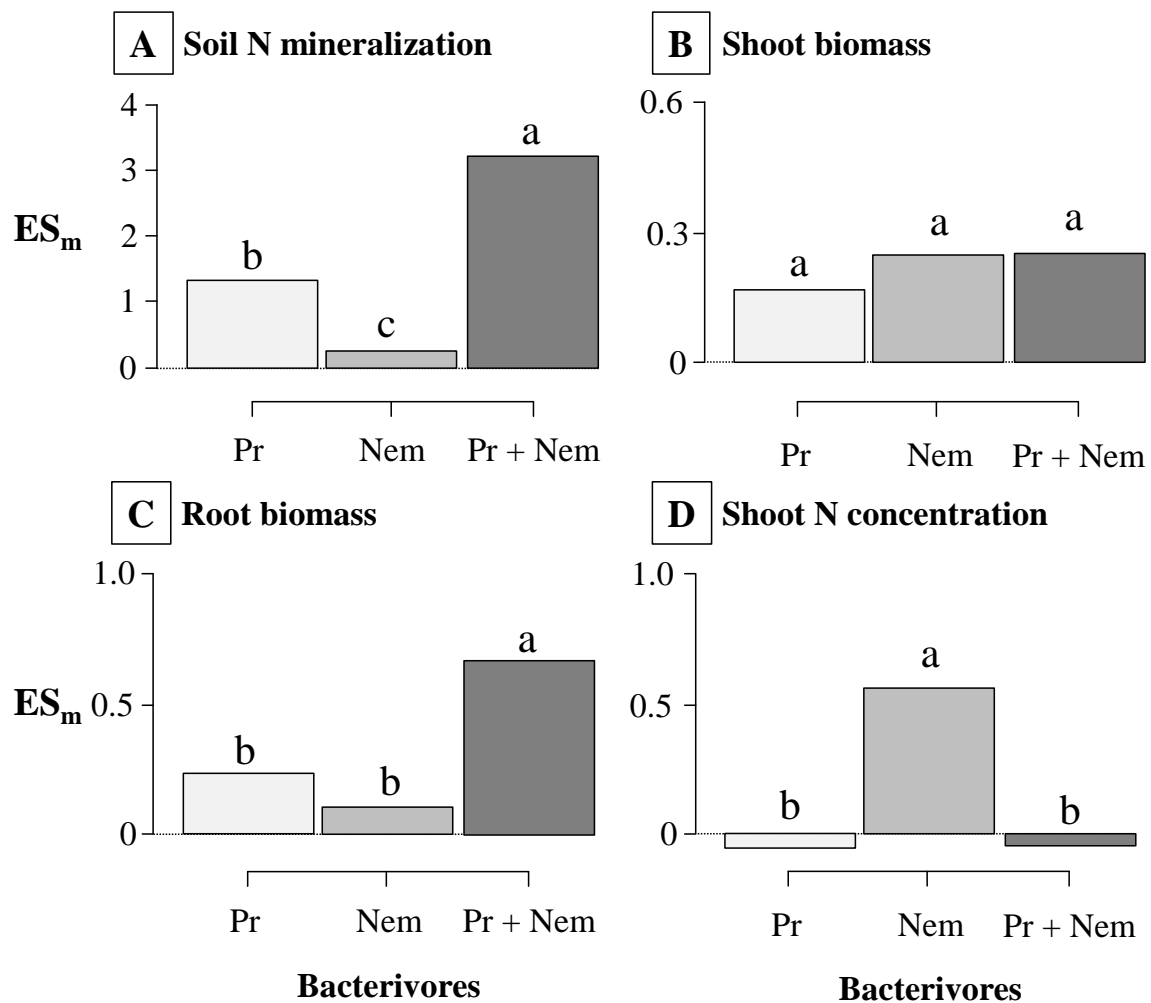

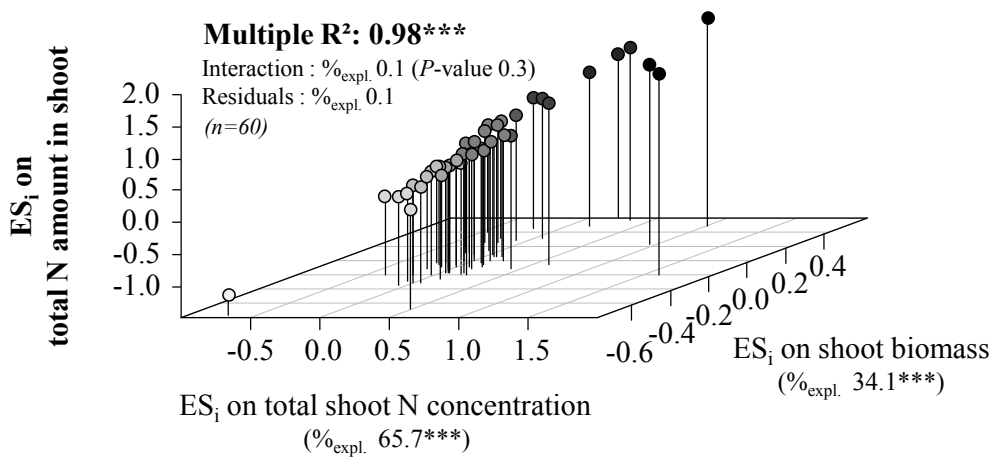

Figure 4. Changes in bacterivore-induced effect size (mean) on shoot N mineralization (A), root biomass (B) and shoot N concentration (C) according to the presence of bacterial-feeding protists (Pr), nematodes (Nem) alone or together (Pr + Nem). Letters (a and b) indicate significant difference in ES_m among media types according to a Kruskal-Wallis test at $P < 0.05$.

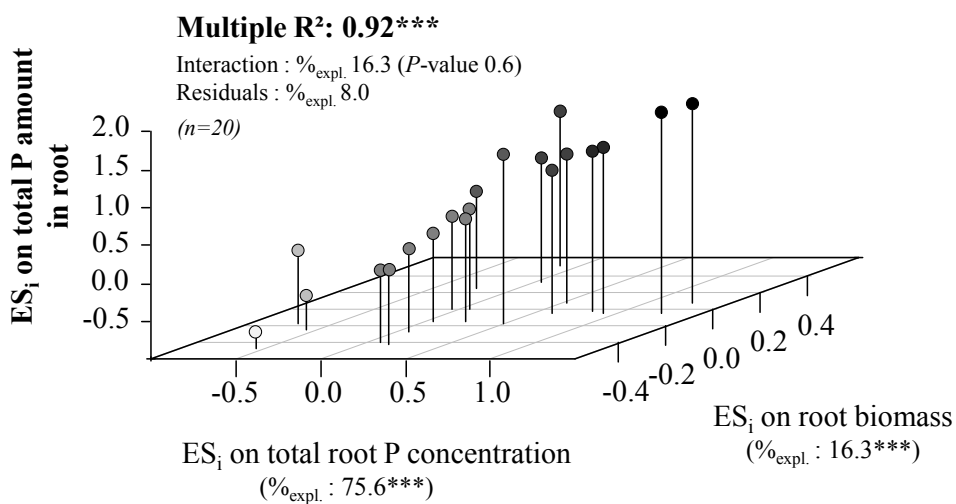

1 **Figure 5.** Multiple linear regressions performed on individual effect-size (ES_i). (A) ES_i of
2 total N amount in shoot (response variable) as a function of ES_i of shoot biomass and ES_i of
3 shoot N concentration (explanatory variables). (B) ES_i on total P amount in root (response
4 variable) as a function of ES_i on root biomass and ES_i on root P concentration (explanatory
5 variables). $\%_{expl.}$ indicates the percentage of total variance of the response variable explained
6 by each explanatory variable and by their interaction. $***P < 0.001$ (n = number of
7 observations).

A Total N amount in shoot

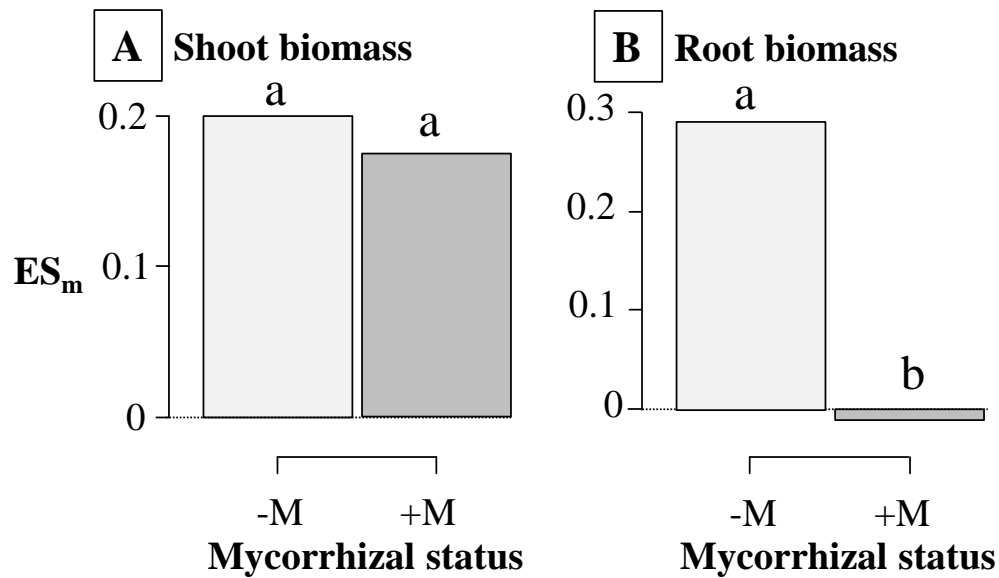

B Total P amount in root

- 1 **Figure 6.** Changes in bacterivore-induced effect size (mean) on shoot (A) and root (B)
- 2 biomass according to the presence of mycorrhizal fungi (-M : non mycorrhizal plant; +M:
- 3 mycorrhizal plant). Different letters (a and b) indicate significant changes according to a
- 4 Kruskal-Wallis test ($P < 0.05$, $n = 14$).

5

6

1 **Figure 7.** Theoretical framework describing the relative dominance* of nutritional and non-nutritional mechanisms involved in bacterivore-
2 effects on plant performance.

3 (A) Relationship between plant relative growth rate and plant C:nutrient ratios (modified from Ågren (2008)). The solid line describes the
4 C:limiting-nutrient (N or P) ratio while the broken lines indicate three different variations in the C:nutrient ratio of a second element (N or P) as a
5 function of relative growth rate. We here defined the *critical* C:limiting-nutrient ratio (R_{cri}) above which the relative growth rate is null.

6 (B) Diagram illustrating four different cases of plant behavior in the presence of bacterivores along a soil C:N and C:P gradients. Solid lines
7 describe the $C:N_{cri}$ and $C:P_{cri}$ according to soil C:N:P ratio, while the broken line indicates a hypothetical zone where the dominant mechanism
8 changes. Grey arrows describe the hypothetical trends in microbial nitrogen- and phosphorus-use efficiency (NUE, PUE) along the soil C:N:P
9 gradient. *the term “dominance” describes the relative importance of mechanisms to initiate and drive the effects of bacterivores on plants at a
10 given moment in the experiment.
