Abstract.   This study explores the manner in which the plasmapause is responsible for dictating which magnetospheric source regions of ELF/VLF chorus are able to propagate to and be received by mid-latitude stations on the ground. First, we explore the effects of plasmapause extent on ground-based observations of chorus via a three-month study of ground-based measurements of chorus at Palmer Station, Antarctica ($L = 2.4$, 50°S geomagnetic latitude) and data on the plasmapause extent from the IMAGE EUV instrument. It is found that chorus normalized occurrence peaks when the plasmapause is at $L \sim 2.6$, somewhat higher than Palmer's L-shell, and that this occurrence peak persists across a range of observed chorus frequencies. Next, reverse raytracing is employed to evaluate the portion of the equatorial chorus source region, distributed in radial distance and wave normal, from which chorus is able to reach Palmer station via propagation in a non-ducted mode. The results of raytracing are similar to those of observations, with a peak of expected occurrence when the plasmapause is at $L \sim 3$. The exact location of the peak is frequency-dependent. This supports the conclusion that the ability for chorus to propagate to low altitudes and the ground is a strong function of instantaneous plasmapause extent, and that peak occurrence of chorus at a given ground station may occur when the L-shell of the plasmapause is somewhat beyond that of the observing station. These results also suggest that chorus observed on the ground at mid-latitude stations propagates predominantly in the non-ducted mode.

1. Introduction

Extremely Low Frequency/Very Low Frequency (ELF/ VLF) chorus emissions are electromagnetic waves which are spontaneously generated in the Earth's magnetosphere. Chorus is characterized as consisting of repeating, usually rising and often overlapping coherent tones and is invariably accompanied by a band of hiss [e.g. *Cornilleau-Wehrlin et al.*, 1978]. In recent years, chorus has received increased attention due to the role that it is thought to play in the acceleration [e.g. *Meredith et al.*, 2002; *Horne et al.*, 2003, 2005] and loss [e.g. *Lorentzen et al.*, 2001; *O'Brien et al.*, 2003; *Thorne et al.*, 2005; *Shprits et al.*, 2006] of energetic electrons in the Earth's radiation belts. Additionally, some fraction of chorus may act via its evolution into plasmaspheric hiss [*Parrot et al.*, 2004; *Santolík et al.*, 2006; *Bortnik et al.*, 2008] as an additional loss agent for energetic electrons [e.g., *Lyons et al.*, 1972; *Lyons and Thorne*, 1973; *Abel and Thorne*, 1998; *Meredith et al.*, 2007].

Chorus waves are believed to be generated by a Doppler-shifted cyclotron interaction between anisotropic distributions of energetic > 40 keV electrons and ambient background VLF noise [*Tsurutani and Smith*, 1974, 1977; *Thorne et al.*, 1977]. These unstable distributions can result from substorm injection, and correspondingly, chorus is predominantly observed across the morning and noon local time sectors in association with eastward drifting electrons. Because magnetic substorms both increase the flux of hot source electrons which generate chorus as well as enhance the auroral electrojet, increases in the AE index have been shown to be a good predictor of chorus occurrence within the inner magnetosphere [*Smith et al.*, 1999; *Meredith et al.*, 2001]. The outer dayside region of the magnetosphere is also conducive to chorus generation, but here waves are less dependent

on substorm activity and can be observed under both quiet and disturbed geomagnetic

conditions [*Tsurutani and Smith*, 1977; *Li et al.*, 2009; *Spasojevic and Inan*, 2010].

Ground-based measurements of ELF/VLF emissions are by definition limited to the

small subset of space-based emissions that are able to penetrate to low altitudes and

through the ionosphere [e.g. *Sonwalkar*, 1995, pp 424-425]. Ground-based observations

may include (1) waves that have propagated such that their wave normals naturally arrive

within the transmission cone at the ionospheric boundary [*Helliwell*, 1965, section 3.7], (2)

waves that have propagated within field-aligned density irregularities known as "ducts"

[e.g., *Smith*, 1961; *Carpenter*, 1966; *Carpenter and Sulic*, 1988], which have the effect of

constraining the wave normals to be nearly field-aligned, or (3) waves that arrive at the

ionospheric boundary with non-vertical wave normals and are then scattered from low-

altitude meter-scale density irregularities [*Sonwalkar and Harikumar*, 2000] that rotate

the wave normals into the transmission cone.

In situ measurements of chorus have shown that chorus occurs in two bands, separated

by half the equatorial gyrofrequency (f_{ceq}) along the observation field line [*Tsurutani and

Smith*, 1974; *Burtis and Helliwell*, 1976; *Tsurutani and Smith*, 1977]. Of the two bands,

only the lower band is thought to reach the ground; the upper band is believed to reflect

at high altitudes due to its highly oblique wave normal angle [*Hayakawa et al.*, 1984;

Haque et al., 2010]. Thus, chorus received on the ground is expected to be exclusively

lower band chorus, generated below half the equatorial gyrofrequency.

The current work is motivated by a recent statistical study by *Golden et al.* [2009] of

chorus and hiss observed on the ground at Palmer Station, Antarctica, at $L = 2.4$, 50°S

geomagnetic latitude. During the course of that study, which spanned 10 months in 2003,

69 chorus was observed on more than 50% of days. This was unexpected for several reasons.

70 First, chorus is generated outside the plasmasphere, according to early satellite studies

71 [e.g. *Gurnett and O'Brien*, 1964; *Dunckel and Helliwell*, 1969] which have shown that

72 chorus is most commonly observed outside the plasmasphere. In addition, chorus observed

73 on the ground has traditionally been interpreted as a ducted emission, and therefore, that

74 the L-shell on which it is received is approximately the same as the L-shell on which it is

75 generated. The presumption that non-ducted chorus cannot penetrate to the ground [e.g.

76 *Imhof et al.*, 1989, p. 10,092] is based on raytracing results that show that nonducted

77 whistlers will magnetospherically-reflect before returning to the ground [*Kimura*, 1966;

78 *Edgar*, 1976] and is supported by occasional observation of chorus-like noise bursts that,

79 in ground observations, appear to have been triggered [*Carpenter et al.*, 1975] or damped

80 [*Gail and Carpenter*, 1984] by ducted whistlers (implying that the observed whistlers

81 and chorus share the same duct). However, in the study of *Golden et al.* [2009], the

82 magnetospheric conditions were such that the plasmapause was often expected to be

83 well beyond Palmer's L-shell during chorus observations. During that study, chorus was

84 observed for Kp $\lesssim$ 2$^+$. According to the plasmapause model of *Carpenter and Anderson*

85 [1992], at Kp = 2$^+$, the plasmapause is expected to be around $L \sim 4.5$. It is only for

86 Kp > 6$^+$ that the plasmapause is expected to reach down to $L < 2.5$. Also, the frequency

87 range of observed chorus suggests that the source region of the waves is well beyond

88 Palmer's L-shell. Satellite studies have shown that lower-band chorus is generated for

89 frequencies in the range $0.1 f_{ceq} \leq f \leq 0.5 f_{ceq}$ [*Tsurutani and Smith*, 1974; *Burtis and*

90 *Helliwell*, 1976]. Waves of frequencies below 500 Hz were observed by *Golden et al.*

[2009], which corresponds to a source location of $L > 5.5$ under a dipole model of the Earth's magnetic field.

It seems clear that the observations of *Golden et al.* [2009] are inconsistent with the theory of ducted propagation of chorus and that the dominant mode of chorus reception at mid-latitude stations like Palmer may instead be non-ducted. In support of this possibility, *Chum and Santolík* [2005] have shown via raytracing that non-ducted chorus, generated in the equatorial magnetosphere with wave normal angles near the local Gendrin angle, may be able to reach the ionosphere and penetrate to the ground at L-shells significantly below those at which the waves are generated. Although *Chum and Santolík* [2005] did not include a plasmasphere in their analysis, it seems logical, given the exo-plasmaspheric source of chorus and the location of Palmer within the plasmasphere, that the location of the plasmapause may play an important role in determining which subsets of chorus may be able to be received at Palmer.

In this study, we address two broad questions. (1) What is the location of the plasmapause when chorus is observed at Palmer? (2) How does the location of the plasmapause affect the portion of the chorus source region that is able to propagate to the ground and be received at Palmer? These questions are answered via a combination of (i) a three-month statistical study of chorus observations using the Stanford ELF/VLF wave receiver at Palmer Station coupled with simultaneous measurements of the plasmapause using the Extreme Ultraviolet (EUV) instrument on board the IMAGE satellite, and (ii) a model-based study of chorus propagation effects via a new Stanford VLF 3D raytracing software package, used to model magnetospheric propagation and Landau damping under

different models of the plasmapause location, as well as a full wave code, used to model

electromagnetic propagation in the Earth-ionosphere waveguide.

2. Experimental Methodology

In order to determine the location of the plasmapause when chorus is observed at Palmer

Station, we employ two separate databases: a database of emissions observed at Palmer

Station and a database of plasmapause locations at Palmer's MLT. Both databases span

three months, from April through June 2001, and are discussed below.

2.1. Palmer Emission Database

Palmer Station is located on Anvers Island, near the tip of the Antarctic peninsula, at

$64.77°$ S, $64.05°$ W, with IGRF geomagnetic parameters of $L = 2.4$, $50°$S geomagnetic lat-

itude, and magnetic local time (MLT) $=$ UTC $- 4.0$ at 100 km altitude. The Palmer VLF

receiver records broadband VLF data at 100 kilosamples per second using two cross-loop

magnetic field antennas, with 96 dB of dynamic range. This analysis uses the North/South

channel exclusively, it being the less subjectively noisy of the two channels; this has the

additional effect of focusing Palmer's viewing area more tightly to its magnetic meridian

than if both channels were used. Data products used in this study are 10-second broad-

band data files, subsampled at a rate of 20 kilosamples per second, beginning every 15

minutes at 5, 20, 35 and 50 minutes past the hour, 24 hours per day.

The year 2001 falls approximately on the peak of Solar Cycle 23, and chorus occur-

rence is frequent at Palmer Station during this period. A combination of automated

emission detection [*Golden and Spasojevic*, 2010] and manual correction is used to deter-

mine the presence of emissions. The automated detector rejects confounding impulsive

133 electromagnetic signals, such as sferics and whistlers, and focuses on chorus and hiss.

134 Chorus is then distinguished from hiss based on its "burstiness," namely, the frequency

135 content of the amplitude modulation of the broadband signal. Bursty signals are classi-

136 fied as chorus, and non-bursty signals are classified as hiss, and discarded. The output

137 of the automated detector is then manually verified to eliminate false positives (e.g., hiss

138 or lightning-generated whistlers erroneously labeled as chorus) and false negatives (e.g.,

139 weak chorus emissions that may have been rejected based on their proximity to sferics

140 or other emissions). Although it is likely that some chorus emissions with low signal-to-

141 noise ratios are erroneously rejected by this algorithm, the profusion of detected chorus

142 emissions still leads to statistically-significant results.

143   We define a "synoptic epoch" as an interval during which Palmer data is sampled for

144 this study. Each universal hour contains four synoptic epochs, at 5, 20, 35 and 50 minutes

145 past the hour. At each synoptic epoch, a binary judgment is made about whether cho-

146 rus is observed or not, based on the results of both the automated detector and manual

147 inspection. The resulting table of true/false values for chorus observation vs. time then

148 becomes the database of Palmer chorus emissions. As an overview, Figure 1 shows a

149 cumulative spectrogram of the chorus emissions used in this study. The cumulative spec-

150 trogram is effectively the logarithmic sum of the spectrums of its constituent emissions,

151 and is a measure of the average chorus spectrum with respect to frequency and local time.

152 The full procedure is described in *Golden et al.* [2009, Section 2.2]. The gap at ~ 1.7 kHz

153 on the cumulative spectrogram is a result of increased attenuation below the first trans-

154 verse electric (TE_1) waveguide mode cutoff during propagation in the Earth-ionosphere

155 waveguide. Only emissions in the boxed region, in the range $4 \leq \text{MLT} \leq 10$ are used in

156 this study.

2.2. Plasmapause Location Database

157 In order to determine the instantaneous plasmapause location at each synoptic epoch,

158 data from the Extreme Ultraviolet (EUV) instrument [*Sandel et al.*, 2000] on board the

159 IMAGE satellite [*Burch*, 2000] are used. The EUV instrument images resonantly scattered

160 sunlight from He^+ ions, which are a minority constituent of the plasma in the Earth's

161 plasmasphere. The He^+ edge, as seen by the EUV instrument, has been shown to be an

162 accurate proxy for the plasmapause [*Goldstein et al.*, 2003], which is the region of the

163 magnetosphere where the electron density exhibits a steep drop with increasing L value.

164 Because this study focuses on emissions observed on the ground at Palmer, the extent of

165 the plasmapause is only considered at Palmer's magnetic local time, $\text{MLT} = \text{UTC} - 4.0$.

166 Raw EUV images are initially mapped to the equatorial plane using the minimum L

167 technique of *Roelof and Skinner* [2000, Section 2.2], assuming a dipole model for the

168 Earth's magnetic field. The radial extent of the plasmapause is then manually selected on

169 each individual EUV image at $\text{MLT} = \text{UTC} - 4.0$ and that plasmapause value is added

170 to the database. EUV images where the plasmapause cannot be found due to excessive

171 noise or EUV camera malfunction, or where the plasmapause is either poorly defined or

172 not visible below $L = 6$, are discarded. After removing data gaps from both databases,

173 1033 synoptic epochs, or approximately 260 hours of data, remain for this study.

3. Dependence of Chorus Observations on Plasmapause Extent

3.1. Choice of AE Metric

Since this study concerns the role of the plasmapause in dictating the observation of chorus emissions, it is instructive to make mention of how the plasmapause is correlated with the AE index, which is itself well correlated with the observation of chorus emissions [e.g. *Meredith et al.*, 2001]. This is done to explore a potential confounding effect where a single event, namely a magnetic substorm, may have two simultaneous consequences: (1) enhancement of the auroral electrojet, causing an increase in AE and (2) erosion of the plasmasphere.

Figure 2 shows the extent of the plasmapause, sampled at $04 \leq \mathrm{MLT} \leq 10$, $\mathrm{MLT} = \mathrm{UTC} - 4.0$, plotted against the instantaneous AE index (left), and the average AE in the previous 12 hours (right), over the three-month period of this study. Averaging the AE index over $N = 12$ hours yields approximately the greatest correlation for any value of N. The plasmapause is moderately correlated with the log of instantaneous AE, with correlation coefficient $\rho = -0.43$ and residual standard deviation $\sigma_{\mathrm{err}} = 0.75$ L, and highly correlated with the log of the average AE in the previous 12 hours, with correlation coefficient $\rho = -0.81$ and residual standard deviation $\sigma_{\mathrm{err}} = 0.49$ L.

However, the manner in which AE is associated with plasmapause extent differs from how it is expected to be associated with chorus occurrence. The time between when AE is enhanced and when chorus is expected to be seen at Palmer may be determined by calculating the expected time required for a chorus source particle to drift from 00 MLT to 06 MLT. Based on *Walt* [1994, Figure B.2], 100 keV electrons at $L = 4$ will drift from midnight to 06 MLT in ~ 21 min; higher-energy particles will drift more quickly. This

time period is on the order of the synoptic epoch used in this study (15 min). Therefore instantaneous AE is used as the metric for predicting chorus in this study. It is significant that, while instantaneous AE is expected to be a good predictor of chorus occurrence, it is only weakly correlated with plasmapause extent. This suggests that source effects, as measured by instantaneous AE, and propagation effects, as measured by plasmapause extent, may exert independent control over the probability that chorus will be seen at Palmer at any given time.

3.2. Chorus Occurrence vs. Plasmapause Extent

In this section, the dependence of chorus normalized occurrence on plasmapause extent is examined. The additional complication of AE is deferred to the multivariate analysis of the next section. Although the detailed structure of the plasmapause boundary layer is complex [*Carpenter and Lemaire*, 2004], the major plasmapause structure is assumed to be field-aligned over much of its range. For the purposes of this study, the plasmapause can therefore be described via the scalar quantity L_{PP}, which represents the equatorial plasmapause extent, in units of Earth radii. A scatter plot of chorus observations at each synoptic epoch versus instantaneous AE and L_{PP} is shown in Figure 3. Synoptic epochs with chorus are indicated with blue squares and epochs without chorus are indicated with red dots. The scattered points themselves are the same as in the left panel of Figure 2, with some data gaps removed. One can get the general impression from this plot that chorus is more likely to be observed at Palmer for low L_{PP} and high AE. To examine the data more rigorously, regression analysis is used to construct a generalized linear model [e.g. *Chatterjee and Hadi*, 2006] of chorus normalized occurrence as a function of plasmapause extent. This provides additional insight into properties that are not obvious

217 from a simple scatter plot, such as at which L_{PP} chorus occurrence is maximized, and

218 how strong that peak is.

219   Under regression analysis, a linear combination of parameters is sought to form an

220 estimate of μ, the probability of chorus occurrence. Because linear models have, in general,

221 unbounded values, a *logit* response function is used for μ, defining the output of the linear

222 model, Y as

$$Y = \log\left(\frac{\mu}{1-\mu}\right), \tag{1}$$

223 and conversely,

$$\mu = \frac{e^Y}{1+e^Y} \tag{2}$$

224 This transforms the bounded parameter $\mu \in [0,1]$ to the unbounded parameter

225 $Y \in (-\infty, \infty)$. Given p distinct independent variables, Y is modeled as

$$Y = X\beta = \begin{bmatrix} 1, & x_1, & x_2, & \ldots, & x_p \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \vdots \\ \beta_p \end{bmatrix}, \tag{3}$$

226 where X is a row vector of predictors, formed by transformations of the independent vari-

227 ables (e.g., $x_1 = L_{\text{PP}}$, $x_2 = L_{\text{PP}}^2$, etc.), and β is a column vector of coefficient estimates.

228   The generalized linear model regression procedure from the MATLAB software package

229 is used to obtain a linear fit. Although it is possible to include an arbitrary number

230 of powers of L_{PP} in the model, we honor the principle of parsimony, and favor simpler

231 models. Bayesian Information Criterion (BIC) [*Chatterjee and Hadi*, 2006, Section 12.6]

232 is employed for this purpose, which assigns any particular model a lower score for better

233 goodness of fit, and a higher score for each included term; lower scores are favored.

234 Additionally, the maximum model order is restricted to four.

235   To determine whether there is any frequency dependence in the degree to which chorus

236   occurrence changes with L_{PP}, the regression analysis is separately performed on three

237   cases: all frequencies, $f < 1.5$ kHz and $f > 3$ kHz. For all frequencies and $f < 1.5$ kHz,

238   the fourth-order model has the lowest BIC and is therefore the favored model.   For

239   $f > 3$ kHz, the second-order model has the lowest BIC. The model parameters for the

240   three cases, along with the p-values, are shown in Table 1. The p-value in this case repre-

241   sents the probability of erroneously assigning a nonzero value to a given coefficient when

242   its true value is zero. Since all of the p-values are well below 0.05, we can safely assume

243   that all coefficients are significant.

244   Figure 4 shows the modeled normalized occurrence as a function of plasmapause extent

245   for the three cases of all frequencies (left), $f < 1.5$ kHz (center) and $f > 3$ kHz (right). μ

246   is indicated by a solid black line, and the 95% confidence intervals of the fit are indicated

247   by the surrounding shaded regions. The model for $f < 1.5$ kHz is quite similar to the

248   one for all frequencies, with the same predictors X and similar coefficients β. The model

249   for $f > 3$ kHz is rather different, with different X. This is a consequence of the fact that

250   80% of chorus observed at Palmer includes frequency components below 1.5 kHz, but only

251   33% of chorus includes components above 3 kHz.

252   A distinct feature of all curves is a "saturation" effect, where chorus occurrence does not

253   increase monotonically with decreasing plasmapause extent; instead, a peak in occurrence

254   can be seen at $L_{PP} = 2.6$ for $f < 1.5$ kHz and at $L_{PP} = 2.7$ for $f > 3$ kHz. Additionally, the

255   curve for $f < 1.5$ kHz has a longer tail for higher L_{PP} than that of $f > 3$ kHz, indicating

256   that a less-disturbed (more-extended) plasmasphere permits only lower frequency chorus

257   access to Palmer.

3.3. Chorus Occurrence vs. Plasmapause Extent and AE

Although it was shown in the previous section that plasmapause extent is strongly related to chorus normalized occurrence at Palmer, it is not yet clear whether this is truly a consequence of the instantaneous plasmapause extent or whether it is simply a consequence of the fact that magnetic substorms both increase the likelihood of chorus and, separately, cause erosion of the plasmapause. To explore this confounding effect, multiple regression is used to separately examine dependence of μ on both plasmapause extent, which may affect chorus propagation, and AE, which is related to chorus generation.

Again, a solution to (3) is sought, except that now X includes L_{PP} and $\log_{10} \mathrm{AE}$ terms as well as interaction terms. Beginning with a model that includes all permutations of L_{PP} through $L_{\mathrm{PP}}{}^4$ and $\log_{10} \mathrm{AE}$ through $(\log_{10} \mathrm{AE})^4$ of total order four or less, terms with high p-values whose removal increases BIC are dropped. Eventually, the model of Table 2 is found. Table 2 shows the selected model parameters, their coefficients, and the p-value of each coefficient.

A plot of μ, the modeled parameter of (2), as a function of L_{PP} and $\log_{10} \mathrm{AE}$ for all frequencies, is shown in Figure 5a. To reduce noise in panel (a), the actual plotted quantity is $\mu \cdot (1 - \sigma_{95}^2)$ instead of μ, where σ_{95} is the range of the 95% confidence interval, obtained by subtracting panel (c) from panel (b). This has the effect of setting areas with high variance to zero, e.g., the lower-left and upper-right portions of the plot. As in Section 3.2, a saturation effect is seen with respect to L_{PP}, and a peak in μ is seen at $L_{\mathrm{PP}} = 2.6$ for $\mathrm{AE} \gtrsim 100$ nT. Additionally, the long tail in L_{PP} is reproduced, with μ retaining a small but nonzero value up to $L_{\mathrm{PP}} \sim 4.5$.

The primary takeaway fact from Figure 5 is that features with respect to L_{PP} persist for a wide range of AE, and features with respect to AE persist for a wide range of L_{PP}. E.g., the peak at $L_{PP} = 2.6$ exists for 200 nT $\lesssim$ AE $\lesssim$ 1000 nT, and the peak at AE = 500 nT exists for $2.1 \lesssim L_{PP} \lesssim 3.1$. This is an indication that effects of AE or L_{PP} near the peak of chorus occurrence are quasi-independent of each other. Had it been otherwise, and the effects of AE and L_{PP} were strongly dependent, the peak in Figure 5 would appear as a diagonal line. Therefore, it is clear that the plasmapause *is* in fact significantly changing the characteristics of chorus propagation to Palmer, and that the correlation between L_{PP} and μ is not merely a confounding effect of the fact that magnetic substorms tend to affect both chorus generation and the plasmapause.

4. Modeling of Chorus Propagation

The effects of plasmapause extent on chorus propagation are further investigated using a combination of raytracing and full wave modeling. First, reverse raytracing is used wherein rays begin above the ionosphere over Palmer with wave normal angles within the ionospheric transmission cone. The rays are then propagated backwards to their magnetospheric source. A valid source location for each ray is outside the plasmasphere at the magnetic equatorial plane [*LeDocq et al.*, 1998; *Santolík et al.*, 2005] at a radial distance such that the wave frequency is in the range $0.1 f_{ceq} \leq f \leq 0.5 f_{ceq}$ [*Tsurutani and Smith*, 1974; *Burtis and Helliwell*, 1976]. Rays that are able to enter a valid source location are binned by radial extent and wave normal angle. This creates a comprehensive picture of the portion of the equatorial source region from which generated rays may reach Palmer. Ray attenuation is calculated via Landau damping on the magnetospheric ray paths using an empirical model of energetic particle fluxes. In addition, we assume that

waves may penetrate the ionosphere some distance from Palmer and propagate within the

Earth-ionosphere waveguide before being received; a full wave model is used to estimate

this additional waveguide attenuation. Full details of the simulation are further discussed

below. The simulation is performed for a range of plasmapause extents. For each plasma-

pause extent, a single scalar quantity is calculated, which we term the Chorus Availability

Factor (CHAF). CHAF is a cumulative measure of the portion of the chorus source region,

integrated over all radial extents and wave normals, and weighted by relative attenuation

and source probability, that is observable at Palmer. Although CHAF is not a probability,

if the plasmapause extent does significantly influence chorus propagation, the trends of

CHAF versus L_{PP} are expected to resemble those of the experimentally modeled chorus

normalized occurrence, μ, from Section 3.2.

4.1. The Stanford VLF 3D Raytracer

The new version of the Stanford VLF raytracer was developed by one of us (F. R. F.) as

a more accurate and complete model to replace Stanford's previous raytracing program

[*Inan and Bell*, 1977], which we refer to as the Stanford VLF legacy raytracer. The new

raytracer, which we refer to as the Stanford VLF 3D raytracer, was written from the

ground up, and is not an extension or revision of the Stanford VLF legacy raytracer. A

description of the raytracer follows.

Hamilton's equations for the propagation of a ray through a medium with spatially-

varying dispersion relation defined by the implicit function $F(\omega, \mathbf{k}, \mathbf{r}) = 0$ can be stated

320 as:

$$\frac{d\mathbf{r}}{dt} = -\frac{\nabla_k F}{\partial F/\partial \omega} \tag{4}$$

$$\frac{d\mathbf{k}}{dt} = \frac{\nabla_r F}{\partial F/\partial \omega} \tag{5}$$

321 With the constraint:

$$F(\omega, \mathbf{k}, \mathbf{r}) = 0 \tag{6}$$

322 For generality, and for the purpose of accommodating any arbitrary function for the

323 plasma density or background magnetic field, the spatial and k-space derivatives are

324 evaluated numerically using finite differences, that is:

$$\frac{\partial F}{\partial k_i} \approx \frac{1}{2\Delta k} \left(F(\omega, \mathbf{k} + \Delta k \mathbf{e}_i, \mathbf{r}) - F(\omega, \mathbf{k} - \Delta k \mathbf{e}_i, \mathbf{r}) \right) \tag{7}$$

$$\frac{\partial F}{\partial r_i} \approx \frac{1}{2\Delta r} \left(F(\omega, \mathbf{k}, \mathbf{r} + \Delta r \mathbf{e}_i) - F(\omega, \mathbf{k}, \mathbf{r} - \Delta r \mathbf{e}_i) \right), \tag{8}$$

325 where $i = \{1, 2, 3\}$, and $\mathbf{e}_i$ are the unit vectors. Since the derivatives are evaluated nu-

326 merically, all that is required to adapt a new plasma density model is a function that

327 evaluates $F(\omega, \mathbf{k}, \mathbf{r})$.

328 After approximating the spatial and k-space derivatives, six ordinary differential

329 equations remain, which are integrated numerically in time using a standard adaptive

330 Runge-Kutta method. In contrast to the approach of *Haselgrove* [1955], a moving B_0-

331 aligned coordinate system is not used; instead, the system of equations is directly solved in

332 global Cartesian coordinates. After one time step, the constraint $F = 0$ is not in general

333 met, and an intermediate solution exists with an error $F(\omega, \mathbf{k}^*, \mathbf{r}^*) = \epsilon$. This is handled

334 using a standard method for solving constrained ODEs, by finding a "nearby" point $(\mathbf{k}, \mathbf{r})$

335 that satisfies $F(\omega, \mathbf{k}, \mathbf{r}) = 0$ after every time step. The specific approach used is to sim-

336 ply re-solve the dispersion relation assuming the wave normal angle is kept constant. If

337 this fails (due to being too close to the resonance cone), the time step is halved and the

338 procedure is attempted again.

339   The Stanford VLF 3D raytracer can accommodate any arbitrary function for the

340 cold background plasma number density. In this study, the Global Core Plasma Model

341 (GCPM) [*Gallagher et al.*, 2000] is implemented, sampled on a regular grid and interpo-

342 lated by a fast, local, C^1 (continuous in the first derivative) tricubic interpolation scheme

343 described in *Lekien and Marsden* [2005]. The plasmasphere modeled by the GCPM is field-

344 aligned to the dipole field, and remains so from the equatorial region down to altitudes

345 between 7800 km ($K_p \sim 3^+$) to 2600 km ($K_p \sim 8^-$). The typical plasmapause represented

346 by the GCPM exhibits a density drop of between 1 ($K_p \sim 3^+$) and 1.5 ($K_p \sim 8^-$) orders

347 of magnitude in the equatorial plane over a range of about 0.3 R_E. The choice of back-

348 ground magnetic field is also arbitrary; in this study, the Tsyganenko-96 (T96) model

349 [*Tsyganenko*, 1995; *Tsyganenko and Stern*, 1996] is used.

350   Thermal losses are included as in *Kennel* [1966]. Equation (3.9) in *Kennel* [1966],

351 corrected for a typographical error [*Chen et al.*, 2009, paragraph 9], is solved for the

352 Landau ($m = 0$) resonance. This yields the temporal damping rate ω_i, which is then

353 related to the spatial damping rate k_i by the relation in *Brinca* [1972]:

$$\omega_i = \overrightarrow{k_i} \cdot \overrightarrow{v_g}. \tag{9}$$

354 The method in *Kennel* [1966] requires the evaluation of the gradients of the hot particle

355 distribution function in $(v_\parallel, v_\perp)$ space, as well the evaluation of a 1D integral over $v_\perp$

356 over the interval $[0, \infty)$. In order to accommodate any arbitrary distribution function, the

357 derivatives are again evaluated numerically using finite differences. The velocity is first

358 normalized by the speed of light for numerical reasons, then mapped into a finite range

359    $t = (0, 1)$ using the mapping $v_\perp = (1 - t)/t$:

$$\int_0^\infty f(v_\perp)dv_\perp = \int_0^1 \frac{1}{t^2} f\left(\frac{1-t}{t}\right) dt. \tag{10}$$

360   Finally, the integral is evaluated numerically using adaptive quadrature. The method

361   used is general and can accommodate any number of resonances. In this study, only the

362   Landau ($m = 0$) resonance is used, since it is the dominant source of loss.

363   The choice of hot particle distribution is crucial to the accurate calculation of Lan-

364   dau damping. Within the plasmasphere, the phase space density expression of *Bell*

365   *et al.* [2002], based on measurements with the POLAR spacecraft sampled in the range

366    $2.3 < L < 4$, is used. Outside the plasmasphere, the methodology of *Bortnik et al.* [2007a],

367   derived from measurements with the CRRES spacecraft outside the plasmasphere up to

368    $L \sim 7$, is used.

369   A hybrid model smooths the two models at the plasmasphere boundary, and is imple-

370   mented as follows. Let f_0^{POL} represent the phase space density (PSD) of *Bell et al.* [2002]

371   from POLAR in units of, e.g., s^3/cm^6, and let f_0^{CRR} represent the PSD of *Bortnik et al.*

372   [2007a] from CRRES in the same units. Define the "weights" of the two distributions at

373   a given L-shell, L_{meas}, for a given plasmapause extent, L_{PP}, as

$$\begin{aligned} w^{\text{POL}} &= \frac{\exp\left(-\alpha(L_{\text{meas}} - L_{\text{PP}})\right)}{1 + \exp\left(-\alpha(L_{\text{meas}} - L_{\text{PP}})\right)} \\ w^{\text{CRR}} &= \frac{\exp\left(\alpha(L_{\text{meas}} - L_{\text{PP}})\right)}{1 + \exp\left(\alpha(L_{\text{meas}} - L_{\text{PP}})\right)}. \end{aligned} \tag{11}$$

374   Then, the implemented hybrid PSD is given by the weighted mean in log-space of POLAR

375   and CRRES PSDs as

$$f_0^{\text{hybrid}} = \exp\left(\frac{\log\left(f_0^{\text{POL}}\right)w^{\text{POL}} + \log\left(f_0^{\text{CRR}}\right)w^{\text{CRR}}}{w^{\text{POL}} + w^{\text{CRR}}}\right). \tag{12}$$

376   Reasonable results are obtained with $\alpha = 5$. For reference, when $L_{\text{meas}} - L_{\text{PP}} = 0$, the

377   two distributions are weighted equally in log-space, and when $L_{\text{meas}} - L_{\text{PP}} = +(-)0.5$,

378 i.e., the measurement location is 0.5 L-shells beyond (within) the plasmapause, f_0^{CRR} is

379 weighted 12 times more (less) than f_0^{POL} in log-space.

380   It should be noted that, although this raytracing procedure is three-dimensional, the

381 following study is restricted to rays that lie approximately in a single meridional plane.

382 Due to azimuthal gradients in the plasma and B-field models, rays exhibit a slight tendency

383 to propagate to earlier local times with increasing L-shell. The maximum azimuthal

384 deviation of any ray considered in this study is 18° (1.2 hours in MLT), with an average

385 maximal deviation per ray of 7° (0.5 hours in MLT). Because this value is small, the local

386 time deviation of rays is neglected in this study, and wave normals and positions are given

387 in two dimensions with respect to the meridional plane of the rays.

4.2. Raytracing Procedure

388   Rays are launched in the vicinity of Palmer, at $\lambda = 50°$S, MLT = 06, UT = 10. The

389 GCPM and Tsyganenko models for plasma density and magnetic field are used, and the

390 rays propagate in the non-ducted mode. Rays are launched at 1000 km altitude, with

391 80 equally-spaced magnetic latitudes within 1000 km of 50°S, and with 13 equally-spaced

392 k-vector angles directed away from the Earth within the transmission cone, for a total of

393 1040 rays per simulation.

394   The transmission cone angle defines the maximum deviation of downward-directed

395 k-vectors, with respect to the normal to the Earth's surface, that may penetrate through

396 the ionosphere and to the ground without suffering total internal reflection at the boundary

397 between the lower edge of the ionosphere and free space [e.g. *Helliwell*, 1965, Section 3.7].

398 To calculate the transmission cone, it is assumed that the plasma density from the ray

399 origin to the ground may be approximated as a stratified medium, and therefore that the

400 horizontal component of the k-vector is conserved. At 1 kHz and 4 kHz, two frequencies of

401 interest for this study, the half angle of the transmission cone, measured from the vertical,

402 is 0.84° and 1.44°, respectively.

403   Each ray is traced for up to 30 seconds, or until it either impacts the Earth, or de-

404 parts from the precalculated density grid in the range $-4 \leq X_{\mathrm{SM}} \leq 4$, $-8 \leq Y_{\mathrm{SM}} \leq 0$,

405 $-3 \leq Z_{\mathrm{SM}} \leq 3$, where all coordinates are in units of Earth radii in the solar-magnetic

406 coordinate system. In practice, under these criteria, no rays survive beyond 10 sec-

407 onds. Each time a ray crosses the equatorial plane, the local plasma density and gyrofre-

408 quency are examined. If the ray is (1) outside the plasmasphere, and (2) within the range

409 $0.1 f_{ceq} \leq f \leq 0.5 f_{ceq}$ (where f_{ceq} is the equatorial electron gyrofrequency along the given

410 field line), which is the frequency range of lower-band chorus [*Tsurutani and Smith*, 1974;

411 *Burtis and Helliwell*, 1976], then that point is saved as a potential chorus source location.

412 A single original ray may give rise to more than one potential chorus source location if it

413 exhibits multiple magnetospheric reflections.

414   The chorus source region (i.e., the region from which chorus is truly generated, which is

415 not the same as the location from which the "reverse" rays are launched) is considered to lie

416 on the equatorial plane, with initial wave normal angles uniformly distributed within the

417 resonance cone. Although several satellite studies have attempted to characterize the wave

418 normal distribution of the equatorial chorus source [e.g. *Haque et al.*, 2010, and references

419 therein], statistics have generally been too low to draw any definitive conclusions, leading

420 to our use of a uniform distribution in this study. The source region is binned on two

421 parameters: R, the distance from the center of the Earth in the equatorial plane, and ψ,

the initial wave normal angle with respect to the ambient magnetic field. Each bin is of

uniform size, with $\Delta R = 0.05 R_{\mathrm{E}}$ and $\Delta \psi = 4°$.

Chorus rays that can reach Palmer tend to occur in several distinct "families," or group-ings of rays with similar initial wave normals and radial extent. Figure 6 shows several facets of the raytracing procedure, along with example rays from the two ray families that are present at 1 kHz. For this simulation, $L_{\mathrm{PP}} = 2.9$. The raytracing procedure is described below with reference to Figure 6.

Panel (a) shows representative rays from the two ray families. We interpret the rays in their "forward" sense, as if they were originally launched from the equatorial plane and eventually arrived at 1000 km altitude. Ray paths are shown in white, with wave normals shown as red ticks, equally spaced every 100 ms. The magenta line indicates a contour of $f/f_{ceq} = 0.1$; all chorus generation happens at values of R beyond this boundary. The upper bound on f_{ceq} for chorus generation, at $f/f_{ceq} = 0.5$ is beyond the scale of the image, at $R \sim 7\ \mathrm{R_E}$. Palmer's location is indicated by the green triangle at $\lambda = -50°$ on the surface of the Earth. The background image is a meridional slice of the GCPM electron density. Ray family 1 consists of rays that propagate directly from the chorus source region to Palmer without magnetospherically reflecting (MR), and family 2 consists of rays that MR at the plasmapause boundary, which allows them access into the plasmapause before reaching Palmer. Because raytracing is performed in three dimensions, the ray paths and wave normals have been projected into the MLT = 06 meridional plane.

Panel (b) shows the initial refractive index surfaces for the representative rays. The direction of the ambient magnetic field, B_0, the wave refractive index, $n_p = c/v_p$, and the group refractive index, $n_g = c/v_g$, as well as the Gendrin angle, ψ_g, are indicated, where c

is the speed of light in free space, v_p is the wave phase velocity and v_g is the wave group

velocity. n_p and n_g point in the direction of the wave k-vector and group velocity vector,

respectively.

Each potential chorus source location represents a ray that originally begins with unity

power and is attenuated in two separate steps. First, panel (c) shows the attenuation

of the representative rays over the course of their magnetospheric propagation due to

Landau damping, as discussed in Section 4.1. The majority of damping occurs at high

L-shells outside the plasmasphere. In particular, once ray 2 enters the plasmasphere, the

attenuation due to Landau damping is negligible. Unlike some other studies of raytracing

[e.g. *Bortnik et al.*, 2007a, b], this study does not include a geometric effect in determining

the power gain or loss due to the focusing of magnetic field lines at low altitudes. Instead,

this focusing or defocusing happens naturally through the use of a large number of rays.

The second mode of attenuation, shown in panel (d), is attenuation from

Earth-ionosphere waveguide propagation. Each ray begins at 1000-km altitude with

the injection point footprint a distance d from Palmer station, where $d \leq 1000$ km.

Earth-ionosphere waveguide attenuation is calculated using the full wave model of *Lehti-*

nen and Inan [2008, 2009]. A summer night-time ionospheric profile and a perfectly

conducting ground layer (representative of Palmer's primarily all-sea paths) are used. A

Gaussian wave packet of the appropriate frequency is injected at 140 km altitude with

vertical (downward) wave normal. The ground power at various distances from the source

is recorded, normalized by the ground power directly beneath the source. The resulting

quantity $A(d)$ represents an attenuation factor for Earth-ionosphere waveguide propaga-

tion, as a function of d, by which each ray's power is multiplied. The full wave model is

468 run only once for any given frequency, and the quantity $A(d)$ is assumed to be valid for

469 all modeled rays within 1000 km of Palmer. The two example rays reach the ground at

470 ~ 450 km and ~ 215 km from Palmer, respectively, and are marked as such in panel (d).

471 When both Landau damping and Earth-ionosphere waveguide attenuation are considered,

472 there can be wide variations in the attenuation of different rays in a given family, due

473 to the fact that slight variations in initial conditions may give rise to large variations in

474 propagation paths and ionospheric penetration points.

475   Panel (e) is a plot of "source factor" as a function of radial extent, R. This plot is

476 derived from *Burtis and Helliwell* [1976, Figure 9c], which shows chorus occurrence as

477 a function of f/f_{ceq}. We define source factor as the observed occurrence of *Burtis and*

478 *Helliwell* [1976, Figure 9c], normalized so that the maximum value is 1. Here, source

479 factor is plotted against R, using the T96 magnetic field model to map from f/f_{ceq} to

480 R. The source factor plot is then the relative expected likelihood of observing a 1 kHz

481 chorus source at a given radial extent in the equatorial plane. Because the measurements

482 of *Burtis and Helliwell* [1976] include both waves inside and outside the plasmasphere, it

483 is possible that the observed chorus percentage is artificially low at low f/f_{ceq} or R due to

484 those measurements being taken within the plasmasphere where chorus is generally not

485 observed. The use of the source factor in deriving the Chorus Availability Factor (CHAF)

486 is discussed in Section 4.3, and due to the possible confounding effects of its constituent

487 data containing measurements inside the plasmasphere, CHAF is derived both with and

488 without implementing the source factor.

489   After building a list of potential chorus source locations from the 1040 original rays, the

490 amplitude of any given R-ψ bin is set to the maximum ray amplitude in that bin after

attenuation both via Landau damping in the magnetosphere and via attenuation in the

Earth-ionosphere waveguide. We refer to a plot of the binned results for a simulation with

a given wave frequency and plasmapause extent as a "source attenuation plot."

Panel (f) shows a source attenuation plot for a simulation where $L_{\mathrm{PP}} = 2.9$, from which

the two example rays are drawn. The local resonance cone angle, ψ_{res}, defined as the wave

normal angle at which the magnitude of the refractive index goes to infinity, is indicated

by the solid black lines. The local Gendrin angle, ψ_g, defined as the nonzero wave normal

angle at which the group velocity vector is parallel to the static magnetic field, is indicated

by the dashed black lines. The two separate ray families, from which the above example

rays are drawn, are highlighted with red boxes. The rays do not show any particular

relationship with the resonance cone or Gendrin angles.

Figure 7 is analogous to Figure 6, but for 4 kHz waves. Because f is increased, the

magenta lines, indicating the contours of $f/f_{ceq} = 0.1$ and $f/f_{ceq} = 0.5$ are now closer to

the Earth, and both boundaries of the chorus source region can be seen. In addition,

there are now four ray families, representing the direct path, and one, two and three

magnetospheric reflections. In all cases, the damping is most significant at large L-shells

outside the plasmasphere, where wave normals are most oblique. Rays 3 and 4 begin with

their wave normals directed away from the Earth, near the resonance cone. After the

first magnetospheric reflection, they appear to be guided by the plasmapause boundary

before reflecting from the inner boundary. This has the effect of rotating the wave normal

towards the Earth, allowing the rays to reach the ground. Because Rays 3 and 4 spend

more time outside the plasmasphere, and have more highly oblique wave normals than do

rays 1 and 2, they are damped more heavily during their propagation.

In the 4 kHz case, the initial wave normals of some ray families do show a relationship with the resonance cone and Gendrin angles. Some rays from families 1 and 2 tend to be generated near the Gendrin angle, while some rays from families 3 and 4 tend to be generated near the resonance cone angle. The associations are loose, and no ray families appear constrained to either the resonance cone or the Gendrin angle. The relation between the wave normals of ray family 1 (the direct path) and the Gendrin angle is consistent with the work of *Chum and Santolík* [2005], who found that certain rays generated with wave normals in the vicinity of the Gendrin angle would reach low altitudes and possibly penetrate to the ground before being magnetospherically reflected. Although this behavior is seen in our results at 4 kHz, it is not observed at 1 kHz. This is possibly due to the fact that *Chum and Santolík* [2005] did not include Landau damping in their calculations. Although some 1 kHz rays in our study do begin at the equatorial plane with wave normals near the Gendrin angle, those waves are damped to negligible power in the simulation, and therefore do not appear on the source attenuation plot in Figure 6f.

4.3. Chorus Availability Factor

Figures 6f and 7f showed source attenuation plots at 1 kHz and 4 kHz for a single plasmapause extent, $L_{PP} = 2.9$. This analysis is repeated for many different values of L_{PP} to gain insight into the particular way in which the plasmapause extent affects the ability for chorus waves to propagate from their source to Palmer. Figure 8 shows source attenuation plots for 1 kHz (upper panels) and 4 kHz (lower panels) for plasmapause extents in the range $2.1 \leq L_{PP} \leq 4.3$. The color scale has been changed slightly for clarity.

535   Initially, we focus our discussion on the 1 kHz case, in the upper panels of Figures 8. At

536   the greatest plasmapause extent, $L_{\mathrm{PP}} = 4.3$, rays from the chorus source region are not

537   accessible to Palmer; reverse rays launched from Palmer are either unable to escape the

538   plasmasphere, and instead reflect off of its inner boundary before impacting the ionosphere

539   in the conjugate hemisphere, or they escape the plasmasphere with oblique wave normals

540   and are heavily damped before crossing the equatorial plane. As the plasmasphere be-

541   comes more eroded down to $L_{\mathrm{PP}} = 2.9$, although rays as far out as $L = 7$ are accessible

542   to Palmer (not shown), most are severely damped; only certain rays that originate within

543    $4.2 \lesssim L \lesssim 4.6$ sufficiently avoid damping to be received above the -70 dB cutoff. Ero-

544   sion of the plasmasphere beyond $L_{\mathrm{PP}} = 2.9$ results in increased propagation time outside

545   the plasmasphere, and hence, increased damping, particularly for waves with initial wave

546   normals $\psi \sim 50°$. The situation is similar for 4 kHz. For high L_{PP}, rays from the chorus

547   source region cannot reach Palmer; reverse rays are unable to escape the plasmasphere.

548   For $L_{\mathrm{PP}} \sim 2.9$, a maximum of rays reach Palmer with significant power. For low L_{PP}, as

549   for high L_{PP} most reverse rays launched from Palmer do not escape the plasmasphere.

550   One important difference between the simulations at 1 kHz and 4 kHz is where the

551   plasmapause lies with respect to the extents of the chorus source region, defined by

552    $0.1 \leq f/f_{ceq} \leq 0.5$. At 1 kHz, the source region is in the range $4.2 \leq L \leq 6.9$, which

553   is beyond the plasmapause for almost all simulations. However, at 4 kHz, the source

554   region is in the range $2.7 \leq L \leq 4.5$, which means that for many of the simulations, the

555   plasmasphere overlaps the chorus source region. This is why, in the lower panels of Fig-

556   ure 8, the chorus source region appears to expand to the left as L_{PP} decreases. The

plasmapause is moving to the left of the plots, and a greater portion of the chorus source region is becoming available.

Because rays may be substantially damped over the course of propagation, in order to properly analyze the results of the simulations, it is necessary to define a "minimum detectable ray power," below which rays are excluded from the analysis. To first order, this can be achieved by comparing the mean power observed on the ground with the mean power observed via in situ measurements. A histogram of observed amplitudes over the course of this study, overlaid with the associated probability distribution, is shown in Figure 9. Chorus amplitudes observed at Palmer are distributed approximately log-normally, as

$$A_{\mathrm{dB}} \sim \ln \mathcal{N}(\mu = 3.5, \sigma^2 = 0.036) \tag{13}$$

with mean 35 dB-fT and standard deviation 6.8 dB-fT. The observed mean of 35 dB-fT at Palmer can be compared with the mean B-field amplitude calculated by *Santolík* [2008], based on equatorial chorus E-field measurements from *Meredith et al.* [2001], of 10-100 pT, or 80-100 dB-fT. Comparing the two numbers, up to ~ 65 dB of attenuation is expected from the equatorial source region to Palmer. However, in this analysis, we are not modeling attenuation suffered through trans-ionospheric propagation. Trans-ionospheric attenuation is expected to be on the order of ~ 5 dB, somewhere between the daytime and nighttime attenuation calculations of *Helliwell* [1965, Fig. 3-35] for 2 kHz waves (since our simulations are run at 06 MLT). This leaves an expected attenuation from Landau damping and Earth-ionosphere waveguide losses of ~ 60 dB. To account for the lower end of our observed power distribution, which reaches down to ~ 25 dB-fT in Figure 9, an additional 10 dB of loss is allowed. Thus, we define our minimum detectable ray power to

579 be -70 dB. Although it is necessary to define a minimum detectable ray power to perform

580 the following analysis, our conclusions are not strongly dependent on its exact value.

581 We define the CHAF for a given frequency and L_{PP} as follows. First, all bins of a

582 given simulation (i.e., from a source attenuation plot, such as Figure 6f) are normalized

583 by adding 70 dB to each bin, which ensures that bin values are all positive, between 0 and

584 70 dB. Then, each bin is multiplied by the source factor (e.g., Figure 6e), at its particular

585 radial extent. E.g., the bins at the lowest radial extent in Figure 6f, at $R \sim 4.2$ $\mathrm{R_E}$,

586 are multiplied by the source factor of Figure 6e at that same radial extent, which is

587 approximately 0.05. This has the effect of reducing the influence of bins that are at radial

588 extents at which chorus is less-commonly observed. Finally, the values of the bins are

589 summed, and the resulting scalar quantity, as a function of frequency and L_{PP}, is the

590 CHAF.

591 The CHAF of the 1 kHz and 4 kHz simulations is shown in the left panels of Figure 10.

592 The calculated CHAF both before and after applying the source factor are shown in gray

593 and black lines, respectively. It can be seen that application of the source factor makes

594 only a minor difference in the trend of CHAF with L_{PP} for either frequency. This shows

595 that, even if the fact that chorus is preferentially generated at certain values of f/f_{ceq} is

596 not included (for example, due to the fact that the source factor may artificially reduce

597 the effect of chorus originating at low L-shells outside the plasmasphere) the plasmapause

598 has a similar effect in dictating the amplitude of received chorus.

599 Because CHAF is derived from the data that makes up the source attenuation plots

600 in Figure 8, its behavior with respect to L_{PP} is analogous to that in Figure 8. As L_{PP}

601 decreases from $L_{\mathrm{PP}} = 4.3$ to $L_{\mathrm{PP}} = 2.1$, the availability of different portions of the chorus

source region wax and wane, which translates into increasing and decreasing CHAF. At 1 kHz, CHAF is maximized for $L_{PP} = 3.1$, where two regions, narrow in ψ and broad in R are accessible to Palmer. At 4 kHz, CHAF is maximized for $L_{PP} = 2.9$, where several broad regions of the source region are accessible to Palmer. These regions are made up of rays from the different ray families discussed in Section 4.2.

4.4. Comparison With Observations

We would like to compare the simulated CHAF to the experimental results of Section 3.2. If the variation in chorus occurrence as a function of L_{PP} observed in Section 3.2 is primarily a propagation effect, then CHAF should behave similarly to the empirically modeled normalized chorus occurrence probability, μ, as a function of L_{PP}. Note that CHAF is merely a proxy measurement of chorus observed probability and is not a probability. To form a proper probability estimation from this data, it would be necessary to estimate the distribution of chorus power as a function of radial distance or f/f_{ceq} and initial wave normal angle. For lack of this information, we have assumed uniform initial power at all wave normals and radial distances.

Figure 10 shows a comparison of the CHAF at 1 and 4 kHz with the equivalent univariate generalized linear model (GLM) results for μ. The GLM results shown here are limited to chorus occurring at 1 and 4 kHz, instead of the ranges $f < 1.5$ kHz and $f > 3$ kHz shown in Figure 4. First, and most importantly, the saturation effect is reproduced for both frequencies. Both μ and CHAF initially increase with decreasing L_{PP}, reach a peak, and then decrease. Their peaks are within 0.5 L. This similarity between CHAF and μ is strongly indicative of the fact that the behavior of μ with respect to L_{PP} is a propagation effect and not a source effect (since only propagation effects are included in the raytracing).

624 However, we also note the important discrepancy between the L_{PP} values for the peaks

625 of CHAF and the peaks of μ. For 1 kHz, the peak of μ is at $L_{PP} = 2.6$, whereas that

626 for CHAF is at $L_{PP} = 3.1$, a difference of 0.5 R_E. The random error in the measured

627 value of L_{PP} for either μ (measured by clicking on equatorially-mapped EUV images) or

628 CHAF (measured by direct examination of an equatorial slice through the GCPM grid)

629 is estimated to be ± 0.1 R_E, but this is too small to account for the observed discrepancy.

630 Similarly for 4 kHz, the observed peaks are at $L_{PP} = 2.7$ and $L_{PP} = 2.9$, respectively, a

631 smaller difference of 0.2 R_E.

632 There are several different possible causes for the discrepancy between the peaks in μ

633 and CHAF. The first and most obvious cause may be errors in particle densities from the

634 GCPM density model, either in the absolute density or in density gradients. The GCPM

635 model necessarily represents "averaged" conditions for its input values, and may contain

636 systematic biases with respect to the true magnetospheric conditions under which chorus

637 is observed at Palmer.

638 Another cause may lie in our use of a hybrid energetic electron distribution when cal-

639 culating Landau damping. The CRRES distribution used outside the plasmasphere uses

640 data from disturbed periods, when AE > 300 nT. However, the POLAR distribution used

641 inside the plasmasphere uses data from quiet-to-moderate conditions, when $K_p \leq 4$. Be-

642 cause chorus tends to peak during active periods, the use of quiet/moderate fluxes within

643 the plasmasphere has the effect of artificially lowering the energetic particle flux inside the

644 plasmasphere, therefore lowering the damping coefficients and allowing rays to propagate

645 for a long time within the plasmasphere. Thus, at 1 kHz, ray family 2 from Figure 6,

which involves extended propagation within the plasmasphere, and which is dominant for $L_{\mathrm{PP}} \gtrsim 2.7$, may be less influential than modeled.

Finally, by excluding the prevalent density irregularities that permeate the plasmasphere [e.g. *Carpenter et al.*, 2002, and references therein], we neglect what may be a significant population of waves that are guided by these irregularities. In particular, in the real plasmasphere, density irregularities in the vicinity of the plasmapause may preferentially guide waves to Palmer when the plasmapause is at lower L-shells [*Inan and Bell*, 1977]. The exclusion of irregularities is an inevitable consequence of using an "averaged" plasma density model, such as the GCPM model for the plasma density. A full discussion of the effects of guiding by density irregularities is beyond the scope of this study.

One other important discrepancy between the plots of μ and CHAF is that the relative value of μ for low frequencies is significantly greater than that for high frequencies (right panels), whereas the opposite relation is true for CHAF (left panels). This may be due to the fact that higher-frequency waves tend to be generated with lower amplitudes [*Burtis and Helliwell*, 1975], whereas we have assumed in our raytracing analysis that the amplitude of generated waves is the same across all frequencies.

5. Conclusions

We have proposed in this study that the extent of the plasmapause, denoted L_{PP}, plays a large role in determining the ability for chorus waves to propagate from their equatorial magnetospheric source region to the ground. Using wave data from the ground-based receiver at Palmer Station, Antarctica, together with plasmapause data from the IMAGE EUV instrument, a generalized linear model regression was employed in Section 3.2 to show the strong dependence of chorus normalized occurrence on L_{PP}.

668   The separability of AE and L_{PP} shown in Section 3.3 provides evidence that the de-

669   pendence of chorus occurrence on L_{PP} is in fact a propagation effect, and not simply a

670   confounding source effect (i.e., a consequence of the fact that magnetic substorms both

671   give rise to chorus generation and, separately, cause erosion of the plasmasphere). In

672   particular, Figure 5 shows that the general trend of normalized occurrence vs. plasma-

673   pause persists across a wide range of AE values. This shows that the relation of chorus

674   occurrence to AE (a proxy measure of a source effect), is separable from the relation of

675   chorus occurrence to L_{PP} (a measure of a propagation effect), and therefore, that there is

676   a significant influence of instantaneous plasmapause extent in determining whether chorus

677   can reach Palmer.

678   These conclusions were solidified via a reverse raytracing study. By launching rays

679   from Palmer and tracking their power, wave normal, and equatorial crossings through

680   the expected chorus source region, a measure of the portion of the chorus source region

681   from which rays may reach Palmer was obtained, which we termed the Chorus Avail-

682   ability Factor, or CHAF. The most salient similarity between how the experimentally

683   observed chorus occurrence (μ) and the raytracing model (CHAF) depend on L_{PP} is the

684   so-called saturation effect, where during experimental observations, chorus is observed on

685   the ground most often for $L \sim 2.6$. It was shown in Section 4.4 that this effect is repro-

686   duced via raytracing (with a small systematic error in the exact value of L_{PP}) by varying

687   only L_{PP}; this eliminates the possibility of a confounding source effect, and further en-

688   forces the conclusion that the plasmapause extent has a direct effect on allowing chorus

689   access to the ground.

The peak of the saturation, either the observed peak of $2.6 \lesssim L_{\mathrm{PP}} \lesssim 2.7$ or the modeled peak of $2.9 \lesssim L_{\mathrm{PP}} \lesssim 3.1$, is somewhat higher than Palmer's location at $L = 2.4$. One might naïvely expect the peak of chorus to occur at $L_{\mathrm{PP}} = 2.4$, because it is at that plasmasphere extent that Palmer station lies on the plasmapause boundary. However, this theory neglects the mechanism of rays reaching Palmer via magnetospherically reflecting at the northern plasmapause boundary, as in ray family 2 from Figure 6 and ray families 2, 3 and 4 from Figure 7. This can can occur at high plasmapause extents, and the prevalence of this mode of propagation may be one explanation for why chorus is often observed at Palmer even when the plasmapause is beyond $L = 2.4$.

Additionally, by raytracing in a smooth magnetosphere (except for the obvious density gradient of the plasmapause itself), it was shown that it is possible for chorus to reach the ionosphere within the transmission cone and penetrate to the ground in the absence of any field-aligned guiding structures. This is in contrast to long-held colloquial belief that only ducted chorus may access the ground. In fact, in light of the similarities between the raytracing and the experimentally-observed results, it seems plausible that non-ducted chorus is the dominant mode of chorus observed on the ground. Without the constraint of a field-aligned guiding structure, chorus is able to cross L-shells as it propagates from the source region to the ground. This explains why Palmer Station, located at a significantly-lower L-shell than that of the typical chorus source region, is able to observe chorus as often as it does.

We conclude by saying that, due to the fact that mid-latitude ground observations of chorus are likely to result from nonducted propagation, these observations are by no means limited to chorus source regions that lie on the same L-shell as the receiver. In addition,

plasmapause extent is an often-neglected but critically important factor in determining

chorus propagation to low altitudes and the ground.

Figure 1. Cumulative spectrogram of chorus emissions from April through June, 2001. Only emissions in the boxed area, between 04 and 10 MLT, are used in this study.

Figure 2. L-shell of plasmapause at $MLT = UTC - 4.0$ within the range $04 \leq MLT \leq 10$ plotted against (left) instantaneous AE, and (right) average AE in the previous 12 hours. Plasmapause extent is moderately correlated with instantaneous AE ($\rho = -0.43$, $\sigma_{\text{err}} = 0.75$ L) and highly correlated with average AE in the previous 12 hours ($\rho = -0.81$, $\sigma_{\text{err}} = 0.49$ L). In each plot, the solid red line is a linear fit between Plasmapause L and the logarithm of AE.

Figure 3. Scatter plot of synoptic epochs with (blue squares) and without (red dots) chorus. Note that AE is displayed on a logarithmic scale, while plasmapause extent is displayed on a linear scale.

$(\log_{10} \text{AE})^2 \cdot L_{\text{PP}}$	-2.588×10^2	1.8×10^{-6}
$(\log_{10} \text{AE})^3$	-1.042×10^2	7.5×10^{-6}
L_{PP}^3	4.518×10^1	5.5×10^{-6}
$(\log_{10} \text{AE})^3 \cdot L_{\text{PP}}$	3.486×10^1	2.0×10^{-6}
L_{PP}^4	-3.245×10^0	9.9×10^{-6}

Figure 5. Model for μ, the normalized occurrence rate of chorus as a function of plasmapause extent and AE, obtained using generalized linear model regression on observations of chorus. Panel (a) shows the expected value of normalized occurrence, and panels (b) and (c) show the upper and lower bounds of the 95% confidence interval for μ.

Figure 6. Two 1 kHz ray families that are capable of being received at Palmer. (a) Representative raypaths from each of two ray families. Family 1 is the direct path from the source region to Palmer, and family 2 includes rays that magnetospherically reflect into the plasmasphere before their reception on the ground. (b) Initial refractive index surfaces for example rays. (c) Attenuation of example rays vs. time over the course of raytracing, via Landau damping. (d) Attenuation of example rays vs. distance within the Earth-ionosphere waveguide, via full wave modeling. (e) Source factor showing relative expected chorus vs. radial extent. (f) Source attenuation plot of relative received power vs. wave normal ψ and radial extent. Solid lines indicate the local resonance cone angle, ψ_{res}, and dashed lines indicate the local Gendrin angle, ψ_g. The two families of similar rays, labeled 1 and 2, correspond to the two example rays from the previous panels.

Figure 7. Same as Figure 6, but for 4 kHz. At this frequency, there are four distinct ray families, representing the direct path, and one, two and three magnetic reflections.

Figure 8. Source attenuation plots for $f = 1$ kHz (upper panels) and $f = 4$ kHz (lower panels) for plasmapause extents in the range $2.1 \leq L_{\mathrm{PP}} \leq 4.3$. Note that the scales of the x-axes in the upper and lower panels are not the same.

Figure 9. Histogram and log-normal probability distribution function (PDF) of observed chorus amplitudes at Palmer. Bins of the histogram have been normalized by the total number of samples and the bin width, so that they have the same units as the log-normal PDF.

Figure 10. Comparison of CHAF from raytracing (left) with generalized linear model of occurrence probability, μ, derived from measurements (right). CHAF is calculated from constituent data of the source attenuation plots of Figure 8. μ is calculated using data at single frequencies 1 kHz and 4 kHz, instead of a range of frequencies as in Section 3.2. As before, on the plot of μ, the solid black line indicates μ, and the shaded area indicates the 95% confidence interval. The lighter-colored line on the plots of CHAF represent the values prior to applying the source factor from *Burtis and Helliwell* [1976], and the darker lines represent values after applying the source factor. The shapes of the curves with and without the source factor applied are very similar. Note that the scales of the x-axes in the upper and lower panels, and on the overlaid plots of CHAF, are not the same.
