10 **Abstract**

11 Reforestation, which converts abandoned farmland back into forestland by planting
12 woody species, can provide habitat for wildlife, including the brown bear (*Ursus arctos*
13 Linnaeus, 1758). In the Shiretoko World Heritage site, northern Japan, where brown bears
14 occur at high density, conifers have been planted since the 1970s to reforest abandoned
15 farmland. In this area, brown bears were first observed digging for cicada nymphs (*Lyristes*
16 *bihamatus* Motschulsky, 1861) from 2000. Our preliminary observations suggested the
17 emergence of digging behavior might be associated with reforestation. We examined
18 whether reforestation provided a foraging habitat for brown bears. We found that digging
19 occurred only within the restored conifer forests, but not within the natural forest. The
20 densities of cicada nymphs in the restored forests were higher than in the natural forest.
21 These results indicate that the reforestation of abandoned farmland provides a foraging
22 habitat for brown bears by increasing the availability of cicada nymphs in the Shiretoko
23 World Heritage site.

26 **Introduction**

27 Forests, which occupy one third of terrestrial ecosystems, harbor the highest
28 biodiversity in the world (Millenium Ecosystem Assessment 2005). From the 1700s to the
29 1990s, approximately 20 % of forests were converted to farmland, and consequently a wide
30 range of forest habitat was lost around the world (Goldewijk 2001). Since the 1900s, large
31 areas of farmland have also been abandoned in developed countries because of declines in
32 human population in agricultural areas as a result of aging populations and migration to
33 urban areas (Ramankutty and Foley 1999). Reforestation, which is a major ecological
34 restoration action in forest ecosystems, aims to convert abandoned farmland to forestland by
35 planting woody species (Chazdon 2008; Aerts and Honnay 2011). The goals of reforestation
36 are not only re-establishment of forest cover, but also the enhancement of forest ecosystem
37 functions such as carbon sequestration, biodiversity conservation and wildlife habitat (Block
38 et al. 2001; Le et al. 2012; Cunningham et al. 2015; Derhé et al. 2016). Because reforestation
39 cannot fully restore the original forest ecosystem, it does not necessarily succeed in
40 recovering forest ecosystem functions. Therefore, it is important for the evaluation of

41 reforestation success to understand the ecological functions of the restored forest (Le et al.
42 2012).

43 The direction and magnitude of reforestation's influence on wildlife, differs among
44 species and taxonomic groups depending on their ecology such as habitat requirements (Law
45 et al. 2017; Whytock et al. 2018; Fuentes-Montemayor et al. 2020). Thus, it is important for
46 deepening the understanding of a function of reforestation as wildlife habitat to clarify the
47 response per each species and taxonomic groups.

48 The brown bear (*Ursus arctos* Linnaeus, 1758), which is one of the most widespread
49 and largest carnivores in terrestrial ecosystems, plays important ecological roles as an apex
50 predator and long-distance seed disperser, and transport of marine-derived nutrients
51 (Reimchen 2000; Helfield and Naiman 2006; Ripple et al. 2014; Steyaert et al. 2019). Brown
52 bears sensitively respond to anthropogenic habitat changes due to forestry (e.g. afforestation
53 and deforestation), cultivation and industrial development (Cristescu et al. 2015; Frank et al.
54 2015; Sorensen et al. 2015; Penteriani et al. 2018). In fact, woodland conversion to cropland
55 leads to an increased attraction of bears to human settlements for crop raiding, and

56 consequently increases their human-caused mortality (Hata et al. 2017; Penteriani et al.
57 2018). In forest ecosystems, clearcuts temporarily change in resource availability for bears
58 via increasing light environment and biomass of coarse woody debris, and influence their
59 habitat selection (Nielsen et al. 2004a, 2004b; Frank et al. 2015). For example, in west-
60 central Alberta, Canada, grizzly bears select clearcut sites, which provide some foraging
61 resources such as ants, herbaceous plants and berries, during summer (Nielsen et al. 2004a,
62 2004b). On the other hand, it is unknown how brown bears respond to reforestation, which
63 significantly alters the habitat from farmland to forest.

64 In the Shiretoko World Heritage site (hereafter; SWH), Hokkaido, northern Japan, a
65 reforestation project started in the 1970s was led by the local government and residents to
66 recover forest landscape from abandoned farmland. In the reforested sites of the SWH,
67 brown bears have been observed digging for cicada nymphs (*Lyristes bihamatus*
68 Motschulsky, 1861) during the summer season since 2000 (Tomita and Hiura 2020). Tomita
69 and Hiura (2020) showed some preliminary observations that this behavior was frequently
70 found in reforested larch plantations (*Larix kaempferi* (Lamb.) Carrière), and that the density

71 of cicada nymphs in the plantations was over 30-fold higher than in natural forests. These
72 preliminary results suggest that reforestation has increased the availability of cicadas for
73 brown bears. However, there is no quantitative data on this behavior, information such as the
74 frequency of this digging behavior between the restored forests and natural forest has yet to
75 be studied. Because cicada emergence density usually fluctuates between years (Sato and
76 Sato 2015), to elucidate if reforestation has provided a foraging habitat for bears, we should
77 examine whether cicada emergence density in the plantations is higher than in natural forests
78 across years.

79 We compared the frequency of this digging behavior and the density of cicada nymphs
80 between the natural forest and plantations. Based on our previous findings (Tomita and Hiura
81 2020), we made the following predictions: (1) brown bears digging for cicada nymphs occurs
82 more frequent in the restored plantations than in the natural forests, (2) the density of cicada
83 nymphs is higher in the plantations than in the natural forests, (3) there is a positive
84 relationship between digging frequency and the density of cicada nymphs.

85 **Material and Methods**

86 **Study site**

87 This study was conducted in the Horobetsu-Iwaobetsu area (44°09′N, 145°02′E)
88 located in the western parts of the SWH (Fig. 1). The elevation ranges from 120 to 220 m.
89 The annual mean temperature at the study site is 6.2 °C. and monthly mean temperature
90 ranged from −10.4 °C in February to 15.1 °C in August (1981–2010). The annual mean
91 precipitation is 1,149 mm (1981–2010). UNESCO certified this area as a World Natural
92 Heritage site because it represents one of the richest northern temperate ecosystems in the
93 world (<http://whc.unesco.org/en/list/1193>). In the study area, approximately 40% of the
94 conifer-broadleaved mixed forests were converted to farmland for grazing by cattle during
95 the post-war period from the 1940s to the 1960s (Shoyama 2008). Agricultural crops such
96 as corn and sugar beet were rarely cultivated in this area. During the period of high economic
97 growth in Japan, from the late 1960s to the 1970s, all the farmland was abandoned because
98 farmers immigrated to urban areas. Since 1977, reforestation of the abandoned farmland has
99 been conducted by the local government and residents through a national trust movement.

100 Coniferous trees such as Japanese larch, Sakhalin spruce (*Picea glehnii* (F.Schmidt) Mast)
101 and Sakhalin fir (*Abies sachalinensis* (F.Schmidt) Mast), have been planted on the
102 abandoned farmland for the purpose of reforestation. Most of the larch and fir plantations
103 were established during the 1970s, whereas the spruce plantations were established during
104 the early 1990s. The restored plantations accounted for 18 % of the total forest area
105 (Shoyama 2008), with Sakhalin spruce, Japanese larch and Sakhalin fir plantations account
106 for 13 %, 4 %, and 1 %, respectively. The natural forests are conifer-broadleaved mixed
107 forests, mainly consisting of Sakhalin fir and Mongolian oak (*Quercus crispula* Blume) and
108 maple (*Acer mono* Maxim.), and account for 82 % of the forest area in the study site. The
109 stand characteristics for each forest type are shown in Table 1. On the abandoned farmland,
110 pasture grass such as *Miscanthus sinensis* Andersson and *Anthoxanthum odoratum* L. are
111 dominant and soft mast species such as *Rubus* spp., which are a common food for bears in
112 summer, rarely grow (Ministry of the Environment, the Government of Japan 2017).

113 The SWH has one of the highest densities of brown bears in the world (Shimozuru et
114 al. 2020a). In the study area, food items of the brown bears change across the seasons,

115 depending on resource availability. Herbaceous plants are consumed in spring, and
116 herbaceous plants, ants and cicada nymphs in summer, from June to August. *Q. crispula*
117 acorns, *Vitis coignetiae* (Pulliat) berries, and anadromous salmon (*Oncorhynchus*
118 *gorbuscha* Walbaum, 1792) are consumed in autumn, from September to November
119 (Ohdachi and Aoi 1987; Matsubayashi et al. 2014; Tomita and Hiura 2020). Home range size
120 of adult female bears is estimated at 26.5 km² in the study area (Kohira et al. 2009). Bear
121 viewing is a major tourism activity in this region which generates an estimate 3 million
122 dollars in revenue (Kubo and Shoji 2014). At the study site in 2018, 11 individual bears were
123 observed digging for cicada nymphs, consisting of 2 sub adults and 2 solitary female adults,
124 and 3 females with cub(s) (Tomita and Hiura 2020). Individual identification and age classes
125 were determined based on color, marks, body size, and family structure of bears. Two native
126 cicada species, *L. bihamatus* and *Yezoterpnosia nigricosta* (Motschulsky, 1866), only occur
127 in forest of the SWH and emerge during late summer and spring to early summer,
128 respectively. No cicada nymphs occur on the farmland because the nymphs feed from tree
129 roots. In the study site, brown bear preys on the final instar nymphs of *L. bihamatus*, but not

130 *Y. nigricosta* (Tomita and Hiura 2020). Hence, this study focuses on the final instar nymph
131 of *L. bihamatus* as a prey of bears; the term “cicada” represents *L. bihamatus*.

132 **Field Survey**

133 We conducted field surveys in two successive years. From late August to September
134 2018 and 2019, 100 m² survey plots were set on the following forest types: larch plantations
135 ($n = 15$), fir plantations ($n = 12$), spruce plantations ($n = 15$), and natural forests ($n = 30$).
136 Since bears dig for cicada nymphs until the end of July when the final instar nymphs fully
137 emerge (Tomita and Hiura 2020), this survey's duration is appropriate for the evaluation of
138 this behavior and cicada emergence density. The locations of the survey plots are shown in
139 Fig. 1. We set more plots in the natural forest because it made up the highest proportion of
140 all forest types. The availability of cicada nymphs was determined by the density of cicada
141 exuviae collected from all trees (diameter breast height, DBH > 2 cm) within the plots, since
142 brown bears forage on only the nymphs in their final instar (Tomita and Hiura 2020). Cicada
143 exuviae attached to trees were collected from trunks and branches under 3 m from the ground,
144 as most exuviae on trees can be observed under this height. We also collected the exuviae on

145 the ground within 1 m from the trunk of a tree, because most exuviae falling from the tree
146 were found within 1 m of the trunk. Since final instar cicada nymphs usually attach to the
147 tree trunk when they emerge, the exuviae density in a survey plot can be regarded as the total
148 emergence density from a given plot. Although exuviae could move a short distance due to
149 the wind, the plot size (i.e. 100 m²) is large enough to cover for passive movement of the
150 exuviae after emergence. Digging marks were regarded as evidence of brown bears foraging
151 on cicada nymphs. According to our preliminary observations using 8 camera traps set in
152 larch plantations where brown bears dug the previous year, brown bears usually dig for
153 cicada nymphs near tree trunks. Thus, we evaluated the digging frequency per plot as the
154 proportion of trees which had the digging traces within 50 cm diameter from the base of a
155 tree, to all trees (DBH > 2 cm) in the plot.

156 **Statistical Analysis**

157 Generalized linear models (GLMs) with log link, Poisson error distribution and Tukey
158 post hoc test were used to examine the differences in the digging frequencies and the
159 densities of cicada nymphs among the forest types. When the GLMs indicated a significant

160 difference (*p-value* < 0.05) of one forest type from others, we performed multiple
161 comparisons among the forest types. The GLMs were used to compare the digging frequency
162 and the density of cicada nymphs between 2018 and 2019. In GLMs for digging frequency,
163 we introduced an offset term as the log-transformed number of trees to adjust for differences
164 in the number of trees among the survey plots. To examine the effects of the density of cicada
165 nymphs on the digging frequency, we performed GLMs for each forest type. All statistical
166 analyses were conducted in R version 3.5.1 (R Core Team 2018).

167 **Biomass measurement of cicada nymphs**

168 In mid-June 2019, we collected 10 cicada final instar nymphs from the larch plantation.
169 In the laboratory, these nymphs were measured individual using dry mass after a 48 hour at
170 60 °C drying period. The biomass of cicada final instar nymphs per 100 m² were calculated
171 by multiplying individual dry mass of the nymph by the density of cicada exuviae.

172

173 **Results**

174 Across all survey plots, we collected a total of 629 and 3344 cicada exuviae in 2018
175 and 2019, respectively and recorded a total of 2176 trees with or without digging traces.

176 The GLMs found a significant effect of forest type on digging frequency and the
177 density of cicada nymphs. Surprisingly, brown bears only dug for cicada nymphs in the
178 restored plantation plots, even when the natural forest plots were mainly composed of fir
179 species (Fig. 2). Digging frequency in the larch plantations was highest in all forest types in
180 both years, but significantly differed between years (Fig. 2). The density of cicada nymphs
181 in the larch plantations did not differ from the fir plantations, which had a lower digging
182 frequency (Fig. 3). The density of cicada nymphs was lowest in the natural forest (Fig. 3).
183 The spruce plantation plots had a lower digging frequency and density of cicada nymphs
184 than other types of plantation plots (Fig. 2, 3). The densities of cicada nymphs across all
185 forest types in 2019 were significantly higher than in 2018 ($p < 0.001$, Fig. 3). The density
186 of cicada nymphs positively correlated to the digging frequencies in fir and spruce
187 plantations ($p < 0.001$), but not in larch plantations in 2018 ($p = 0.19$) (Fig. 4). Individual

188 dry mass of the final instar nymphs was evaluated at 1.12 ± 0.20 g (mean \pm SD), and the
189 biomass density of nymphs in each forest type is shown in Table 2.

190 **Discussion**

191 The results of this study generally supported our predictions. In particular, brown
192 bears foraged on cicada nymphs only in plantations, not in natural forests (Fig. 2). This
193 clearly indicates that reforestation provided a foraging habitat for brown bears by increasing
194 the availability of cicada nymphs. To our knowledge, this is the first study showing that
195 reforestation provides a foraging habitat for brown bears.

196 Our results indicate that the difference in the digging frequency among forest types
197 can generally be explained by the density of cicada nymphs (Figs. 2, 3, 4). The digging
198 frequency showed that brown bears preferentially dug for cicada nymphs in the larch
199 plantations, although there were no differences in the density of cicada nymphs between
200 larch and fir plantations (Figs. 2, 3). Brown bears might indirectly search for the nymphs by
201 using larch trees as an aboveground landmark for detecting the location of underground
202 cicada nymphs. In the study site, larch trees do not occur in the natural forest because larches
203 are an introduced plantation species. Thus, brown bears may have learned to associate
204 nymphs with larch trees. This potential explanation is supported by our finding that a lower

205 density of cicada nymphs did not affect digging frequency in larch plantations during 2018
206 (Fig. 4A). Another possible explanation is that brown bears have fewer chances of
207 encountering fir plantations than larch plantations, because the total area of larch plantations
208 is larger than that of fir plantations in the study site.

209 Within the same forest type, digging frequencies were positively affected by the
210 density of cicada nymphs (Fig. 4B-F). This indicates that brown bears can accurately detect
211 the location of the cicada nymphs within a certain distance, perhaps using their remarkable
212 olfactory senses (Gittleman 1991; Rosell et al. 2011). Other fossorial mammals can use the
213 smell of volatile signals from unseen belowground resources to detect food (Sørensen et al.
214 2019; Stephens et al. 2020). Thus, bears may identify locations where there are high densities
215 of cicada nymphs by smelling the volatile signals. We note that it is unclear yet whether
216 cicada nymphs emit volatile signals to the surface.

217 If bears rely on olfaction while searching for cicada nymphs, the relationship between
218 digging frequency and cicada density should be significantly positive in the larch plantations.
219 The possible reason is that the searching tactics of bears are different among individuals;

220 some bears rely on spatial learning, associating cicada with larches, while others use
221 olfactory cues. Behavioral differences among individuals are common in bears (Leclerc et
222 al. 2016; Lesmerises and St-Laurent 2017). Data based on the digging behavior of
223 individuals is required to deepen our understanding of how bears search for cicada nymphs.

224 Across all forest types, the density of cicada nymphs in 2019 were significantly higher
225 than that of 2018 (Fig.2), suggesting that emergence density of *L. bihamatus* varies among
226 years. Emergence densities of annual cicada vary among years because of the age structure
227 in the nymphal stage (Sato and Sato 2015), so this inter-annual difference is probably a
228 general pattern for cicada species. Importantly, the emergence densities of cicadas in the
229 restored forests were significantly higher than in the natural forest, despite the different
230 density of cicadas over the study period. Given that the plantations are located proximate to
231 the natural forests in the study site (see Fig.1) and dispersal distance in adult cicadas is
232 estimated at about 100-250 m (Andrade et al. 2020), adult cicadas can easily come and go
233 between the plantations and the natural forest. Since emergence schedule in cicada is usually
234 homogeneous within same population (e.g. periodical cicadas (Dybas and Lloyd 1974)),

235 periodicity of cicada emergence doesn't differ between the plantations and natural forests.
236 These strongly indicate that the restored forests play a role as foraging habitat for brown
237 bears across years.

238 We speculate that the reason for high densities of cicada nymphs in the conifer
239 plantations is because adult cicadas intensively oviposit on coniferous species. The spatial
240 distribution of cicada nymphs is determined by the oviposition preference of adult cicadas
241 because the nymphs cannot move a long distance in the soil (Oberdörster and Grant 2006).
242 A study showed that oviposition density of the periodical cicada (*Magicicada sp.*) increased
243 with increasing canopy openness (Yang 2006). Although the canopy openness of larch
244 plantations was higher than natural forests, fir and spruce plantations were similar to the
245 natural forests (Table 1), suggesting that variations in light among forest types was
246 insufficient for explaining the difference in cicada density. Another possible factor is the host
247 tree architecture (Mattingly and Flory 2011). Several annual cicada species in Japan lay their
248 eggs on dead branches attached to living trees (e.g. *Cryptotympana facialis* (F. Walker, 1858),
249 Moriyama et al. (2016)). In the study site, oviposition scars by *L. bihamatus* were frequently

250 observed on dead branches of the living larch trees (K. Tomita *personal observation*),
251 suggesting that this species also deposits its eggs on the dead branches of living trees. Since
252 conifer plantations usually have a larger number of attached dead branches than natural
253 forests (Yoshida and Hijii 2006) , the former would have a higher availability of oviposition
254 sites for cicadas than the latter.

255 Our previous study showed that the proportion of cicada nymphs in bear scats was
256 estimated at 14.3% (Tomita and Hiura 2020). Given that brown bears forage on cicada
257 nymphs only in the restored plantations (Fig.2), the plantation could contribute to the bears'
258 summer diet to some extent, even though it only accounts for 18% of the total forest area.
259 Insects such as ants (Formicidae) and the army cutworm moth (*Euxoa auxiliaris* Grote,
260 1873) are some of the most important summer foods for brown bears around the world
261 (Mattson et al. 1991*a*, 1991*b*; Elgmork and Kaasa 1992; Sato et al. 2005; Bojarska and Selva
262 2012). Mattson et al. (1991*b*) estimated the proportion of army cutworm moths in bear scats
263 during summer was at 42-77% in alpine areas of the Yellowstone National Park, North
264 America. The proportions of ants, the most common insect prey for bears across their

265 distributional range, in Sweden, North America, Slovenia and Japan was reported at 16%,
266 <5%, 25% and 18%, respectively (Swenson et al. 1999; Mattson 2001; Große et al. 2003;
267 Sato et al. 2005). These suggest that the dependency of brown bears on cicada nymphs in
268 this area seems to be to the same extent as ants in other regions, though not as significant as
269 army cutworm moths in Yellowstone National Park.

270 The dry biomass of the final instar nymphs of cicada in the larch plantation was
271 estimated at 22.62 and 97.51 g/100 m² in 2018 and 2019, respectively (Table 2). In Sweden,
272 Slovenia and Japan, the dry biomass of ants was estimated at 96, 1.35 and 0.59 g/100 m²,
273 respectively (Swenson et al. 1999; Große et al. 2003; Yamazaki et al. 2012). This indicates
274 that the biomass density of the nymphs in the plantations is more or equal than that of ants,
275 which is a major summer food for bears. Nevertheless, this does not mean that the total
276 biomass of cicada nymphs in the whole forest is higher than that of ants or other food sources,
277 because a large biomass of cicada nymphs only occurs in the restored plantations, accounting
278 for a small proportion (ca. 18%) of the study site. Further data on the foraging ecology, such
279 as the nutrients provided by the nymphs and energetic cost of the digging behavior, are

280 required to deepen our understanding of the value of cicadas as a food resource for bears.

281 In the SWH, the body condition of brown bears declines from June to August (Shirane
282 et al. 2020), suggesting that their nutritional status is lowest in summer. Because their body
283 condition rapidly increases during autumn, from September to November (Shirane et al.
284 2020), how bears overcome poor nutrition in the summer might be important for their fitness.
285 The restored plantations, in which bears dig for cicada nymphs, might play a role in
286 mitigating the poor nutrition in summer, to some extent, via food supplementation in summer
287 (i.e. cicada nymphs).

288 **Concluding Remarks**

289 The primary goal of the reforestation program in the SWH to recover the forest
290 landscape from abandoned farmland has already been achieved (Shoyama 2008), but its
291 ecological functions remain largely unknown (but see Fujii et al. (2017)). Our findings shed
292 light on an ecological function of the restored forests for brown bears via providing a food
293 resource (i.e. cicadas). In the SWH, brown bears play important roles in ecological and
294 economical services, such as the transporting of salmon-derived nutrients and nature tourism

295 (Koshino et al. 2013; Kubo and Shoji 2014). However, bear appearances along the roads
296 have often occurred in the study site (Shimozuru et al. 2020b), and this is a potential cause
297 for increasing human-bear conflicts like "bear jams" (Herrero et al. 2005). Because large
298 areas of the restored plantations located near the roads are frequently used by tourists (Fig.1),
299 bears would need to approach the roads to forage on cicada nymphs. In fact, wildlife
300 managers often observed bears digging for the nymphs within the plantations adjacent roads
301 (Shiretoko Nature Foundation *personal communication*). Perhaps, the plantations might not
302 only provide a foraging habitat for bears, but also intensify human-bear conflict by attracting
303 bears towards the roads. Of course, it is also possible that human-habituated bears mainly
304 dig for the nymphs in the plantations. Testing this hypothesis requires more data on space
305 use by bears.

306 We found that brown bears foraged on cicada nymphs only in the monoculture
307 plantations, but not the natural forests with higher tree diversity. Nevertheless, it doesn't
308 mean that monocultures are an overall more valuable habitat for bears than natural forests
309 because tree diversity assumes to enhance the ecological value of forests as wildlife habitat

310 (Stephens and Wagner 2007). Recently, there is growing evidence indicating that
311 monoculture plantations are more valuable as wildlife habitat than previously thought
312 (Brockerhoff et al. 2008; Sakamaki and Enari 2012). Given this evidence, including our
313 finding, monocultures might be regarded as distinct habitat compared with mixed forests,
314 not as less valuable habitat for wildlife. Especially, larch, one of the typical pioneer tree
315 species, can rapidly recover forest canopy. Moreover, due to high light availability on the
316 forest floor of larch plantations, biomass of herbaceous species on the plantation have same
317 extent as natural forests and deciduous broadleaved trees can easily invade into the plantation
318 (Kitaoka and Koike 2004; Takafumi and Hiura 2009). Larch plantations with high
319 availability of cicadas are the potential foraging habitat for predators consuming cicadas (e.g.
320 birds (Pons 2020), mammals (Lovari et al. 1994; Way 2008; Tomita and Hiura 2020)).
321 Therefore, larch may be a candidate species for tentative reforestation on abandoned land
322 although it should consider that in the Hokkaido island, larch is now an alien species but had
323 distributed during the last glacial period (Ooi et al. 1997). When selecting tree species for
324 reforestation, we need to consider the ecological functions of the species, not only following

325 an assumption that the value of restored forests increases as tree diversity increases.

326 **Acknowledgments**

327 We thank members of Shiretoko Nature Foundation for providing information on the
328 study site. We also thank H. Maita, Daisetsu I., and T. Itoh for field survey assistance, M.
329 Jinbo for cicada biomass measurements, two anonymous reviewers and I. Koizumi for
330 providing helpful comments on the manuscript, and A. Chris for advice on the English of
331 this manuscript.

536

Forest type (Number of plots)	Dominant tree species (%Basal area)	Density of trees (Trees 100 m ⁻²)	Basal area (m ² 100 m ⁻²)	Canopy openness (%)
Larch plantation (n=15)	Larix kaempferi (97%)	32.07 \pm 7.78	0.12 \pm 0.04	12.69 \pm 2.63
Fir plantation (n=12)	Abies sachalinensis (84%)	30.17 \pm 10.34	0.11 \pm 0.04	2.41 \pm 0.62
Spruce plantation (n=15)	Picea glehnii (95%)	27.33 \pm 6.19	0.09 \pm 0.03	1.83 \pm 0.82
Natural forest (n=30)	Abies sachalinensis (31%) Quercus crispula (28%)	31.57 \pm 10.36	0.10 \pm 0.05	2.20 \pm 1.06

537 Table 2 The density and estimated biomass of final instar nymphs of cicada *Lyristes*
 538 *bihamatus* in the plot (100 m²) across forest types. Biomass of the nymphs was calculated as
 539 multiplying mean individual dry mass of the nymph (=1.12 g) by their density. Mean ± SD

Forest type	Density of the nymphs in 2018 (/100 m ²)	Density of the nymphs in 2019 (/100 m ²)	Biomass of the nymphs in 2018 (g/100 m ²)	Biomass of the nymphs in 2019 (g/100 m ²)
Larch plantation	20.20 ± 18.71	87.07 ± 47.72	22.62 ± 20.96	97.52 ± 53.44
Fir plantation	16.92 ± 13.71	93.50 ± 66.55	18.95 ± 15.36	104.72 ± 74.54
Spruce plantation	5.67 ± 6.22	44.40 ± 63.08	6.35 ± 6.96	49.73 ± 70.65
Natural forest	1.27 ± 1.41	8.33 ± 9.44	1.42 ± 1.58	9.33 ± 10.57

541 Figure 1 Location of the survey plots in vegetation map of the study site. Black lines
542 indicate roads. This vegetation map was created by Shiretoko Nature Foundation (Shiretoko
543 Nature Foundation unpublished information). This figure was created using QGIS version
544 3.14.0 (QGIS Development Team 2020).

545

546 Figure 2 The digging frequencies of brown bear *Ursus arctos* across all forest types in
547 2018 (dark grey) and 2019 (white). Upper case and lower letters indicate significant
548 differences among forest types in 2018 and 2019 according to post-hoc Tukey's test,
549 respectively ($p < 0.05$). Single asterisk indicates significant differences in the digging
550 frequency between 2 years by generalized linear model ($p < 0.001$).

551

552 Figure 3 The number of cicada *Lyristes bihamatus* exuviae across all forest types in 2018
553 (dark grey) and 2019 (grey). Upper case and lower letters indicate significant differences
554 among forest types in 2018 and 2019 according to post-hoc Tukey's test, respectively ($p <$
555 0.05). Single asterisk indicates significant differences in the number of cicada exuviae
556 between 2 years by generalized linear model ($p < 0.001$).

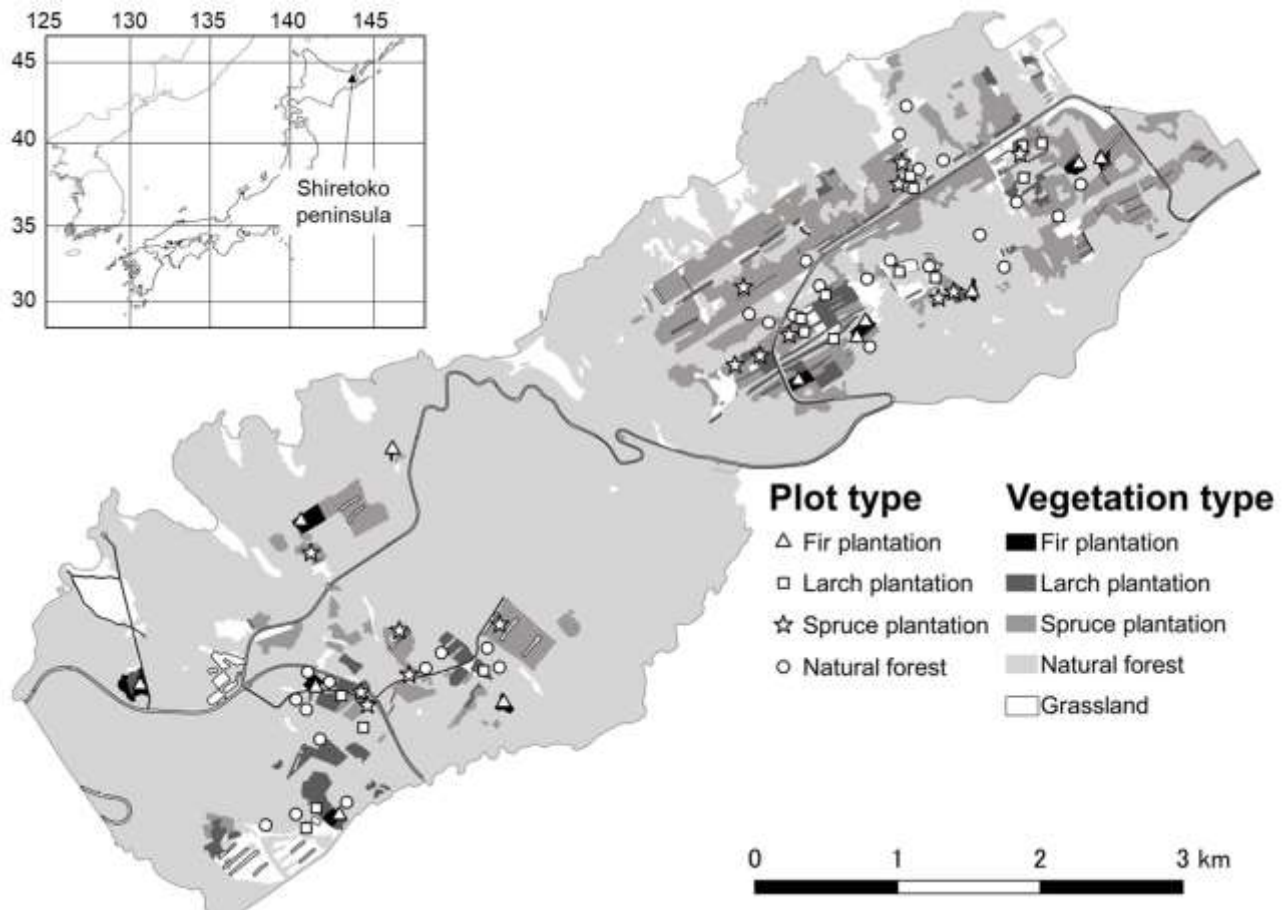

557

558 Figure 4 Relationships between the digging frequencies of brown bear *Ursus arctos* and
559 the densities of cicada *Lyristes bihamatus* nymphs in the restored forests; (A) larch and (B)
560 fir, (C) spruce in 2018, (D) larch and (E) fir, (F) spruce in 2019. Dashed lines show the
561 linear model predictions with shaded areas indicating the 95% CI.
