GaN-based bipolar transistors are good candidates for applications in RF power amplifiers. In contrast to more common AlGaIn/GaN high electron mobility transistors (HEMTs), GaN based bipolar transistors have not drawn much attention because of the difficulties in good p-type material and ohmic contact. Most of the problems associated with p-type quality and contact come from growth and etch damage during fabrication.

In this work, a low damage etching technique with an undercut profile was developed to solve the problems associated with p-type ohmic contact quality and to realize the self-aligned GaN bipolar transistor fabrication. The etching process consists of bias-assisted photoenhanced electrochemical oxidation of GaN in deionized water (BPECO/DI) and its subsequent etching in diluted acid solution. By this technique, we demonstrated good Schottky contacts on samples etched more than 100 nm and p/n doping selective etching was shown. Furthermore the most critical point for self-aligned fabrication is undercut profile and

it was also obtained by BPECO/DI etching. Hence this technique is ideal for fabrication of self-aligned bipolar transistors.

There are some problems during fabrication of self-aligned bipolar transistor. First, due to the impossibility of activation annealing after emitter etch, activation annealing had to be done at the beginning where emitter layer is on the base and this was a problem for Mg activation. More importantly, there were still uncertainties with BPECO/DI etching like roughening up the etched surface, low etch rate for npn structures and disturbing the material uniformity near the surface.

In this work, it was shown that BPECO/DI etching is a very efficient tool that provided low damage etching of GaN and enabled the self aligned RF bipolar transistor structures. It was found that self aligned base-emitter junctions were successfully formed and the BPECO/DI etching was almost stopped at top of the base layer. Self-aligned bipolar transistors were fabricated and their base-emitter and base-collector junctions were measured. The results obtained in this work demonstrated that BPECO/DI etching can bring solutions to the lack of low damage etching and the impossibility of self-aligned base contact in fabrication of today's GaN based bipolar transistors.

Keywords: Gallium nitride, bipolar transistor, photo-enhanced electrochemical etching, low damage etching, self-aligned process

ÖZET

KENDİNDEN YERLEŞMELİ GALYUM NİTRİT TABANLI İKİ KUTUPLU TRANSİSTÖRLERİN FABRİKASYONU İÇİN POTANSİYEL YARDIMLI FOTON KATKILI ELEKTROKİMYASAL AŞINDIRMA

GaN tabanlı iki kutuplu transistörler RF güç yükselteci uygulamaları için iyi adaylardır. İyi p-tipi materyal büyütmedeki ve p-tipi üzerine iyi kontak yapmadaki güçlüklerden dolayı, GaN tabanlı iki kutuplu transistörler, AlGaIn/GaN yüksek elektron hareketlilikli transistörler kadar ilgi toplamamışlardır. P-tipi kalitesi ve kontak yapmadaki problemlerin çoğu büyütmeden ve fabrikasyon aşamasındaki aşındırma hasarından kaynaklanmaktadır.

Bu çalışmada, p-tipi kontak kalitesiyle ilgili sorunları çözmek için az hasarlı bir aşındırma tekniği geliştirilmiştir. Aşındırma işlemi potansiyel destekli fotoelektrokimyasal oksitleme ve ardından gelen seyreltilmiş asit içinde bu oksitin kaldırılmasından oluşur. Bu teknikle, 100 nm'den daha fazla aşındırılmış yüzeyler üzerine iyi Schottky kontaklar yapılmıştır ve bu aşındırmanın p/n katkılı katmanlardaki seçiciliği gösterilmiştir. Bununla beraber, kendinden yerleşmeli fabrikasyon için en kritik nokta olan negatif eğimli aşındırmanın, BPECO/DI aşındırma methoduyla olabileceği gösterilmiştir. Bu nedenlerden dolayı bu teknik, kendinden yerleşmeli kutuplu transistörlerin fabrikasyonu için

idealdir. Sonuç olarak, bu teknikle transistör karakteristikleri önemli ölçüde iyileştirilebilir.

Kendinden yerleşmeli transistör fabrikasyonunda bazı sorunlar vardır. İlk olarak aktivasyon tavlama aşımının yayıcı aşındırmasından sonra yapılmasının mümkün olmamasından dolayı aktivasyon aşındırması taban üzerinde yayıcı katmanı varken yapılmak zorundadır ve bu Mg aktivasyonu için bir problemdir. Daha önemlisi yüzey pürüzlülüğü, npn katmanların düşük aşındırılma hızı ve materyal yüzeyinin düzgünlüğünün bozulması gibi BPECO/DI aşındırmada halen belirsizlikler mevcuttur.

Bu çalışmada BPECO/DI aşındırmanın, GaN için az hasarlı bir aşındırma yöntemi olduğu ve kendinden yerleşmeli RF iki kutuplu transistör fabrikasyonunu mümkün kıldığı gösterilmiştir. Taban-yayıcı bağlantısı başarıyla kurulmuştur ve BPECO/DI aşındırmanın taban katmanında durduğuda gösterilmiştir. Kendinden yerleşmeli iki kutuplu transistörler başarılı bir şekilde fabrike edilmiş ve taban-yayıcı ve taban-toplayıcı bağlantıları akım voltaj karakteristikleri ölçülmüştür. Bu çalışmadaki sonuçların BPECO/DI aşındırmanın bugünkü GaN tabanlı iki kutuplu transistör fabrikasyonu için az hasarlı aşındırma yöntemi yokluğuna ve kendinden yerleşmeli taban kontağı kurmaya çözüm getirdiği gösterilmiştir.

Anahtar Kelimeler: Galyum nitrat, iki kutuplu transistör, ışık katkılı elektrokimyasal aşındırma, az hasarlı aşındırma, kendinden yerleşmeli işlem

ACKNOWLEDGMENTS

I would like to express my sincere gratitude to my supervisor Assist. Prof. Dr. Özgür Aktaş. His personal and academic virtue has shaped my academic personality and my approach to science. It was a great chance and pleasure for me to study under his supervision. This work would not be possible without his guide and encouragements.

I would like to thank to the members of my thesis committee, Prof. Cengiz Beşikçi, Assist. Prof. Mehdi Fardmanesh, Dr. Tarik Reyhan and Assist. Prof. Ceyhun Bulutay for reading the manuscript and commenting on the thesis.

I would like to express my special thanks to Murat Güre, Ergün Hırlakoğlu, S. Ersin Başar and Ergün Karaman, for their support and help.

I want to thank Aşkın Kocabaş for his support and numerous fruitful discussions on experiments.

Special thanks belong to my family, for their nonstop support and care. I dedicate this labor to them.

Finally, I would like to acknowledge the financial support from TUBITAK that made this work possible.

Chapter 1

Introduction

1.1 Motivation for GaN based bipolar transistors

The material system GaN has pioneered wide application area in optoelectronics. Its direct and wide band gap have made GaN based optoelectronic devices at green to ultraviolet spectrum possible [1]. In addition to superior GaN optoelectronic devices, the electronics applications based on GaN have shown very promising performance. Especially in the area of amplifiers for communications and military purposes, GaN high electron mobility transistors, HEMTs, have demonstrated high speed and high power performance [2, 3, 4]. Also in application of low loss and high power switches, GaN based devices are widely used.

GaN has a relatively large band gap of 3.47 eV, a very high breakdown field 3.3 MV/cm and a high saturation velocity of $1.9 \times 10^7 \text{ cm s}^{-1}$ [5, 6]. All these properties make GaN a good candidate for high power and high speed applications.

Together with its good characteristics, alloys of GaN are also utilized in device engineering. InGaN and AlGaIn materials offer a wide range of band gap 0.8 eV to 6.2 eV. This enables to design and fabricate novel devices.

The most interesting feature of GaN and its alloys is their highly piezoelectric structure offering devices not possible with other III-V material systems like GaAs or InP. A two dimensional electron gas (2DEG) region forms when AlGaIn/GaN heterostructures are grown. This highly concentrated and high mobility region lead to the fabrication of today's superior HEMT devices.

Comparison of semiconductor materials figures of merit is an efficient way to find out their device characteristics. Power handling, power loss and RF performance of a semiconductor material can be estimated from its figures of merit. The Johnson's figure of merit, $JFOM=(v_{sat}E_B/2\pi)^2$ is a merit for RF performances like cutoff frequency (f_c) and maximum power handling capacity. Since it relates saturation velocity and breakdown voltage, it demonstrates the high power and high frequency capability of material. In Table 1.1, normalized JFOMs for different materials are given and normalization is done by setting JFOM of Si to 1. It is seen that in high power and high frequency applications GaN based devices capability is much better than Si and GaAs, and better than 4H-SiC.

<i>Material</i>	μ (cm^2/Vs)	E_B (MV/cm)	V_{sat} ($\times 10^7 cm/s$)	$E_g(eV)$	<i>Normalized JFOM</i>
Si	1500	0.3	1	1.1	1.0
GaAs	8500	0.4	0.6	1.42	0.64
4H-SiC	900	3.0	2.0	3.26	400
GaN	1500	3.3	1.9	3.47	436.8

Table 1.1: Figures of merit for different materials.

High power handling of GaN power transistors have already been demonstrated by fabrication of GaN high electron mobility transistor (HEMT) and field effect transistor (FET) devices. Although the progress of GaN field effect

transistors is impressive, advances in GaN bipolar transistor has been slowed down by the difficulties associated with GaN p-type material. The motivation behind bipolar transistors is the inherent device characteristics of higher power handling capacity, linearity, higher transconductance and uniform turn-on voltage. Furthermore surface problems which most FET devices suffer from do not affect bipolar transistor characteristics that much.

In the literature, AlGaIn/GaN and InGaIn/GaN based bipolar transistors were fabricated with dc current gains of 1.5 to 10 [7, 8, 9]. Transistor fabrication methods require base regrowth to renew the etched surface so that better contacts can be achieved. However regrowth is a complex, tedious and difficult process, some other fabrication methods are demanded in order to overcome etch damage. BPECO/DI etching can be a tool for the required etching method. We have demonstrated that BPECO/DI etching is a low damage etching method and p-type contacts on BPECO/DI etched surfaces are much better than plasma etched surfaces.

Furthermore BPECO/DI etching is an isotropic etching and this provides undercut profile after etching that is not possible with dry etching methods. This undercut profile makes self aligned transistor fabrication possible. Self aligned fabrication is a key for RF device fabrication. There was no self aligned bipolar transistor fabricated yet due to the unavailability of etching that both gives undercut and does not attack metal contacts.

We have demonstrated that these two features of BPECO/DI etching can solve two problems in fabrication of bipolar transistors. To sum up, by using BPECO/DI etching, self aligned bipolar transistors were fabricated.

1.2 The objective and scope of the thesis

In this work, a low damage wet etching method bias assisted photoelectrochemical oxidation in deionized water (BPECO/DI) is introduced and then it is utilized in bipolar GaN transistor fabrication for the first time in literature.

The thesis consists of 6 chapters. Chapter 1 contains the introduction and motivation. In chapter 2, the theory of Schottky diode and bipolar transistor are described.

Chapter 3 explains the BPECO/DI etching experiment setup and its experimental results. Fabrication methods and bipolar transistor fabrication process are given in chapter 4.

Chapter 5 goes into the experimental results of Schottky contacts on etched surfaces by low damage etching method BPECO/DI etching and results for fabricated GaN based bipolar transistors. Finally, chapter 6 contains the discussions regarding this work and conclusion.

Chapter 2

Theory and Design

2.1 Basics of Schottky Diodes

In surface damage studies due to etching mechanisms, comparison of Schottky diode characteristics is an efficient and commonly used way [10, 11, 12]. In order to analyze the damage, we have compared Schottky characteristics of contacts on etched and unetched surfaces [13]. To understand the effects of damage, it is essential to know the metal-semiconductor contact properties and the causes behind their changes. Hence, in this section, we will give some introductory knowledge on Schottky contacts, analysis of the forward and reverse characteristics, and some mechanisms for their changes.

Rectifying metal-semiconductor contact is named Schottky after W. Schottky proposed a model for barrier formation in 1931 [14]. When a metal is contacted with a semiconductor, a potential barrier is formed due to separation of charges at the metal-semiconductor interface. Energy band diagrams of Schottky contacts on n- and p-type contacts under thermal equilibrium are given in Figure 2.1.

Figure 2.1: Energy band diagrams of metal contact to n-type (a) and p-type (b) semiconductor under thermal equilibrium.

Because of the thermionic electron emission over the barrier, the current-voltage characteristic is given by the relation,

$$I = I_s \left[\exp\left(\frac{qV}{nkT}\right) - 1 \right] \quad (2.1)$$

where I_s , n and A^* are the reverse saturation current, ideality factor and the modified Richardson constant, respectively. The formula implies that the diode reverse current saturates and the forward current increases exponentially with applied bias. However, in experimental results, there are deficiencies from ideal due to surface states, traps, field emission (FE), thermionic field emission (TFE), surface roughness, inhomogeneity in Schottky barrier heights and other damage mechanisms during fabrication.

Although dry etching systems cause more damage than wet etching systems due to damage created by highly energetic atoms, both etching systems can result in change of surface morphology by changing the crystal structure of surface, by depositing etching residues, by forming interface layers or by creating antisites on the surface. These surface deficiencies can significantly affect the Schottky diode characteristics [10, 11, 12].

The reverse characteristics like reverse breakdown voltage and leakage current degrade with damage mechanisms, and these can be improved by various treatment methods. The trap assisted tunnelling, hopping through the increased surface states, surface roughening, barrier lowering, barrier inhomogeneity due to surface nonuniformity or antisites can increase the reverse current. These also degrades the breakdown voltage. Various treatments like low damage wet etching [15], annealing [16] or surface passivation [17] were tried to get the original characteristics back.

While the observations on leakage current and breakdown voltage are not anomalous, there are conflicted observations on ideality factor. One explanation for the anomaly in ideality factor is given by Tung [18] as nonuniform Schottky barrier height. In order to understand the reason for anomaly in ideality factor, we should examine the current transport mechanisms for metal-semiconductor interfaces. In Figures 2.2, a metal-semiconductor interface at different biases are given. There are 4 conduction mechanism shown (1. Thermionic emission, 2. Tunneling through surface traps, 3. Field emission (and thermionic field emission) tunneling, 4. Hopping through the deep trap states). From thermionic emission model, thermionic emission current saturates at reverse biases and exponentially increases with forward bias voltages. In ideal diodes, only this current transport is taken into account and the other mechanisms are ignored. However in real life this is not so.

In Figure 2.2-a, if very small biases are applied, the dominant current mechanism depends on temperature and the density of the surface states. If the diode is near ideal, then second and third mechanisms can be ignored. And in this case, if the temperature is low then field emission tunneling dominates and for moderate temperatures both conduction mechanisms contribute to the current conduction.

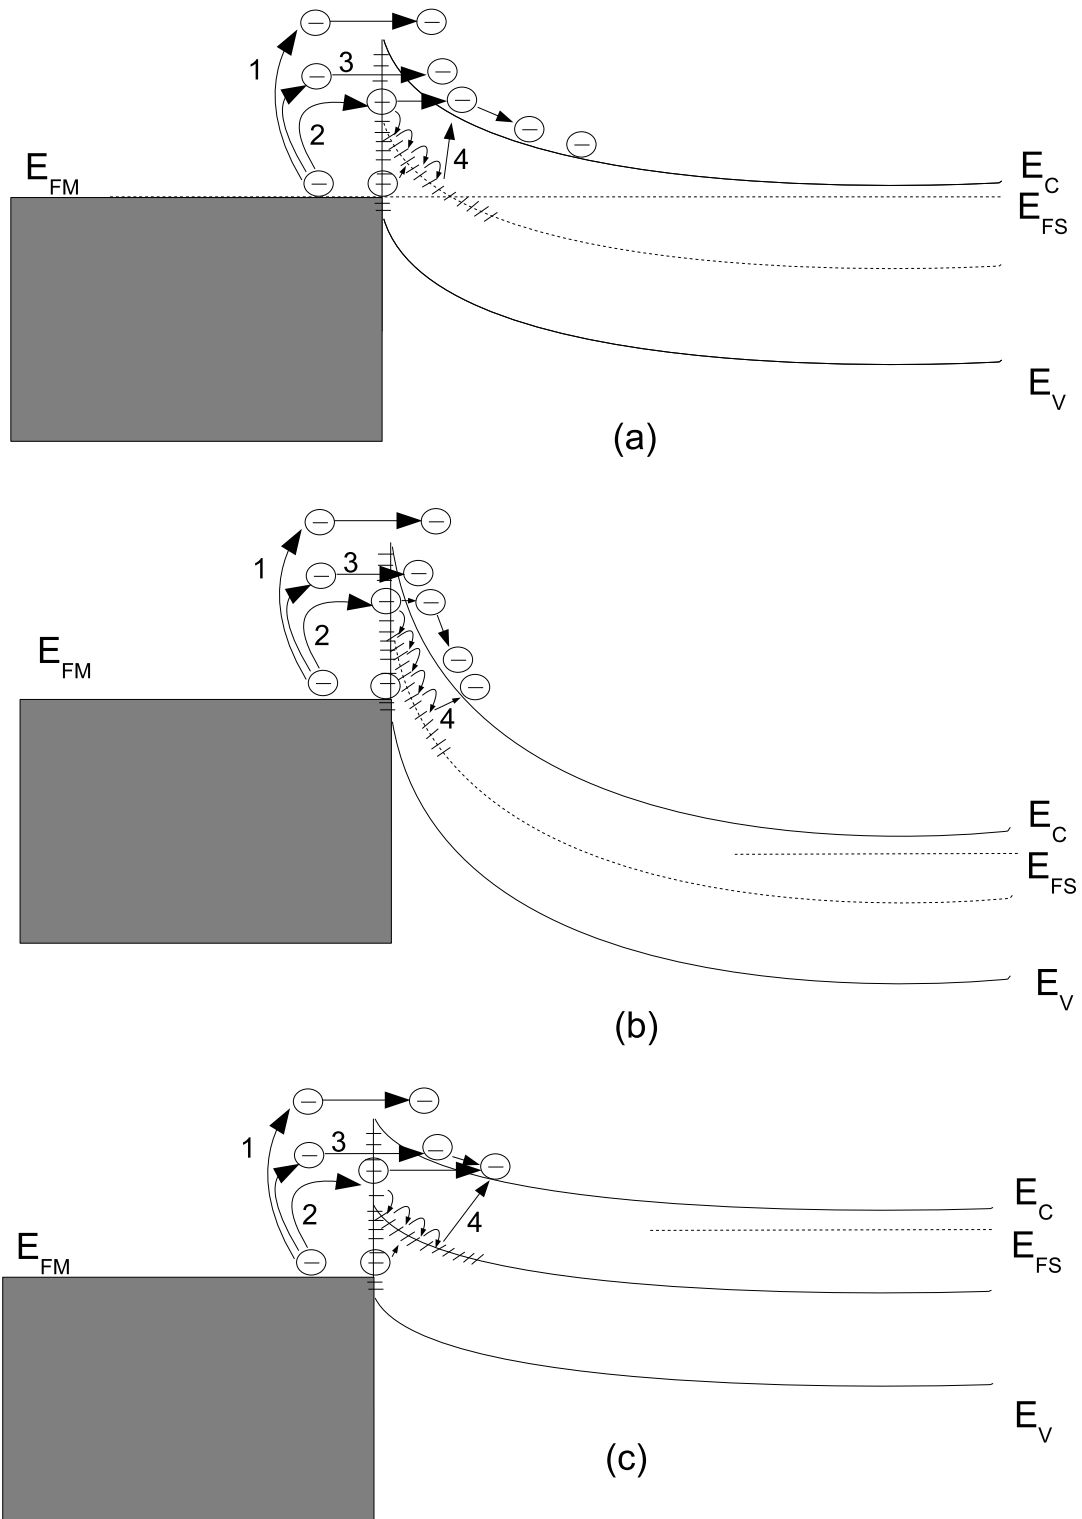

Figure 2.2: Conduction mechanisms for metal-semiconductor contact under very small bias (a), reverse bias (b), forward bias (c)

At reverse bias voltages, as seen in Figure 2.2-b, since the barrier thickness decreases significantly, tunneling through near surface states and field emission tunneling mechanisms, that exponentially depend the barrier thickness, dominate the overall current.

At forward bias voltages, as seen in Figure 2.2-c, in contrast to reverse bias conduction, effect of tunneling through near surface states and field emission tunneling mechanisms decreases. Therefore the dominant mechanisms become thermionic emission current and hopping through the deep trap states.

Some damage mechanisms can create both deep traps and surface states. Treatments like annealing or H_2 plasma passivate the surface states and cannot improve the deep traps in the bulk. Hence, while ideality factor is not improved, the reverse characteristics improve after treatments. In other words, the anomaly in ideality factor lies under different damage mechanisms than near surface states.

2.2 Basics of Bipolar Transistors

Explanation of principles of bipolar transistors can be readily found in textbooks [19]. To follow the main idea of this work, a brief summary of operation of bipolar transistors is given in the following.

In Figure 2.3, a bipolar transistor schematic is given where the basic forward active operation of a bipolar transistor is illustrated. In forward active operation, base-emitter junction is forward biased and base-collector junction is reverse biased. By forward biasing base-emitter junction, electrons are emitted from emitter to base and holes are emitted from base to emitter. These holes injected to the emitter form one base current component (I_{pe}). Then some of electrons leaving emitter recombine at depletion region of base-emitter junction (I_{rd}) and some recombine at neutral region of base (I_{rn}). These three terms are the main

Figure 2.3: Bipolar transistor operation at forward active mode.

components of base current. Since the current diffuses to collector region is too low compared to the terms mentioned above, it can be neglected. Therefore, the base current can be given by three components.

$$I_b = I_{pe} + I_{rd} + I_{rn} \quad (2.2)$$

There are two important parameters defined γ and α_T , emitter injection coefficient and base transport factor. The emitter injection coefficient γ is defined as the ratio of current injected to base to total emitter current.

$$\gamma = \frac{I_{ne}}{I_{ne} + I_{rd} + I_{pe}} \quad (2.3)$$

From the equation above, having an efficient emitter requires to have $I_{rd} + I_{pe}$ much smaller than I_{ne} . It can be satisfied, by designing emitter doping much higher than base doping or using heterostructure where the offset between base and emitter valance bands provides a barrier to avoid holes to diffuse into emitter region. On the other hand, I_{rd} depends on the material type and quality. Since GaN is a direct band gap material and its p-type is problematic, this term dominates the base current and results in large base currents.

The base transport factor α_T is defined as the ratio of current reaching to collector to current injected from base.

$$\alpha_T = \frac{I_{nc}}{I_{ne}} \quad (2.4)$$

The difference between the current terms, I_{nc} and I_{ne} is the recombination current in the neutral base region. Hence the quality and thickness of the base material have significant effects on both transport parameters.

The common base current gain α and the common emitter current gain β are the most important DC parameters in bipolar transistor characterization. As in Equation (2.5) and (2.6), α is the ratio of collector current to emitter current and β is the ratio of collector current to base current.

$$\alpha = \gamma\alpha_T \quad (2.5)$$

$$\beta = \frac{\alpha}{1 - \alpha} \quad (2.6)$$

In bipolar transistor design, the device structure thicknesses and doping levels are needed to be optimized to improve current gain β , breakdown voltage V_B and RF performance of the device.

As given in Equation (2.5) and (2.6) to increase β , the emitter injection coefficient and base transport factor are demanded. The emitter injection coefficient can be improved by engineering AlGaIn/GaN or GaN/InGaIn heterostructures. The wider band gap emitter blocks hole current from base to emitter and this increases γ . On the other hand, good base transport factor requires thin base and large D_n . Thin base and large D_n decreases the recombination in neutral region and gets α_T closer to 1.

Together with the above design criterions, the base material quality and the low damage etching mechanisms are essential to improve both γ and α_T . The base material quality reduces recombination and increases minority carrier life time τ_n . To decrease τ_n , base structure can also be engineered by band gap and

doping grading. As τ_n decreases, cut-off frequency of the device is also improved. Finally, the base material quality and low damage etching are very critical to obtain high β 's and good RF results.

Chapter 3

Bias-Assisted Photoenhanced Electrochemical Oxidation in Deionized Water

GaN dry etch process is well established for electronic and photonic device fabrications. There are several plasma etching systems like electron cyclotron resonance (ECR), inductively coupled plasma (ICP), chemically assisted ion beam etching, and reactively ion beam etching (RIE). The common properties of these plasma etching systems are high etch rates and uniform etching properties. However, plasma etching results in significant surface damage that degrades optical and electronic properties of material. There can be three results of plasma etching on the etched surface; 1) Deposition of residue on the surface, 2) Diffusion of the plasma constituents or etching products, and 3) Generation of defects in the crystal lattice. These surface damage mechanisms result in leakage current by creating traps and these traps increase the tunnelling current between semiconductor and metal deposited on the surface.

Techniques for low-damage etching of GaN and its alloys are important for optimization of devices such as HEMTs and HBTs [20, 21, 22, 23]. Ultraviolet photoenhanced electrochemical (PEC) etching and oxidation of GaN is a versatile method that is both band-gap and doping selective [24, 25, 26, 27]. PEC etching can achieve a smooth surface with low etch damage [28, 29]. A process similar to PEC etching and oxidation of GaN in alkaline solutions is the bias-assisted photoenhanced electrochemical oxidation of GaN in deionized water (BPECO/DI) [30]. In this approach, the oxide that forms on the surface remains intact and thick oxide layers can be obtained. To achieve etching of the GaN surface, the oxide grown by BPECO/DI can be removed by an HCl or HF etch following the oxidation. In this study, the etching process employing bias-assisted photoenhanced electrochemical oxidation in DI water and a subsequent acid bath removal of the oxide is called "BPECO/DI etch".

Similar to the PEC etching in alkaline solutions, the BPECO/DI etching process is attractive due to the band gap and n/p doping selectivity that can be achieved. However, this process has additional advantages that the BPECO/DI oxidation and etching can be performed with a photoresist mask in place and also without damaging existing ohmic or Schottky metalization on the sample. Catalytic titanium masks are not needed for BPECO/DI etching and the process can be applied to relatively large areas. Hence, the process does not suffer from the inhomogeneities commonly observed close to the titanium mask edges used with PEC and bias-assisted PEC (BPEC) processes. Thus, BPECO/DI etching has the potential to be a technique that is more widely applied than PEC etching.

Doping selective etching by BPECO/DI etching was achieved. The different band bending for n- and p-type GaN materials, as seen in Figure 3.1, explains the reason behind the selectivity. Since n-type material band at the semiconductor/electrolyte interface bends upwards, holes prefer to move to the surface. However in p-type material, due to downward band bending, holes are taken

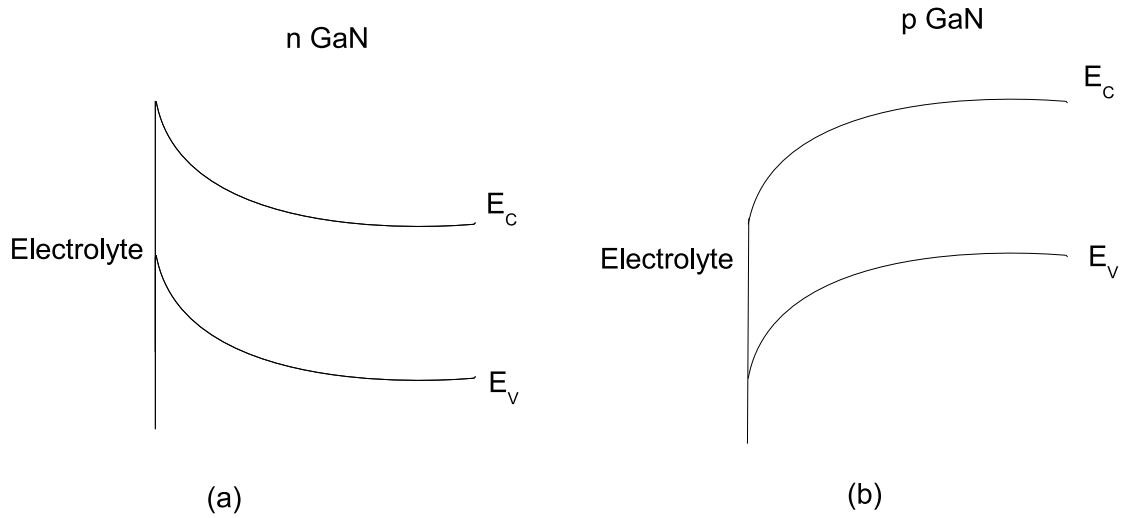

Figure 3.1: Different band bending of n- and p-type GaN/electrolyte interface away from the surface. In other words, to accumulate holes on the p-type material surface, more potential is needed.

Oxide formation mechanism is given by Equation 3.1. As it is seen, the photo-generated holes are essential for oxide formation. The oxidation products are Ga_2O_3 , $3H_2O$ and N_2 . Due to the reaction product N_2 , bubbles going out from the sample surface were observed during the oxidation .

3.1 Experimental Setup

The BPECO/DI oxidation setup is given in Figure 3.2. The sample is biased in deionized (DI) water in the range of 4 to 20 Volts and the light from a 200 W Hg-Xe UV lamp was focused by an elliptical mirror. The sample was placed close to the focal point. We have used Al as counter electrode. And in case of oxidation of Al electrode, before all oxidations, the electrode was dipped into HCl. There is a cooling fan to prevent overheating of the sample by UV light. Different

Figure 3.2: The experiment setup of BPECO/DI etching system

methods were tried to have contact to the sample, but the most convenient way was found a nickel coated iron tip. The coating nickel is to prevent the corrosion. During oxidation, the voltage on the sample and the current passing through were measured to ensure that the contact to the sample was not lost and to record the current during oxidation. The oxidation time was limited by thickness of the undoped layer and was selected to be 3 hours after preliminary tests. The water level was almost the same for all experiments and it was 1 cm above the sample surface. Also in long oxidation times, the water evaporated by UV light was refreshed by adding new DI water so that the water level was kept constant. The DI water resistance was more than $13 \text{ M}\Omega\text{cm}$ for all the oxidation experiments.

3.2 Experiment

The layer structure used in this study consisted of a 0.5 μm undoped GaN layer grown on top of 0.5 μm and $2 \times 10^{18} \text{ cm}^{-3}$ Si doped GaN layer at the bottom. All samples were grown on sapphire substrates using MOCVD. Before the oxidation of the samples with BPECO/DI, mesa etching and ohmic contact fabrication steps were completed. The mesa structures were needed for establishing ohmic contacts to the highly doped GaN layer. A few of the mesa structures were partially masked with sputtered Si_xN_y to enable etch depth measurement. For the collection of photogenerated electrons, 1 mm wide ohmic contact metalization was fabricated on the four edges of the samples.

In order to measure the BPECO/DI oxide thickness, the top of the mesa structures were patterned by photoresist following BPECO/DI oxidation, and the oxide was etched from the exposed areas by a 1:5 HCl:DI etch. After the measurement of the oxide thickness from the exposed edge by using a profilometer, the photoresist mask was removed and all of the remaining oxide on the surface was etched. Next, in order to measure the etch depth, the Si_xN_y mask was removed by a 1:100 HF:DI etch and the etch depth was measured from the exposed edge on top of the mesa structures. Some of the samples were annealed at 700 °C for 30 seconds in an effort to remove the BPECO/DI etch damage. As a final step, Ni/Au (45/50 nm) Schottky structures were patterned and evaporated on the mesas. Immediately before loading of the samples to the evaporator for Ni/Au evaporation, the samples were dipped to 1:2 HCl:DI solution for 30 seconds, rinsed, and blown dry with nitrogen. AES and AFM measurements were taken from bare samples without mesas and Schottky structures, but with the BPECO/DI contact metalization in place on four edges of the sample. Capacitance-voltage measurements were done using an HP-4284 LCR meter at 10 and 100 kHz. AES measurements were performed on a PHI 660

scanning Auger microprobe. The AES spectra was taken from a 5x5 micron area on the surface. All measurement results are given in Chapter 5.

3.3 Experimental Results

<i>Voltage(V)</i>	<i>Time(min)</i>	<i>EtchDepth(nm)</i>	<i>OxideThickness(nm)</i>
4	60	50	400
6	60	65	450

6	180	220	780
8	60	120	600

Table 3.1: Oxide thicknesses and etch depths measured at different oxidation conditions.

Etch depth versus time and voltage data obtained as described above are given in Table 3.1. The etch depths and oxide thicknesses given in Table 3.1 were measured from the top of the mesa structures as noted above. In earlier work [30], saturation of oxide thickness with time was observed to set in after 1 hour of oxidation and the saturated oxide thickness reported at 5 V bias was 175 nm. In the present study, a similar saturation of oxide thickness is observed. However, it takes about 2 hours for strong saturation to be observed, and the resulting oxide thickness is much larger. Crucially, it needs to be noted that the etch depth saturation was not observed at the maximum feasible etching time, despite the strong saturation observed in the oxide thickness. Otherwise, we can observe that the etch rate increases with increasing anode bias, and in general stays in the same range as the values reported in earlier work [30].

The undercutting of annealed Ti/Al/Ni/Au ohmic pads were observed by scanning electron microscopy. A representative image is shown in Figure 3.3, where the undercutting of the metalization is clearly observed. For this specific sample, the oxidation was performed for 60 minutes under 10 V bias. The

Figure 3.3: An SEM image of the Ti/Al/Ni/Au metalization undercut by the BPECO/DI etching.

roughness observed on top of the metalization is typical of Ti/Al/Ni/Au and other Ti/Al based annealed ohmic contacts to GaN. The roughness of the etched surface can also be seen in Figure 3.3.

	<i>Ga</i>	<i>N</i>	<i>O</i>	<i>C</i>	<i>S</i>	<i>Cl</i>
As grown	40.1	40.3	10	8.1	1.5	-
Oxidized	34.4	-	58.8	6.7	-	-
Oxidized etched	37.9	37.9	11.9	11.9	-	0.4
Oxidized etched and annealed	34.4	32.3	12.8	19.7	0.5	0.3

Table 3.2: Atomic concentration percentages as measured by Auger electron spectroscopy on samples at various stages of etching process.

The relative percentages of atoms on the surface given by AES is shown in Table 3.2. It is seen that oxidation results in a surface without any nitrogen content. After the removal of the oxide, the atomic percentage of oxygen on the surface was very close by 1% to the levels in the original sample. It can also be

seen that, annealing of the etched sample did not create a significant change in atomic percentages.

Besides p-type etching tests were performed. A p-type layer of 1.0 μm thick and $2 \times 10^{19} \text{ cm}^{-3}$ Mg doped was used in these tests. Prior to BPECO/DI oxidation, for activation, the layer was annealed at 750 $^{\circ}\text{C}$ for 20 minutes. It was observed that the p-type material was etched at bias voltages more than 12 V while n-type material etch was done over 4 V. This implies that by biasing the sample between 4 to 12 Volts, p/n selective etching is achieved.

Chapter 4

Fabrication of Bipolar Transistors

The fabrication process of self-aligned bipolar transistor consists of 10 steps. These steps are emitter metallization, base etch, base metallization, collector etch, collector metallization, mesa isolation, post formation, air bridge metallization, planarization and RF pad formation. In this fabrication, the most critical point is the low damage base etching and self-aligned base contact formation. It was demonstrated that BPECO/DI etching is a low damage etching method and gives undercut that makes the self-aligned base contact possible. Hence, we have managed to fabricate low damage and self-aligned base contacts by engineering BPECO/DI etching.

4.1 Metal Organic Chemical Vapor Deposition (MOCVD) Growth

Metal-organic chemical vapor deposition (MOCVD) and molecular beam epitaxy (MBE) growth are two major GaN growth methods [31, 32]. All samples used

in this work were grown in the MOCVD machine located in Nanotam Research Center in Bilkent University. All GaN bipolar transistor structures were grown on sapphire substrates. An unintentionally doped buffer layer was first grown and followed by an n-type subcollector and an unintentionally doped collector. Then a p-type Mg doped base and n+ emitter layers were grown. The carrier concentrations for the emitter, base and collector were estimated to be $n=5x10^{18}$, $p=1x10^{17}$ and $n=7x10^{16} \text{ cm}^{-3}$. The layer structure used in this study is given in Figure 4.1.

200nm Emitter n^+ GaN Si $5x10^{18} \text{ cm}^{-3}$

Figure 4.1: Structure of Bipolar Junction Transistor

4.2 Process Steps

4.2.1 Sample Preparation

The samples used in the fabrication were cut into $8x8mm^2$ square pieces because the masks that we used were $7x7mm^2$ and 1 mm edge was required to have contacts for BPECO/DI oxidation. After cleaving into small pieces, the samples were cleaned by two step process before fabrication. First, the samples were dipped into acetone for 3 minutes under ultrasound, then dipped into isopropanol for 3 minutes under ultrasound. Finally, the samples were rinsed in deionized water, dried with nitrogen and baked at $110 \text{ }^\circ\text{C}$ for 1 minute for dehydration.

4.2.2 Lithography

Photolithography (PL) is a process to pattern a mask on thin layer of radiation sensitive photoresist and it is required to define the areas to be etched or coated by metal. Positive photoresist, AZ5214E, was used in our lithography processes and the alignment and exposure were done by using Karl-Suss MJB3 mask aligner.

Normal Lithography for Etching

In normal lithography process for etching, first the photoresist, AZ5214E, was spined at 4000 rpm for 40 seconds and at this rate, the photoresist thickness was around 1.5 μm . Then it was soft baked at 110 $^{\circ}\text{C}$ for 50 seconds and exposed to 6 mW UV light for 28 seconds. Then the pattern was developed in AZ 400K/DI(1:4) for approximately 32 seconds and post baked at 110 $^{\circ}\text{C}$ for 3 minutes.

Normal Lithography for Metal Evaporation

We have utilized lift-off photoresist (LOR 5B) in our photolithographies for metallization to ease the lift-off process. LOR is a polymethylglutarimide (PMGI) based polymer and it dissolves in AZ400K developer. First, the lift-off photoresist (LOR 5B) was spinned at 4000 rpm for 40 seconds. At this spin rate, the approximate LOR thickness was about 1.2 μm . Then it was baked at 170 $^{\circ}\text{C}$ for 5 minutes. After LOR bake, the photoresist, AZ5214E, was spinned at 5000 rpm for 40 seconds. Next it was baked at 110 $^{\circ}\text{C}$ for 50 seconds and exposed to 6 mW UV light for 28 seconds. Then the pattern was developed in AZ400K/DI(1:4) for 35-40 seconds. The development took 3-5 seconds more because of development of LOR resist.

Image Reverse Lithography

In some parts of our process like collector etch, bridge post and mesa definition, image reverse lithography is needed. First the photoresist, AZ5214E, was spun at 5000 rpm for 40 seconds and its thickness was around $1.3 \mu\text{m}$ at this rate. Then it was soft baked at 110°C for 50 seconds and exposed to 6 mW UV light for 14 seconds. Next it was post baked at 120°C for 120 seconds and flood exposed to 6 mW UV light for 28 seconds. The pattern was developed in AZ 400K/DI(1:4) for approximately 25 seconds. For collector etch, the photoresist was post baked at 110°C for 3 minutes to decrease the etch rate of photoresist.

4.2.3 Etching

In our fabrication, GaN was etched by either BPECO/DI etching system in polymer laboratory or RIE etching system in Class 100 laboratory in Advanced Research Laboratory.

Dry Etching

In our processes, an ultra high vacuum Leybold RIE system was used as dry etching system. GaN based materials can be etched by using CCl_2F_2 gas plasma. Also in planarization step, we have etched PMGI by using CHF_3 and O_2 gas mixture.

BPECO/DI Etching

BPECO/DI etching is our newly developed etching mechanism. This technique is not well established as RIE etching and there are still problems with this system as explained in Chapter 3. The importance of utilizing BPECO/DI etching is

that base etching is preferred to be low damage and the etching profile should have negative slope so that the self-aligned structure can be obtained without shorting the emitter and base as shown in Figure 4.2.

Figure 4.2: Self-aligned metallization on a) positive and b) negative slope etched surfaces

The BPECO/DI etching was performed at 20 V for 2x60 minutes to etch 200 nm GaN emitter layer. After 60 minute oxidation, the grown oxide was etched in HCl and then another 20 V 60 minute oxidation was performed to etch 200 nm emitter layer.

4.2.4 Metallization

The metallization is a step to make ohmic or Schottky contacts to the desired regions defined by photolithography step. For this process, the metals were evaporated by using ultra high vacuum LE590 boxcoater. All the metallization processes were done under vacuum less than 5×10^{-6} mBar. The metallization step is also very critical to make good ohmic and Schottky contacts, therefore the samples were dipped into HCl/DI (1:2) solution right before loading to vacuum chamber to remove the native oxide on the surface. As a result, contact quality was increased.

4.2.5 Annealing

The contacts were annealed by using rapid thermal annealing (RTA) system to have better ohmic contacts on n- and p-type materials. The ohmic contacts deposited were annealed at $750\text{ }^{\circ}\text{C}$ under nitrogen and $550\text{ }^{\circ}\text{C}$ under air for n- and p-types, respectively. Also annealing is very critical before BPECO/DI oxidation because non-annealed metals and metals annealed at temperatures higher than $750\text{ }^{\circ}\text{C}$ or lower than $650\text{ }^{\circ}\text{C}$ were oxidized during BPECO/DI etching and they were removed in HCl bath. However, if the metals were annealed at $680\text{ }^{\circ}\text{C}$, they were not affected by BPECO/DI etching and they were not removed during HCl bath.

4.3 Bipolar Transistor Fabrication Process

The bipolar transistor fabrication is a 10 step process and the device structure given in Figure 4.3. Also a scanning electron microscope (SEM) image of the device before planarization can be seen in Figure 4.5.

4.3.1 Activation Annealing

During MOCVD growth, magnesium (Mg) in the p-type material is deactivated by hydrogen (H) atoms. A high temperature annealing was required to activate Mg atoms. Hence the samples were annealed at $750\text{ }^{\circ}\text{C}$ for 60 minutes. The activation temperature was kept high enough so that the activation was completed and low enough so that the GaN crystal structure was not deformed and the Mg diffusion to n-type layers were avoided. The activation time was usually between 15-30 minutes if p-type materials at the top most layer but in npn structure,

Figure 4.3: Bipolar junction transistor device structure

there is a 200nm emitter layer on the base and its duration was increased to 60 minutes to increase the outdiffusion of H atoms.

4.3.2 Emitter Contact

The emitter contact was patterned by a normal photolithography and then Ti/Al/Ni/Au (200 Å/1500 Å/800 Å/6000 Å) was evaporated. The total metal thickness was approximately 850 nm. Since the contact hills to RF pads were defined at this step, the thick emitter metal made the planarization easier and reliable. Then the metal was annealed to increase ohmic quality and not to be oxidized in the next BPECO/DI etching process. The emitter metal after annealing is seen in Figure 4.4.

Figure 4.4: The emitter metal after annealing

4.3.3 Base Etch

Before base etching by BPECO/DI etching, a 200nm Si_xN_y layer region was patterned by photolithography, and Si_xN_y was grown by PECVD and then lift-off. This Si_xN_y layer protected some unused parts on the sample so that the BPECO/DI etch depth was measured. After Si_xN_y growth, the layer was BPECO/DI oxidized at 20 V for 60 minutes and the oxide was removed by HCl bath. Then the etch depth was measured from Si_xN_y features on the sample. The etch depth was usually in the range of 90-120 nm. Therefore to etch total of 200nm, once BPECO/DI oxidation was done at 20 V for 60 minutes and the oxide was removed by HCl bath. Finally, the Si_xN_y layer was removed in a diluted HF/DI(1:100) solution and the final etch depth was measured.

4.3.4 Base Contact

After base etching, base PL was done and Ni/Au (100 Å/200 Å) metallization was used to have ohmic contact to p-type GaN material. After lift-off, the metal was annealed at 550 °C for 180 seconds under air to make ohmic contact.

4.3.5 Collector Etch

The collector contact should be on the highly doped subcollector region so that a good ohmic contact was done to collector region. Therefore the base and unintentionally doped (UID) collector layers were needed to be etched. With an image reverse lithography of base, it was etched down to subcollector region via RIE etching.

4.3.6 Collector Contact

After collector contact PL, Ti/Al/Ni/Au (200 Å/1500 Å/400 Å/500 Å) was evaporated. The collector contact was not annealed but since it was made on a highly doped n region, it showed good ohmic quality.

4.3.7 Mesa Isolation

The devices on the sample and more importantly the base hill and subcollector region should be isolated. For this reason, mesa PL was done and etched down to the middle of the undoped buffer layer.

4.3.8 Post Formation

Post between the base hill and base metal was required before bridge metallization because the bridge would go over this post. The post material was a polymer PMGI. PMGI is widely used for this purpose, because of its desired reflow properties and its suitable chemistry to the normal PL. After PMGI spinned, post PL was done and then it was exposed under 200 W UV source. After exposure, PMGI was developed in developer MF319/DI (1:1) and the photoresist was removed with acetone. Finally, the post was baked to reflow. The reflow is needed to provide a smooth and continuous way for the bridge or to prevent breaking the bridge from edges.

4.3.9 Air Bridge Process

After post reflow, bridge metallization PL was done and Ti/Au (300 Å/8000 Å) was evaporated. The bridge metal should be thick enough to increase its endurance. The SEM picture of the device after air bridge formation is given in Figure 4.5.

4.3.10 Planarization

The planarization is required for RF pad metal formation. We have used benzocyclobutene (BCB) for planarization. After hard bake, BCB is very resistive to chemicals and has a very high resistance ($1 \times 10^{19} \Omega \text{cm}$), hence it is widely used for this purpose. After spinning BCB and hard baking, by RIE etching with CHF_3 and O_2 gas mixture, BCB was etched below the level of emitter, base and collector hills. It has to be noted that BCB etching is very critical. Etching less than the required level, would make open all the contacts and etching more would short the emitter base contacts. Hence the emitter metal was evaporated

thick (850nm) to prevent shorting emitter base contacts. Together with emitter region thickness (200nm), there was a 1 μm safe region to stop etching.

4.3.11 RF Pad Metal Formation

After planarization, the RF pad metal PL was done and Ti/Au (300 Å /6000 Å) was evaporated. Thick metal pads decrease the parasitic resistances and increase the device performance. The RF pad metal formation was the last step of fabrication and final view of the device pictures taken by optical microscope is given in Figure 4.6.

Figure 4.6: The final view of the fabricated device

Chapter 5

Measurements and Results

5.1 Schottky Measurements and Results

The current-voltage characteristics of Schottky contacts fabricated on surfaces with various treatments are summarized in Table 5.1. The estimated breakdown voltage was calculated assuming uniform field in the undoped GaN.

Voltage (V)	Time (min)	Etch Depth (nm)	Post Etch Treatment	Breakdown Voltage (V_{BR} (V))	Ideality Factor	Estimated Break-down Voltage V_{BR} (V)
-	-	0	-	-70	1.25	-70
4	60	50	-	-54	1.52	-63
4	60	50	annealed	-60	1.89	-63
6	60	65	-	-44	1.71	-61
6	60	65	annealed	-51	1.72	-61
6	120	130	-	-33	1.67	-52
6	120	130	annealed	-41	1.82	-52
8	60	120	-	-38	1.93	-52
8	60	120	annealed	-54	1.97	-52

Table 5.1: Characteristics of Schottky contacts fabricated on GaN surfaces with various treatments.

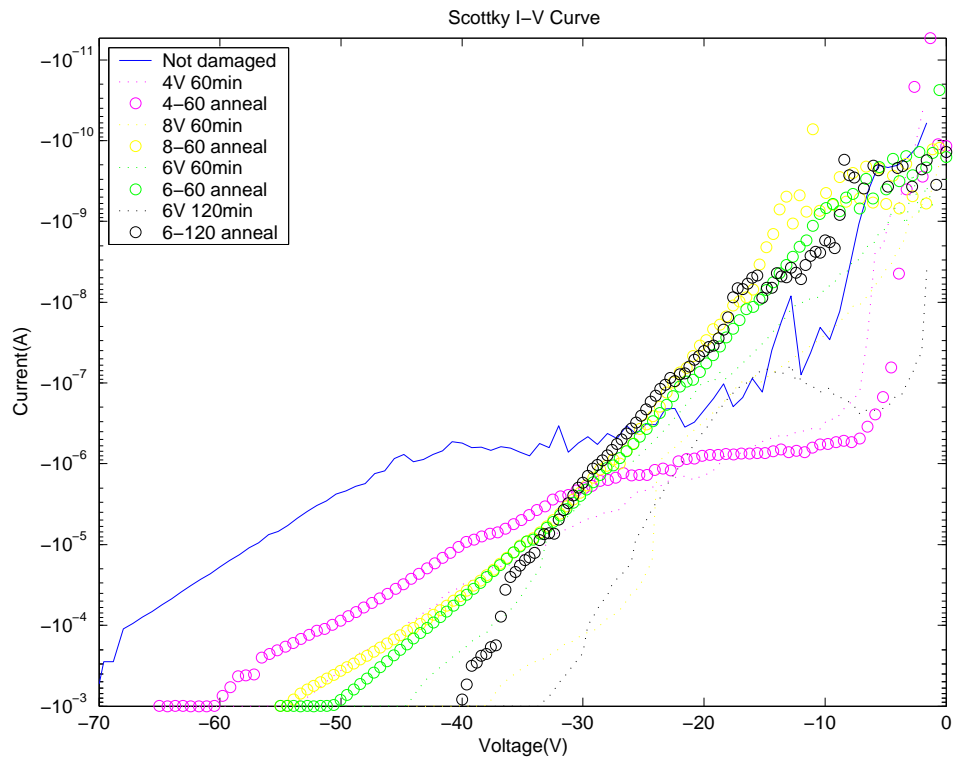

Figure 5.1: Reverse current-voltage characteristics of Schottky contacts fabricated on surfaces after various treatments.

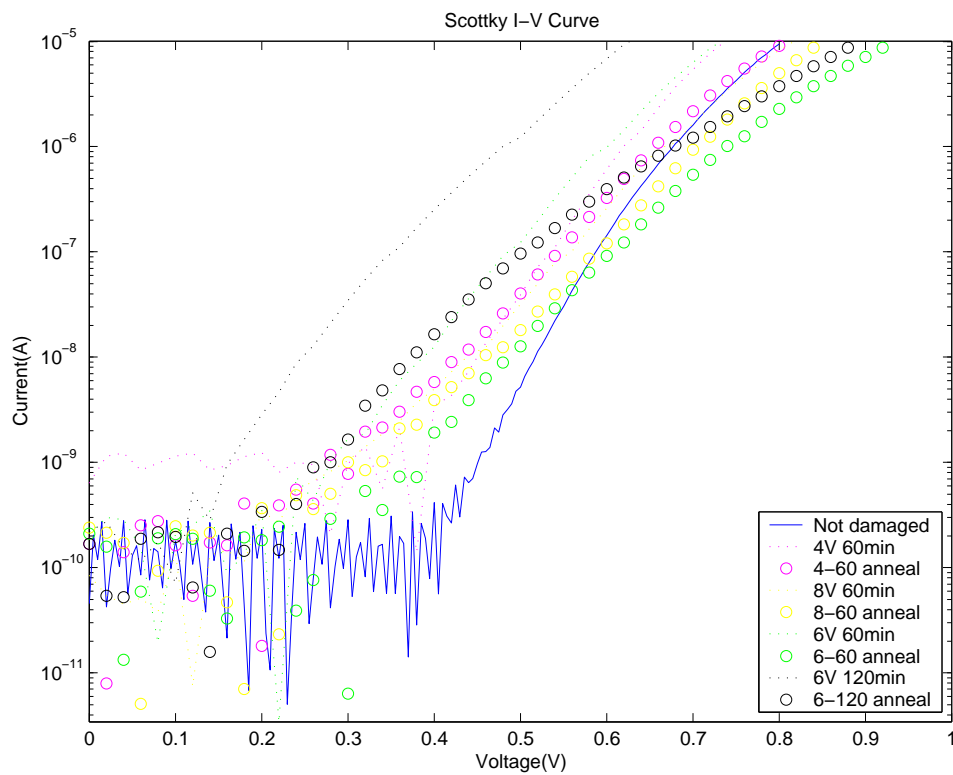

Figure 5.2: Forward current-voltage characteristics of Schottky contacts fabricated on surfaces after various treatments.

Figure 5.1 and 5.2 show the reverse and forward current characteristics of these devices. From these results, we saw that the BPECO/DI etching results in a reduction in breakdown voltage and an increase in the ideality factor. The breakdown voltages were higher for samples that have been annealed after the removal of the BPECO/DI oxide. After annealing, under certain conditions, breakdown voltages increased back to a value that was expected from the decrease in the undoped layer thickness. Thus, it was demonstrated that by etching of BPECO/DI oxide and subsequent annealing it is possible to fabricate good quality Schottky diodes on surfaces etched as much as 120 nm. Thus, it can be suggested that after the oxidation, etching, and annealing procedures the surface obtained is low damage.

The capacitance-voltage (C-V) characteristics presented in Figure 5.3.a-c indicated that all diodes were fully depleted at reverse biases and the untreated surface had uniform carrier density profile. After etching of the PEC grown oxide, the surface had a region of low carrier density as indicated by the high slope observed in Figure 5.3.b for bias voltages close to 0 V. After annealing, the C-V characteristics shown in Figure 5.3.c approached to that of an untreated surface shown in Figure 5.3.a. Given the information about the point defects in GaN [33, 34], it may be concluded that the defects created by bias assisted PEC oxidation are gallium vacancies bound to oxygen interstitials. Previous studies based on photoluminescence investigation of GaN etched by PEC in KOH solution have reached the same conclusion [35].

AFM scans indicated a roughening of the etched surfaces after oxidation. The mean roughness of the as grown sample was 0.3 nm. As measured from a sample that was oxidized for 2 hours with 6 V bias, the root mean square (RMS) roughness of the etched surfaces was 15.6 nm and the mean RMS roughness of the etched surfaces after annealing was 10.3 nm. The increased roughness of the

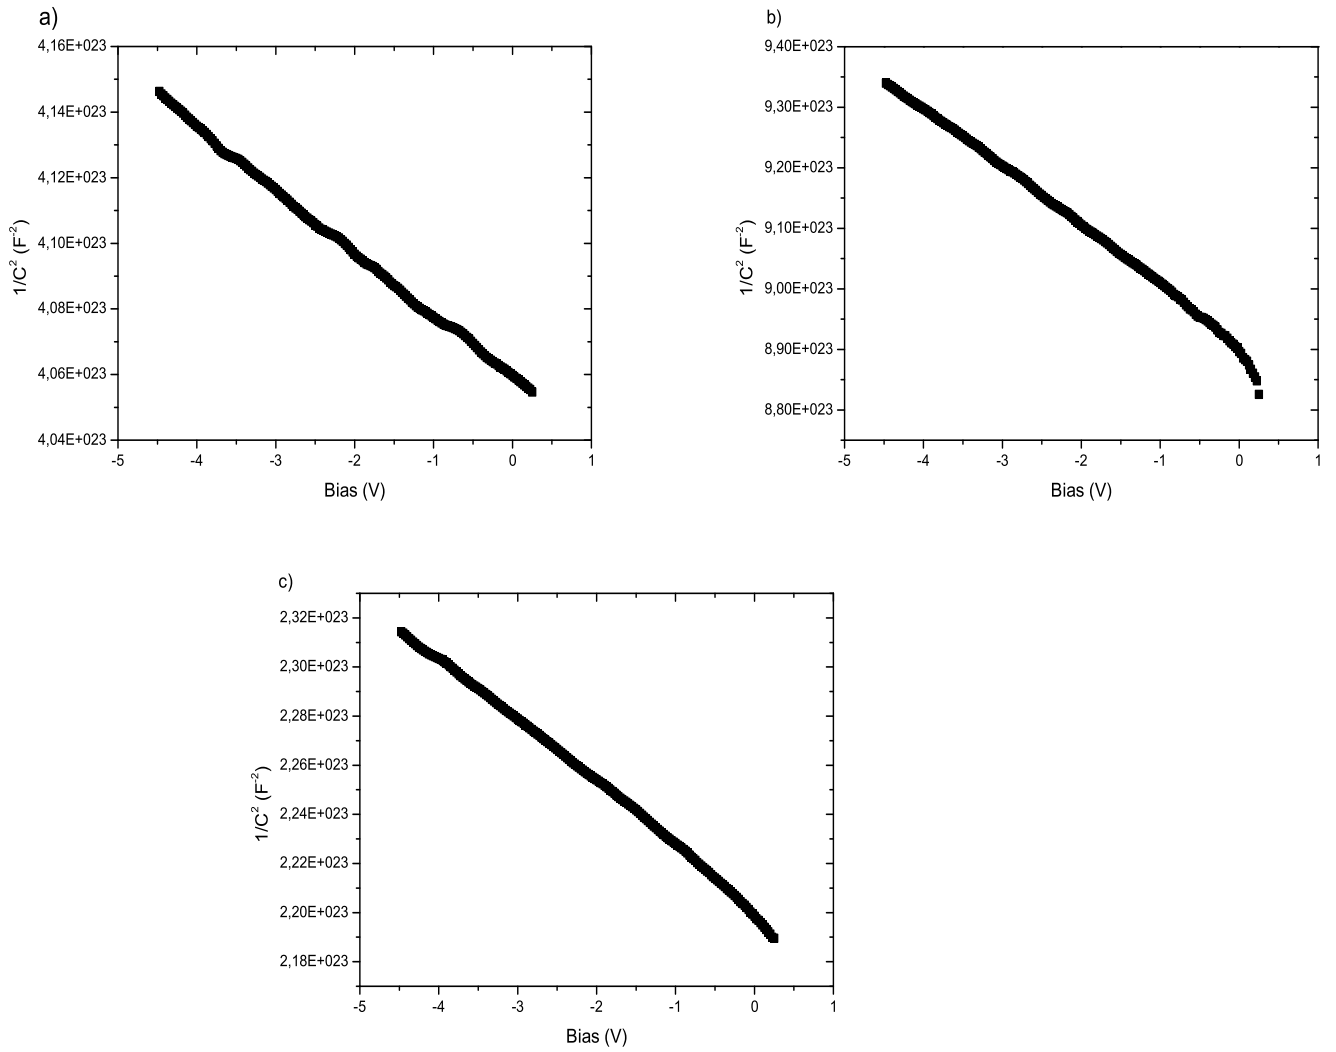

Figure 5.3: The $1/C^2$ as a function of bias for a Schottky structure a) on untreated surface b) on surface etched by PEC oxidation at 6 V for 120 minute c) on surface etched as in b) and annealed as described in the text.

etched surface indicated that the oxidation process was not diffusion limited despite the presence of an oxide cover. This indicated that our process of oxidation likely had some deficiencies manifesting itself in the nonsaturating etch depths and the increase in roughness. It was also possible that the increased roughness was related to the defects in the material being etched [36].

The fact that near ideal breakdown voltages and C-V characteristics were obtained on 120 nm etched surfaces after a 700 °C 30 s anneal indicated that the damage induced by BPECO/DI was shallow and could easily be removed.

In contrast, surfaces etched by RIE by only 10 nm using the best techniques requires a 850 °C, 30 s anneal for damage removal. Deeper RIE etches requires etching of the sample by KOH for damage removal, making the process unusable for practical purposes. Similarly, the PEC process is not suitable for use in self-aligned emitter-base etching GaN HBT structures, since PEC employs KOH during the etching process which needs to be performed at low etching rates to achieve low damage. Thus, etching of GaN by etching of BPECO/DI oxide stands out as a unique tool for deep etching without creating extensive surface damage. Such a process is critically needed for GaN based HBT fabrication.

The reduction of the roughness after annealing might be a factor in the improvement of the Schottky characteristics seen with annealing. However, the C-V and AES results showed that the improvement was more likely to be related to removal of point defects. The reduction of the RMS roughness observed with the annealing may be attributed to decomposing of the oxide that remains on the surface after oxide etching. However, no change in oxygen ratio was observed with AES. So, the mechanism with which the annealing resulted in smoothing of the etched surface remained unclear.

We have demonstrated good quality Schottky contacts on surfaces etched 120 nm using the BPECO/DI process. These results presented here are the first experiments reporting a good quality Schottky devices on GaN surfaces etched more than a few tens of nanometers by any method. The good quality of the Schottky contacts indicated that low-damage etching of GaN surfaces could be achieved by BPECO/DI process. Annealing of the etched surfaces at 700 °C for 30 seconds in nitrogen resulted in successful removal of the etch damage. After this anneal, the Schottky breakdown voltages approached to the values expected from the reduced thickness of the n-GaN layer. Capacitance-voltage measurements indicated the reduction in Schottky breakdown voltages after etching and the improvement observed after annealing was most likely due

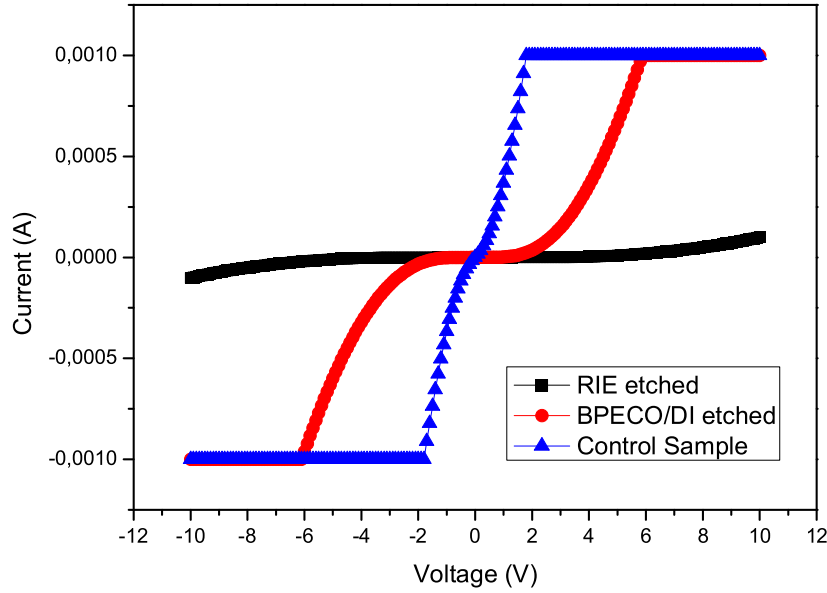

Figure 5.4: I-V characteristics of $7\mu\text{m}$ TLM pattern on control, BPECO/DI etched and RIE etched surfaces

to point defects. The roughening that resulted from the BPECO/DI oxidation and etching was not clearly understood and was likely to be related to deficiencies in our specific equipment and should be investigated further on.

In addition to Schottky contact study, p-type and n-type ohmic contacts were formed on BPECO/DI etched surfaces. From the measured n-type ohmic contacts, no difference was observed between the I-V characteristics of TLM patterns on etched surface and unetched surface. However for the p type contacts, the measured I-V characteristics degraded with BPECO/DI etching but it was much better than the I-V characteristics of the contact on the RIE etched p-type.

The changes in Schottky diode characteristics and ohmic characteristics suggest that the BPECO/DI etching results in a damage near surface. Improvement of reverse characteristics and nearly unchanged ideality factors support that some of the damage can be improved and some cannot be removed by short annealing.

An explanation for the observed Schottky characteristics and ohmic behaviors can be that BPECO/DI etching creates defects on or close to surface. These states cause trap assisted tunnelling and degrade reverse leakage as explained in Chapter 2. Annealing removes these states and therefore passivation of surface states improves reverse characteristics. Also compensating defects very near to surface decrease the free carrier density near the surface by capturing electrons. This was observed in C-V measurements and it got close to the original case after annealing out the near surface states. This defect can be gallium vacancies bound to oxygen interstitials $V_{Ga} - O_N$, because during oxidation, OH^- ions prefer to make chemical reactions with gallium (Ga) atoms instead of nitrogen (N) atoms. This fact and presence of oxygen (O) atoms increase the density of gallium vacancies V_{Ga} . Hence a consistent picture is that there are gallium vacancies V_{Ga} and gallium vacancies bound to oxygen interstitials $V_{Ga} - O_N$, that is, gallium vacancy-oxygen complexes [33, 34]. This defect was also observed in PEC etched surfaces as the origin of yellow luminescence [35]. Since these defects are compensating, the degradation in p-type ohmic quality can also be explained by decreased hole concentration on the p-type surface.

The change in ideality factor of Schottky diodes might be explained by nonuniform Schottky barrier height (NSBH) explanation of Tung [18]. It is known that the Schottky barrier height is nonuniform for inhomogeneous surfaces. This inhomogeneity can be due to the nonuniform etching, surface roughness due to nonuniformity sources coming from the etching system like light intensity, potential distribution, etc. As a result of this nonuniformity, there are patches with different SBH's and the current conduction occurs through these patches. This conduction mechanism is called "parallel conduction mechanism" and a sum of individual currents flowing through the patches with area (A_i) and SBH (ϕ_i) is given by;

$$I = \sum_i I_i = A^* T^2 [\exp(\beta V_a) - 1] \sum_i \exp(-\beta \phi_i) A_i \quad (5.1)$$

Tung claims that "The parallel conduction mechanism is in significant error when the SBH varies spatially on a scale less than, or comparable to, the depletion region width. The error arises because the equation fails to take into account the interaction between neighboring patches with different SBH's." The situation can be explained by the conduction path through a low SBH patch with neighbor high SBH patches is pinched off. The pinch off is defined as majority carriers see a barrier higher than the band-edge at metal-semiconductor interface. This pinch off results in deficiencies in ideality factor.

The being pinched off for a patch is directly related to its size. The potential distribution by solving the Poission equation gives that the potential increases up to a distance then it decreases along the patch, if the patch size is less than the peak point position, then the patch is pinched off due to the potential distribution electrons see a higher barrier than the band edge barrier. This condition is given by the equation:

$$\frac{\Delta}{V_{bb}} > \frac{2R_0}{W} \quad (5.2)$$

where Δ is the barrier height difference between low SBH and neighbor SBH's, V_{bb} is the band banding potential, R_0 is the radius of the patch, and W is the depletion width.

As it is mentioned, the patch sizes less than or comparable to depletion width are pinched off. Since the doping of semiconductor controls the depletion width, the number of pinched off patches are directly related to the doping of semiconductor. After knowing the potential distribution, the current flowing to and from low SBH patches can be calculated.

$$n = 1 + \frac{\gamma}{3\eta^{1/3}V_{bb}^{2/3}} \quad (5.3)$$

where $\eta \equiv \frac{\epsilon_s}{qN_D}$ and the patch size characteristics γ is defined as $\gamma \equiv 3(\Delta R_0^2/4)^{1/3}$

Then an ideality factor can be calculated from dI/dV and it is given in Equation (5.3). This also explains the doping and applied potential dependence of the ideality factor and enlightens the anomaly on the ideality factor.

Explanations given above can enlighten the measurement results. Although we have used all available measurement instruments to investigate the etching damage, temperature dependent measurements and deep level transient spectroscopy (DLTS) can be done for further understanding of the damage mechanism of BPECO/DI etching.

5.2 Bipolar Transistor Measurements and Results

The fabricated devices, as explained in Chapter 4, were measured on HP 4145B. The I-V characteristics of TLM patterns on all regions, base-emitter and base-collector junctions were measured to characterize the device performance.

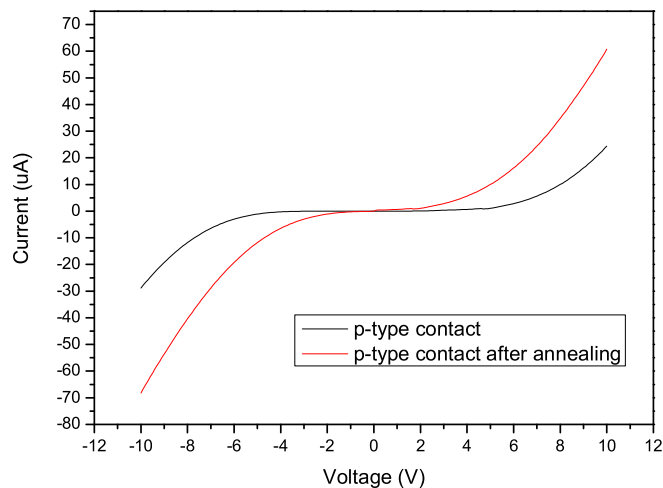

Figure 5.5: I-V Characteristics of 6 μm TLM on the base region

After etching the emitter layer and forming the self-aligned base contact, the current-voltage characteristics of TLM patterns on base region were measured. The I-V characteristic of a 6 μm TLM pattern of 40x100 μm is shown in Figure 5.5. In addition to the high base resistance, a rectifying voltage of 5V for nonannealed base contact and 2 V for annealed base contact were observed in the base TLM measurements. These nonidealities, the high base resistance and rectifying voltage, are mainly due to the low doping concentration in the base and poor base contacts. A similar rectifying, 2 V, voltage can also be seen in Figure 5.4, the I-V characteristics of TLM pattern on bare p-type material and it could be deduced that it would be much worse if RIE etched.

I-V characteristics of base-emitter junction and base-collector junction were shown in Figure 5.6 and Figure 5.7. Figure 5.6 demonstrates that self aligned base-emitter junction was not shorted and diode characteristics proved that the base metal was on p-type layer. In order to further determine the base contact placement, two experiments were performed. We have intentionally etched one sample less than emitter thickness and another sample more than total of emitter and base thicknesses. In other words, base metals were placed on emitter and collector layers. Both I-V measurements showed back-to-back Schottky characteristics. Figure 5.8 shows I-V characteristics of TLM patterns on sample intentionally etched less than emitter thickness. Therefore it was sure that in our experiment, we achieved to place the base metal on the p-type layer.

The ideality factor and breakdown voltage of base-emitter junction were in the range of 2-3.5 and 14-22 V respectively. On the other hand, the ideality factor and breakdown voltage of base-collector junction were between 4-5.5 and 50-75 V respectively. High ideality factors for GaN based p-n junctions have commonly been seen because of low doped base region. Furthermore high ideality factor of base-collector junction could be related to the low doping of collector region. Also the low breakdown voltage of base-emitter junction was due to the high

doping of emitter and thin base layer. The effect of high base resistance is also effective on both the degradation of ideality factors and the low current densities in both junctions. Due to high access base resistance, the current density in base-emitter junction was too low because base-emitter junction is affected by access base resistance much more than base-collector junction.

Chapter 6

Discussions and Conclusions

The lack of a low damage etching process that is compatible with rest of the fabrication steps has been a factor hindering GaN HBT fabrication. For the fabrication of GaN HBTs, an n/p doping selective etch process that does not result in damaged surfaces after 100 to 150 nm etching is necessary.

In this study, we demonstrated that BPECO/DI etching yields low-damage surfaces after etching as much as 120 nanometers. A post-etch anneal at 700 °C is required to improve the surface characteristics to near ideal. The properties of surfaces oxidized and etched by BPECO/DI were investigated using Schottky diodes fabricated on etched surfaces and also by using Auger electron spectroscopy (AES) and atomic force microscope (AFM) measurements. The results presented here should motivate further investigation of BPECO/DI for use in GaN HBT processing.

Then we have fabricated self aligned bipolar transistors by engineering BPECO/DI etching. The fabricated devices did not work as estimated. The reasons that degrade the transistor performance can be base material quality associated with growth or fabrication. First of all, the fabricated p-type layer with the similar conditions of p-type material of npn layers has shown 1 Ωcm sheet

resistance and this is comparable to the p-type sheet resistances in the literature. However, the p-type surface was always very rough compared to n-type materials and hexagonal shaped defects were intensively seen on the surface.

On the other hand, the problems might come from fabrication. First of all, the activation annealing has to be done before emitter etch because the emitter contact cannot stand for long and high temperature activation annealing. Furthermore since there is undercut, the mushroom like emitter structure melts and the emitter-base junction shorts. Hence while activating p-type base, there is a 200nm emitter layer on the base. This might prevent the outdiffusion of the H atoms that inactivate the Mg atoms in p region.

There are also some uncertainties with BPECO/DI etching. For instance, the roughening mechanism still cannot be understood fully. The reason of roughening in PEC etching is proposed to be dislocations and this can be overcome by increasing the UV light intensity or decreasing the concentration of electrolyte. However, we could not achieve smooth surface as in PEC etching. Also while etching npn layers, the etch rates were decreased and surface roughness was significantly increased compared to n layers etched with the same conditions. This can be explained by the reduction of hole lifetime in highly doped emitter layer. Also the high defect and dislocation density in p-type region affect n+ emitter region grown afterwards. Hence this also explains that the etch rate of n+ emitter layer decreases and the surface roughness increases.

The future study can be focused on npn layer growth and also on HBT fabrication by utilizing BPECO/DI etching. Even though currently there are still problems that should be solved for good bipolar transistor characteristics, this fabrication method is a very strong candidate for the future GaN bipolar transistor fabrication.
