ABSTRACT: We calculate the spectral dimension for a nonperturbative lattice approach to quantum gravity, known as causal dynamical triangulations (CDT), showing that the dimension of spacetime smoothly decreases from ~ 4 on large distance scales to $\sim 3/2$ on small distance scales. This novel result may provide a possible resolution to a long-standing argument against the asymptotic safety scenario. A method for determining the relative lattice spacing within the physical phase of the CDT parameter space is also outlined, which might prove useful when studying renormalization group flow in models of lattice quantum gravity.

1 Introduction

Three of the four fundamental interactions of nature have been successfully quantised, the notable exception being gravity. The central difficulty in formulating a theory of quantum gravity is that the computational techniques applied so successfully to the other forces do not give consistent results when applied to quantum general relativity. The origin of this incongruity stems from the fact that gravity is distinguished from the other fundamental interactions of nature by its dimensionful coupling constant G_N . In d -dimensional spacetime Newton’s gravitational coupling has a mass dimension of $[G_N] = 2 - d$, meaning that in the case of 4-dimensional spacetime higher-order loop corrections generate a divergent number of counterterms of ever increasing dimension. One can clearly see this from the perturbative quantum field theoretic treatment of gravity in d -dimensional space, showing that momentum p scales with loop order L as

$$\int p^{A-[G_N]L} dp, \tag{1.1}$$

where A is a process dependent quantity that is independent of L [1]. Equation (1.1) is clearly divergent for $[G_N] < 0$, because the integral will grow without bound as the loop-order L increases in the perturbative expansion [1]. Interestingly, eq. (1.1) is divergence free for $d \leq 2$, meaning that gravity as a perturbative quantum field theory can be renormalizable by power counting if the dimension of spacetime is equal to, or smaller than, two. This raises the exciting possibility that spacetime could act as its own ultraviolet regulator via the mechanism of dynamical dimensional reduction, possibly yielding a finite and predictive theory of quantum gravity.

Remarkably, a number of seemingly independent approaches to quantum gravity have reported that the dimension of spacetime exhibits a scale dependence. Causal dynamical

triangulations (CDT) [2], exact renormalization group methods [3], Hořava-Lifshitz gravity [4], loop quantum gravity [5], and string theory [6, 7] all provide evidence that the dimension of spacetime appears to reduce from approximately four on macroscopic scales to approximately two on microscopic scales. Individually these results do not constitute substantial evidence in support of dimensional reduction; collectively, however, they form a compelling argument that demands further attention.

One of the original formulations of lattice gravity is Euclidean dynamical triangulations (EDT) [8, 9], which defines a spacetime of locally flat n -simplices of fixed edge length, where a n -simplex is the n -dimensional analogue of a triangle. However, the original EDT model quickly ran into significant problems. The parameter space of couplings contained just two phases, neither of which resembled 4-dimensional semi-classical general relativity, and the two phases were separated by a first order critical point, making it unlikely that one could take a continuum limit [10, 11]. In response to these problems a causality condition was added, giving rise to the method of causal dynamical triangulations (CDT) [12].

In close analogy to the sum over all possible paths in Feynman's path integral approach to quantum mechanics, CDT is an attempt to construct a nonperturbative theory of quantum gravity via a sum over different spacetime geometries. In CDT, such spacetime geometries are defined by locally flat n -dimensional simplices that are glued together along their $(n - 2)$ -dimensional faces, forming a n -dimensional simplicial manifold. A key ingredient of CDT is the introduction of a causality condition, in which one distinguishes between space-like and time-like links on the lattice. In this way one can define a foliation of the lattice into space-like hypersurfaces, each with the same fixed topology. Only geometries that can be foliated in this way are included in the ensemble of triangulations that define the path integral measure.

The introduction of the causality condition in the CDT approach to quantum gravity has produced a number of promising results, in contrast to the original EDT version. A four-dimensional de Sitter like phase was shown to emerge within the parameter space of CDT [13], and the likely identification of a second-order phase transition line suggests the exciting possibility that the theory may have a well defined continuum limit [14]. Another key result is that within the de Sitter-like phase of CDT the dimension appears to be scale dependent, dynamically reducing from approximately four on large scales to approximately two on small scales [2]. Since a scale dependent dimension may have important implications for the renormalizability of quantum gravity it forms the central focus of this work.

At first glance one might think that performing a weighted sum over geometries constructed by gluing together n -dimensional building blocks will always result in a n -dimensional geometry, however, this is not necessarily the case. For dynamical triangulations the dynamics is contained in the connectivity of the n -simplices, where the geometry is updated by a set of local update moves [15]. These local update moves can result in the deletion or insertion of vertices within simplices, and so it is possible to obtain a geometric structure that has self-similar properties at different scales; meaning the geometry can be a fractal. A fractal geometry admits non-integer dimensions, so recovering n -dimensional space from n -dimensional building blocks is a non-trivial test of the theory; a test that CDT has passed by demonstrating that a four-dimensional geometry emerges on large scales [2].

The CDT approach to quantum gravity allows the fractal dimension of the ensemble of triangulations to be computed numerically, typically this is done by computing the Hausdorff dimension and the spectral dimension.

The Hausdorff dimension [16] generalises the concept of dimension to non-integer values, and can be defined by considering how the volume of a sphere with topological dimension D_T scales with radius r in the limit $r \rightarrow 0$,

$$D_H = \lim_{r \rightarrow 0} \frac{\ln(V(r))}{\ln(r)}. \tag{1.2}$$

The spectral dimension, on the other hand, is related to the probability of return $P_r(\sigma)$ for a random walk over the ensemble of triangulations after σ diffusion steps. One can derive the spectral dimension (following refs. [2, 17]) starting from the d -dimensional diffusion equation,

$$\frac{\partial}{\partial \sigma} K_g(\zeta_0, \zeta, \sigma) - g^{\mu\nu} \nabla_\mu \nabla_\nu K_g(\zeta_0, \zeta, \sigma) = 0, \tag{1.3}$$

where K_g is known as the heat kernel describing the probability density of diffusion from ζ_0 to ζ in a fictitious diffusion time σ . ∇ is the covariant derivative of the metric $g_{\mu\nu}$. The diffusion process is taken over a d -dimensional closed Riemannian manifold M with a smooth metric $g_{\mu\nu}(\zeta)$.

In the case of infinitely flat Euclidean space, eq. (1.3) has the simple solution,

$$K_g(\zeta_0, \zeta, \sigma) = \frac{\exp(-d_g^2(\zeta, \zeta_0)/4\sigma)}{(4\pi\sigma)^{d/2}}, \tag{1.4}$$

where $d_g^2(\zeta, \zeta_0)$ is the geodesic distance between ζ and ζ_0 .

The quantity that is measured in the numerical simulations is the probability $P_r(\sigma)$ that the diffusion process will return to a randomly chosen origin after σ diffusion steps over the spacetime volume $V = \int d^d\zeta \sqrt{\det(g(\zeta))}$,

$$P_r(\sigma) = \frac{1}{V} \int d^d\zeta \sqrt{\det(g(\zeta))} K_g(\zeta, \zeta, \sigma). \tag{1.5}$$

The probability of return to the origin in asymptotically flat space is given by,

$$P_r(\sigma) = \frac{1}{\sigma^{d/2}}, \tag{1.6}$$

and so we can extract the spectral dimension D_S by taking the logarithmic derivative with respect to the diffusion time, giving

$$D_S = -2 \frac{d \log \langle P_r(\sigma) \rangle}{d \log \sigma}. \tag{1.7}$$

Equation (1.7) is strictly only valid for an infinitely flat Euclidean space. However, one can still use this definition of the spectral dimension to compute the fractal dimension of a curved, or finite volume, by factoring in the appropriate corrections for large diffusion times σ . Specifically, the probability that the random walk will return to the origin approaches

unity as the ratio of the volume and the diffusion time approaches zero, i.e. when the diffusion time is much greater than the volume. The mathematical explanation for this is that the zero mode of the Laplacian $-\Delta_g$, which determines the behaviour of $P_r(\sigma)$ via its eigenvalues λ_n , will dominate the diffusion in this region, causing $P_r(\sigma) \rightarrow 1/N_4$ for $\sigma \gg N_4^{2/D_S}$ [2]. One can therefore factor in the appropriate finite volume corrections by omitting values of $D_S(\sigma)$ for which $\sigma \gg N_4^{2/D_S}$.¹ The spectral dimension allows one to probe the geometry of spacetime over varying distance scales. The Hausdorff and spectral dimensions coincide with the standard measure of the dimension, the topological dimension, when the manifold is non-fractal.

2 Asymptotic safety

As first suggested by Weinberg [1], the concept of the renormalizability of gravity might be generalised to include the nonperturbative regime via the asymptotic safety scenario. In this scenario gravity would be nonperturbatively renormalizable if a finite number of relevant couplings end on an ultraviolet fixed point (UVFP). In a lattice theory of gravity, such as CDT, an UVFP would appear as a second order critical point, the approach to which would define a continuum limit.

However, there exists an argument due to Banks [18] (see also Shomer [19]) against the possibility of asymptotic safety. The argument compares the density of states at high energies expected for a theory of gravity to that of a conformal field theory. Since a renormalizable quantum field theory is a perturbation of a conformal field theory by relevant operators, a renormalizable field theory must have the same high energy asymptotic density of states as a conformal field theory. It follows from dimensional analysis, and the extensive scaling of the quantities considered, and the fact that a finite temperature conformal field theory has no dimensionful scales other than the temperature, that the entropy S and energy E scale as

$$S \sim (RT)^{d-1}, E \sim R^{d-1}T^d \tag{2.1}$$

where R is the radius of the spatial volume under consideration and T is the temperature. It follows that the entropy of a renormalizable theory must scale as²

$$S \sim E^{\frac{d-1}{d}}. \tag{2.2}$$

For gravity, however, one expects that the high energy spectrum will be dominated by black holes.³ The d -dimensional Schwarzschild solution in asymptotically flat spacetime has a black hole with event horizon of radius $r^{d-3} \sim G_N M$, where M is the mass of the black hole.⁴ The Bekenstein-Hawking area law tells us that $S \sim r^{d-2}$, so that

$$S \sim E^{\frac{d-2}{d-3}}. \tag{2.3}$$

¹The curvature of the space on which the diffusion process occurs should also be corrected for due to the fact that it will change the probability that the diffusion process will return to the origin [2]. Curvature corrections are not estimated in this work.

²See ref. [20] for a critique of the reasoning that leads to this scaling.

³Although this assumption has been questioned by Percacci and Vacca [21], among others.

⁴Asymptotically safe black holes are actually Schwarzschild-de Sitter black holes whose entropy is given by the Cardy-Verlinde formula, which may itself resolve the apparent contradiction between black hole entropy and asymptotic safety [22].

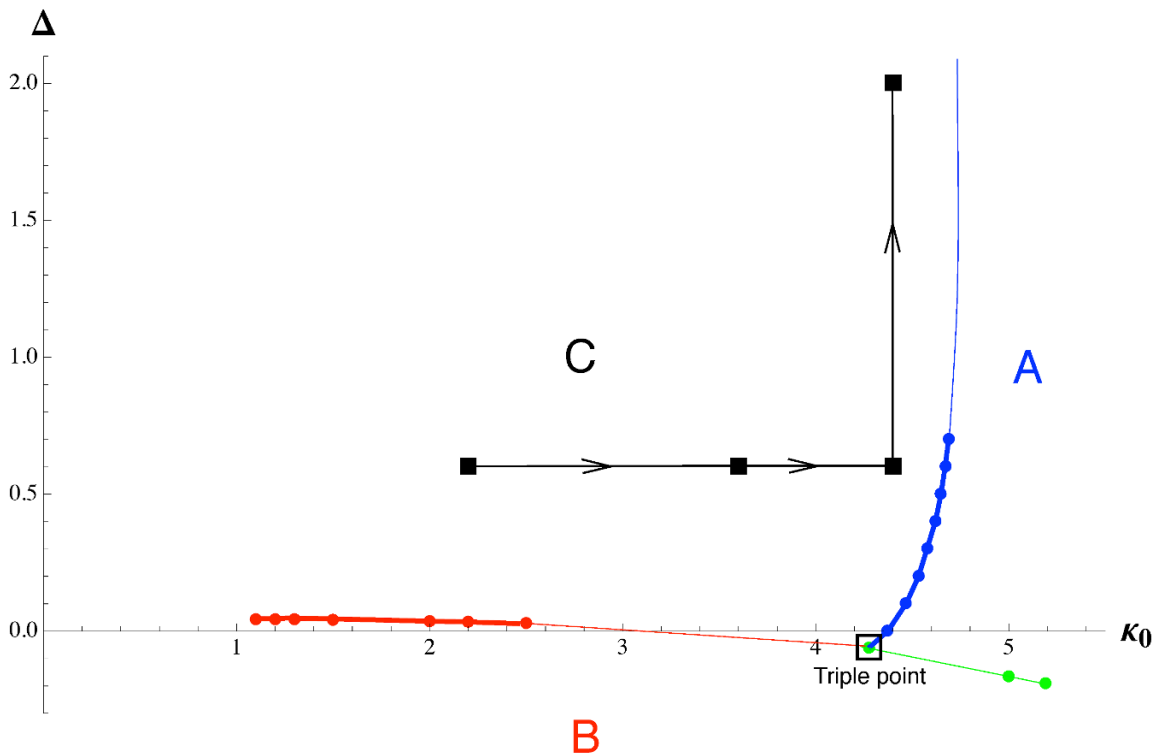

Figure 1. A schematic representation of the phase diagram of 4-dimensional CDT. We observe three main phases: a *branched polymer-type phase* (phase A), a *crumpled phase* (phase B) and the physically interesting *de Sitter phase* (phase C). The thicker transition lines represent previously measured phase transition points and the thinner lines an interpolation. Superimposed on the phase diagram are the 4 locations within phase C at which the spectral dimension is determined in this work, as indicated by the black squares. The arrows indicate the apparent direction of decreasing relative lattice spacing.

This scaling disagrees with that of eq. (2.2). Assuming the argument leading to eq. (2.3) is valid then one is led to conclude that gravity cannot be formulated as a renormalizable quantum field theory. This is a potentially serious obstacle for asymptotic safety, a possible resolution of which is provided in the following section.

3 Measurements of the spectral dimension in CDT

The canonical point in the physical de Sitter phase of CDT, namely $(\kappa_0 = 2.2, \Delta = 0.6)$, has previously been shown to exhibit a scale dependent spectral dimension, yielding $D_S(\sigma \rightarrow \infty) = 4.02 \pm 0.10$, and $D_S(\sigma \rightarrow 0) = 1.80 \pm 0.25$. With a fit to the functional form

$$D_S(\sigma) = a - \frac{b}{c + \sigma}, \tag{3.1}$$

giving $a = 4.02$, $b = 119$ and $c = 54$ [2]. As the authors of ref. [2] correctly claim the short distance spectral dimension is thus consistent with the integer 2. However, the fact that this measurement is for just a single point in the parameter space, coupled with the relatively

large statistical error makes definitive conclusions difficult. Since this result has potentially important consequences for the renormalizability of gravity, we revisit this calculation, attempting a more comprehensive study of the spectral dimension in phase C of CDT.

We calculate the spectral dimension as a function of diffusion time for three different κ_0 values along the $\Delta = 0.6$ line, in addition to a fourth point $\kappa_0 = 4.4, \Delta = 2.0$, within the physical phase of CDT, as indicated by the black squares in figure 1. For three of these points, namely $(\kappa_0 = 2.2, 4.4, \Delta = 0.6)$ and $(\kappa_0 = 4.4, \Delta = 2.0)$, we have also calculated $D_S(\sigma)$ for multiple lattice volumes. This multi-volume study and related discussion can be found in the subsection on systematic errors (section 3.2).

In the calculation of the spectral dimension presented in this work we take the starting point of our diffusion to be in the time slice containing the maximal number of $N_{4,1}$ simplices, as is done in e.g. ref. [2]. In this way we can be sure that we are investigating the bulk properties of the geometry with each diffusion. The diffusion process is followed out to a maximum of 500 diffusion steps. Simulations were performed with a time extension of $t = 80$. The attempted Monte Carlo moves that update the geometry were performed in units of 10^6 , with each unit defining a sweep. The number of sweeps required to reach a thermalized configuration grows approximately linearly with $N_{4,1}$, and is typically of the order $\sim 10^8$ sweeps for the largest ensembles [2]. We implement an effective linear four-volume fixing constraint

$$\delta S = \epsilon |N_{4,1} - N_{4,1}^{\text{target}}|, \tag{3.2}$$

with $\epsilon = 0.05$ during thermalization and $\epsilon = 0.02$ afterwards. We choose to fix $N_{4,1}$ as opposed to the total four-volume $N_{4,1} + N_{3,2}$ for technical convenience. We have checked that for a given number of $N_{4,1}$ simplices we also obtain a sharply peaked number of $N_{3,2}$ simplices, and hence a well-defined average total four-volume $\langle N_{4,1} + N_{3,2} \rangle$ at each point sampled in phase C of the parameter space (see table 1).

The main results of this work are presented in figure 2 and table 2. We find that the long distance spectral dimension is consistent with the semiclassical dimensionality of 4, and that the spectral dimension smoothly decreases to a value consistent with 3/2 on short distance scales and for sufficiently fine lattice spacings.

Both correlated and uncorrelated fits to the data give similar results, as demonstrated by the fits to the (2.2, 0.6) 160K data in figure 2. However, using the full covariance matrix in the estimation of χ^2 we obtain a relatively large $\chi^2/d.o.f = 1.92$. In the absence of any

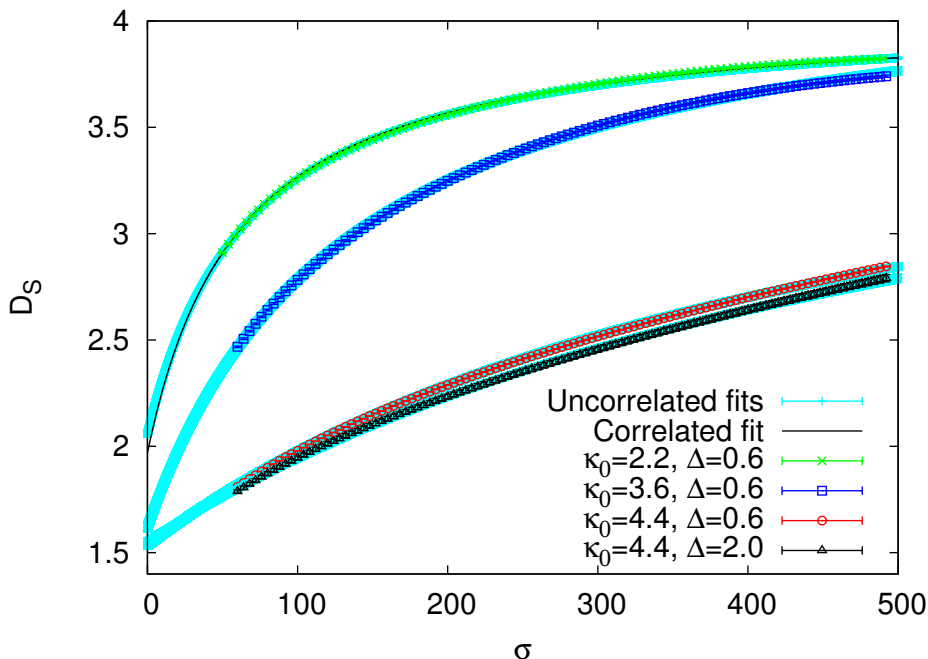

Figure 2. The spectral dimension D_S as a function of the diffusion time σ for four different points in the de Sitter phase of CDT. The $D_S(\sigma)$ curves corresponding to points along the $\Delta = 0.6$ line are calculated using 160,000 $N_{4,1}$ simplices. $D_S(\sigma)$ for $\kappa_0 = 4.4, \Delta = 2.0$ is calculated using 300,000 $N_{4,1}$ simplices. The light blue error bands come from uncorrelated fits to the data using the functional form of eq. (3.1) and using the fit range $\sigma \in [50, 494]$ for the point $\kappa_0 = 2.2, \Delta = 0.6$ and $\sigma \in [60, 492]$ for the other three points. We extrapolate to $\sigma = 0$ and $\sigma \rightarrow \infty$ using the fit function of eq. (3.1). The uncorrelated fit shows only the central value for comparison. Errors presented here are statistical only. Errors in table 2 include the total statistical and systematic error estimate.

(κ_0, Δ)	$N_{4,1}$	$D_S(\infty)$	$D_S(0)$	s.d. of $D_S(0)$ from 2	a_{rel}

Table 2. A table of the long $D_S(\sigma \rightarrow \infty)$ and short distance spectral dimension $D_S(\sigma \rightarrow 0)$ for several different (κ_2, Δ) values. $D_S(\sigma \rightarrow \infty)$ and $D_S(\sigma \rightarrow 0)$ are determined from a fit-function of the form $a - \frac{b}{c+\sigma}$ as first proposed in ref. [2]. The fifth column gives the number of standard deviations (s.d.) of the values of $D_S(\sigma \rightarrow 0)$ from the integer 2. The rescaling factor a_{rel} is determined by the method of best overlap of the rescaled spectral dimension curves.

better theoretical guidance as to the correct functional form of the spectral dimension we use an uncorrelated version of the fit function of eq. (3.1) as our fit ansatz, and attempt to more accurately estimate systematic errors by varying the fit functions and the fit range. We obtain the central values of $D_S(\infty)$ and $D_S(0)$ quoted in table 2 by using the uncorrelated fit function of eq. (3.1) over the data range $\sigma \in [50, 490]$ in steps of 4 for the point (2.2, 0.6) and $\sigma \in [60, 490]$ in steps of 4 for the other three points. The errors quoted in table 2 are determined by varying the fit function and the fit range as discussed above and adding the statistical error in quadrature.

We now return to the holographic argument against the asymptotic safety scenario presented in the introduction. We wish to highlight the fact that eqs. (2.2) and (2.3) agree if, and only if, the spacetime dimension d is equal to $3/2$;⁵ which is precisely the value we find for the small distance spectral dimension of CDT.⁶ The idea that the value of the short distance spectral dimension might resolve the tension between asymptotic safety and holography was first proposed in the context of Euclidean dynamical triangulations [24]. However, a detailed study of the particular region of parameter space considered the best candidate for a semiclassical phase revealed an effective dimension inconsistent with four dimensional semiclassical spacetime on macroscopic scales [25, 26]. A central motivation of the present work was then to measure the small distance spectral dimension using the causal version of dynamical triangulations (CDT); a formulation known to have a semiclassical phase [27].

3.1 Searching for a continuum limit in CDT

In a lattice formulation of an asymptotically safe field theory, the fixed point would appear as a second-order critical point, the approach to which would define a continuum limit. The divergent correlation length characteristic of a second-order phase transition would allow one to take the lattice spacing to zero while keeping observable quantities fixed in physical units. Hence, developing a method to determine the lattice spacing may prove useful when investigating renormalization group flow within the physical de Sitter phase of CDT, and in particular in the search for a fixed point at which $a \rightarrow 0$. Here we outline one such method that could be used to determine the relative lattice spacing via a comparison of the running spectral dimension at different values of the bare parameters.

Moving along the black line in the direction of the arrows in figure 1 the spectral dimension curves flatten out, as shown in figure 2. The implication being that as one increases κ_0 and Δ the lattice spacing a decreases (similar results were reported in ref. [28]), since it takes a greater number of diffusion steps before the same dimension is obtained. One can then rescale the diffusion time σ by a factor a_{rel} for each curve until they overlap, as shown in figure 3. Equation (1.3) seems to suggest the rescaling factor a_{rel} should be proportional to the square of the lattice spacing a , which should be taken into account when

⁵This counter-argument relies on the plausible assumption that the relevant dimension in the holographic scaling argument is also the spectral dimension as suggested by e.g. ref. [23].

⁶In ref. [20] the authors argue that the scaling relation of eq. (2.3) is incorrect for the class of black hole considered, due to the fact that R depends on the energy E of the black hole, whereas to obtain eq. (2.3) R must be treated as a constant. This leads to a modified version of eq. (2.3) of the form $\frac{S}{R^{d-1}} \sim \left(\frac{E}{R^{d-1}}\right)^\nu$, with $\nu_{cft} = \frac{d-1}{d}$ for a conformal field theory, and $\nu_{BH} = \frac{1}{2}$ for a semiclassical black hole. The authors of ref. [20] then point out that $\nu_{BH} = \nu_{CFT}$ when $d = 2$ [20]. This result appears to have some tension with the values we obtain for $D_S(0)$ in this work, at least for some of the points we sampled in phase C of CDT.

Figure 3. Rescaled spectral dimension fits according to the functional form $D_S = a - \frac{b}{c+\sigma/a_{\text{rel}}}$, with a_{rel} chosen such that the curves give the best overlap.

determining the cut-off scale in physical units. The fit curves are used in the comparison rather than the actual data because it is easier to determine the rescaling factor a_{rel} for which the best overlap occurs. The curves are normalized such that the scale factor a_{rel} is set to unity for the $\kappa_0 = 2.2, \Delta = 0.6$ curve.⁷ The factor a_{rel} that each curve must be rescaled by to obtain agreement with the other curves will then be related to the change in lattice spacing. The rescaling factor a_{rel} , as well as the long and short distance spectral dimension, are displayed in table 2 for each (κ_0, Δ) value. Interestingly, going from the point $(\kappa_0 = 2.2, \Delta = 0.6)$ to $(\kappa_0 = 3.6, \Delta = 0.6)$ we find qualitatively similar behaviour to that observed in ref. [27] between the same two points in parameter space, although the exact quantitative agreement strongly depends on the arguments used. If we assume that the change in the rescaling parameter a_{rel} between different points in the parameter space is proportional to the change in the square of the lattice spacing a , as suggested by eq. (1.3), and by using the values of the absolute lattice spacing reported in ref. [27], we are led to the conclusion that simulations for the bare parameters $\kappa_0 = 4.4, \Delta = 0.6$ and $\kappa_0 = 4.4, \Delta = 2.0$ have a lattice spacing already in the sub-Planckian regime.

3.2 Systematic errors

Approximating continuous spacetime with a discrete and finite lattice inevitably introduces systematic errors, the main sources being finite-size effects and discretization errors.

Due to finite computational power it is only ever possible to simulate with finite lattice volumes, however, one can quantify finite-size effects by calculating an observable for several

⁷This is obviously a matter of preference and one is free to make any of the (κ_0, Δ) points the canonical value against which the others are compared.

different lattice volumes and extrapolating to the infinite volume limit. Thus, one can estimate the lattice volume required such that finite-size effects become negligible. Figures 4 and 5 show the spectral dimension as a function of diffusion time for different lattice volumes at three different points in the parameter space. For the point $\kappa_0 = 2.2, \Delta = 0.6$ there exists a statistically significant difference between the spectral dimension curves for the 80K and 160K ensembles for large diffusion times. As mentioned in the introduction this is because when σ becomes much greater than N_4^{2/D_S} finite-size effects begin to dominate, eventually driving D_S to zero. Finite-size effects can be seen to play a significant role for the 80K ensemble at $\kappa_0 = 2.2, \Delta = 0.6$ for σ greater than approximately 350, as evidenced by $D_S(\sigma)$ reaching a maximum and then beginning to decrease. However, this is not true of the 120K and 160K ensembles as the condition $\sigma \gg N_4^{2/D_S}$ is not met for these larger lattice volumes within the σ range presented. Furthermore, as we move to points in the parameter space corresponding to finer lattice spacings, i.e. $\kappa_0 > 2.2$ with fixed $\Delta = 0.6$, the value of D_S is smaller for an equivalent σ value, and thus the condition $\sigma \gg N_4^{2/D_S}$ is only met for much larger σ values.

For the point $\kappa_0 = 4.4, \Delta = 2.0$ the much finer lattice spacing results in a much smaller absolute lattice volume, and so one should be careful to simulate with a large enough volume so as to not underestimate the large distance spectral dimension, as suggested in figure 5. Figure 5 indicates that the value of $D_S(\infty)$ increases quite rapidly when comparing the relatively smaller lattice volumes of 160K, 240K and 270K at this point, but that when comparing the larger 270K and 300K ensembles the $D_S(\sigma)$ curves appear to stop growing, becoming statistically comparable. Figures 4 and 5 suggest that finite-size effects are mostly under control for the largest lattice volumes at each point, as presented in figure 2 and table 2.

Errors associated with using a discrete lattice to approximate continuum physics, discretization errors, can be estimated by using an effective field theory and extrapolating down to the continuum. One estimates discretization errors by performing numerical simulations at successively smaller values of the lattice cut-off a , i.e. taking the limit $a \rightarrow 0$. Hence, discretization errors become increasingly insignificant as one decreases the lattice spacing. Large discretization errors are typically associated with the small scale spectral dimension. For a small number of diffusion steps the behaviour of $D_S(\sigma)$ can be significantly different when considering an even or odd number of diffusion steps. These odd-even oscillations become negligible for $\sigma \sim 50$ for the coarsest lattice, namely $\kappa_0 = 2.2, \Delta = 0.6$, and for $\sigma \sim 60$ for the finer lattices $\kappa_0 = 3.6, 4.4, \Delta = 0.6$ and $\kappa_0 = 4.4, \Delta = 2.0$ as demonstrated in figure 6. To reduce discretization errors we omit values of D_S for which $\sigma \leq 50$ for the coarse lattice, and $\sigma \leq 60$ for the finer lattices, from the fit to the functional form of eq. (3.1).

We obtain a more complete estimation of the systematic error associated with our spectral dimension measurements by varying the range of σ values over which the fit function of eq. (3.1) is applied. Furthermore, due to the absence of any solid theoretical motivation for using the functional form of eq. (3.1) in the fit to our data we also estimate a contribution to the systematic error associated with using the alternative asymptotic functional forms $D_S(\sigma) = a - b \exp(-c\sigma)$ and $D_S(\sigma) = a - (b/(c + \sigma))^d$, where a, b, c and d are unconstrained fit parameters, the values of which are given in tables 3 and 4.

Figure 4. A multi-volume study of the spectral dimension at two different points in the parameter space of CDT. Finite-size effects for the $\kappa_0 = 2.2$ and $\kappa_0 = 4.4$ at $\Delta = 0.6$ ensembles appear to be under control for the larger 160K lattices.

Figure 5. A multi-volume study of the spectral dimension at the point $\kappa_0 = 4.4, \Delta = 2.0$. Since this point in the parameter space corresponds to a very small lattice spacing in Planck units one must use a much larger lattice volume of 270K or 300K so as to not underestimate the large distance spectral dimension due to the much smaller absolute lattice volume for a given number of $N_{4,1}$ simplices.

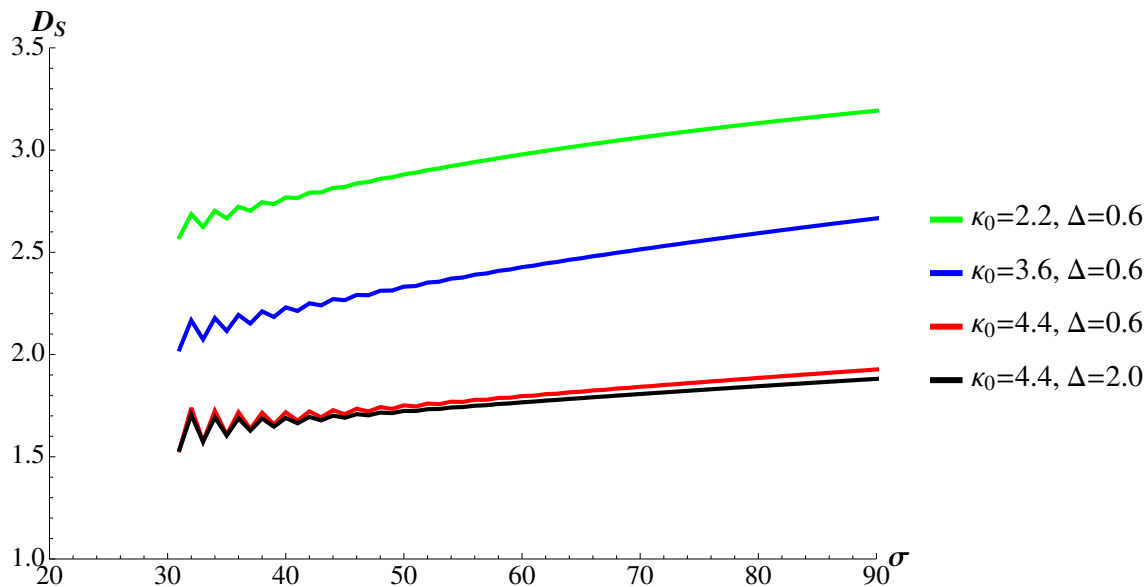

Figure 6. Odd-even oscillations in the small scale spectral dimension for four different values of the parameters κ_0 and Δ . Note the oscillations have a larger amplitude and σ extension for values of the bare parameters that correspond to finer lattices. In the calculation of $D_S(\sigma)$ we omit $\sigma < 50$ values for the coarsest lattice, namely $\kappa_0 = 2.2, \Delta = 0.6$, and omit $\sigma < 60$ values for the finer lattices $\kappa_0 = 3.6, 4.4, \Delta = 0.6$ and $\kappa_0 = 4.4, \Delta = 2.0$.

Fit-function	(2.2, 0.6)				(3.6, 0.6)			
	a	b	c	d	a	b	c	d
$a - b \exp(-c\sigma)$	3.74	1.73	0.013	-	3.74	2.14	0.0078	-
$a - (b/(c + \sigma))^d$	4.20	108.17	21.69	0.62	4.01	479.57	339.14	2.43

Table 3. The fit parameters a, b, c and d for the two alternative fit functions used in estimating the systematic error for the bare parameters (2.2, 0.6) and (3.6, 0.6) with $N_{4,1} = 160,000$.

Fit-function	(4.4, 0.6)				(4.4, 2.0)			
	a	b	c	d	a	b	c	d
$a - b \exp(-c\sigma)$	3.83	2.18	0.0016	-	4.12	2.46	0.0013	-
$a - (b/(c + \sigma))^d$	3.99	1213.56	586.11	1.24	4.00	1337.74	648.10	1.25

Table 4. The fit parameters a, b, c and d for the two alternative fit functions used in estimating the systematic error for the bare parameters (4.4, 0.6) with $N_{4,1} = 160,000$ simplices, and for the bare parameters (4.4, 2.0) with $N_{4,1} = 300,000$.

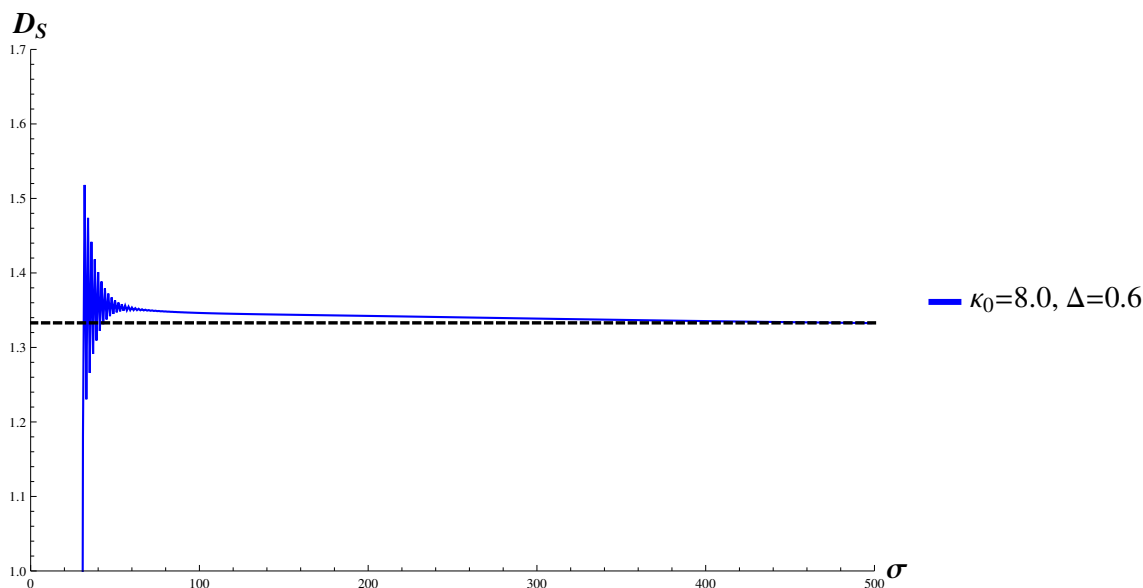

Figure 7. The spectral dimension in phase A of CDT, calculated at the point $\kappa_0 = 8.0, \Delta = 0.6$ using 160,000 $N_{4,1}$ simplices.

3.2.1 Investigating systematic errors in phase A

Using two-dimensional toy models the spectral dimension in the branched polymer phase of Euclidean quantum gravity has been determined from purely analytic considerations [29, 30] to be $4/3$. Although such a result is yet to be established in the full four-dimensional theory the geometric properties in phase A of four-dimensional CDT are largely expected to be analogous to the branched polymer phase of EDT. In this work we numerically determine the spectral dimension in phase A of CDT and find a value consistent with the constant $4/3$ over the σ range studied $\sigma \in [60, 492]$, as can be seen in figure 7. This result suggests that the geometry in phase A of CDT at least shares some universal properties with branched polymer systems. If we assume that the analytical value of $4/3$ found in two-dimensional models [29, 30] is also valid in the full four-dimensional theory then it would be possible to get a sense of how small we can reliably take σ by comparing our numerical results for the spectral dimension in phase A with the constant value $4/3$. Such a comparison also suggests discretization effects are small for $\sigma > 60$ for this lattice volume.

3.3 Statistical errors

If one calculates an observable using a lattice that is not thermalized one will obtain an erroneous result. It is therefore important to check all lattices are thermalized before one begins taking measurements. Once thermalization has been achieved, increasing the number of configurations used in the calculation of the observable will just result in the mean approaching the correct value with an increasingly small statistical error.

For each point in the parameter space we check that the ensemble is thermalized using two methods. Firstly, we begin with a thermalized smaller volume and allow it to evolve

towards a larger target volume. During thermalization, the width of the distribution of $N_{4,1}$ simplices increases very slowly, eventually reaching a plateau. This is the same method of defining thermalization as defined in ref. [15]. Secondly, after the ensemble has reached a configuration that satisfies the above condition we then plot the observable to be measured as a function of Monte Carlo time and check that there is statistical agreement between the first and second half of the data set over which we perform the measurement.

Here we apply a best fit to the spectral dimension data using the functional form of eq. (3.1) and extract values for $D_S(\sigma \rightarrow \infty)$ and $D_S(\sigma \rightarrow 0)$, plotting them as a function of Monte Carlo time. We conclude that a particular ensemble of triangulations is thermalized over a specific σ range if there exists no statistically significant difference between the first and second half of the data range, after passing the first thermalization test. As an example, figures 8a and 8b show the values of $D_S(\infty)$ and $D_S(0)$ for the point $\kappa_0 = 4.4, \Delta = 0.6$ as a function of Monte Carlo time using $N_{4,1} = 160,000$ simplices. For a configuration number greater than $\sim 20,000$ there is no statistical difference in the mean values of $D_S(0)$ and $D_S(\infty)$ when comparing the first and second half of the data set, and we thus conclude this ensemble is thermalized for such a configuration range. All results presented in this work are calculated using thermalized lattices as detailed above. Statistical errors are estimated using a single-elimination jackknife procedure. The total error estimate of our spectral dimension measurements are determined by adding the total systematic and statistical errors in quadrature, and are presented in table 2.

4 Discussion and conclusions

The aim of this work is to make a more detailed study of dimensional reduction previously found in the CDT approach to quantum gravity, in which a dimensional reduction from 4.02 ± 0.1 on large distance scales, to 1.80 ± 0.25 on small distance scales is reported [2]. The small distance spectral dimension is of particular interest, as a more precise determination of this result could have important implications for the renormalizability of gravity. In this work we give a more detailed study of the running spectral dimension by calculating its value at several different values of the bare parameters and for multiple lattice volumes. Our results are summarised in table 2. From these results we conclude that the small distance spectral dimension in the de Sitter phase of CDT is more consistent with $3/2$ than with the integer 2, as previously thought [2]. This is the principal result of this work. We wish to point out that this value of the dimension is precisely the value for which eqs. (2.2) and (2.3) agree, and thus it may resolve the tension between asymptotic safety and holography, as originally proposed in ref. [24].

Our studies indicate that as one increases κ_0 and Δ within the physical phase of CDT the spectral dimension curves flatten out. The implication being that as one moves along such trajectories in the parameter space the lattice spacing a decreases, because for larger values of the bare couplings it takes a greater number of diffusion steps before the same dimension is obtained. One can then rescale the diffusion time by a factor that is related to the relative lattice spacing for each curve until the variance is minimised, i.e. until the curves give “the best overlap”. This method for determining the relative lattice spacing may prove

Figure 8. $D_S(\infty)$ and $D_S(0)$ as a function of Monte Carlo time for the bare parameters $\kappa_0 = 4.4$ and $\Delta = 0.6$. The data range we believe to be thermalized is divided into two data sets that are compared with each other for statistical agreement to within 2 standard deviations. The fit function and fit range used to obtain these results are the same as those used in figure 2, namely eq. (3.1) and $\sigma \in [60, 492]$, respectively.

useful when studying the renormalization group flow in CDT (e.g. ref. [28]), and aid in the search for a putative second order critical point at which one may take a continuum limit.

The most rapid decrease in the rescaling factor a_{rel} appears to result from maximising κ_0 within phase C of the CDT phase diagram (see figure 1), and thus tuning κ_0 to its critical value at the first-order transition dividing phase C and phase A. There also seems to be a significantly weaker dependence of a_{rel} on Δ , with a_{rel} appearing to decrease slightly as Δ increases. Tuning κ_0 to the C-A transition and then studying the effect of varying Δ on a_{rel} would be a natural next step.

The novel value of the short distance spectral dimension of CDT obtained in this work, $D_S(0) \sim 3/2$, differs from the value of $D_S(0) \sim 2$ inferred by previous measurements of the spectral dimension of CDT [2]. We find a tension of ~ 8 standard deviations with the integer value 2 for our finest lattices. Furthermore, the fact that the measurements of $D_S(\sigma)$ presented in this work exhibit a monotonic decrease to a value that is consistent with $3/2$, and that $D_S(0)$ shows no sign of changing even for points in the parameter space that appear to be probing the sub-Planckian regime, suggests that our results, at least at present, have some tension with renormalization group predictions that $D_S(0) = 2$. In light of such suggestive comparisons it may be worth revisiting the renormalization group arguments leading to the result $D_S(\sigma \rightarrow 0) = 2$.

Determining the absolute lattice spacing by measuring fluctuations about de Sitter space, as presented in ref. [27], for all values of the bare couplings investigated in this work would allow one to more thoroughly assess the reliability of using the rescaling of the spectral dimension in determining the change in lattice spacing. Furthermore, determining the absolute lattice spacing via the method presented in ref. [27] for points corresponding to our finest lattices would indicate whether measurements at these values of the bare couplings really are probing the sub-Planckian regime, and possibly give a definitive answer as to whether $D_S(0)$ remains consistent with $3/2$ as one probes the manifold on yet smaller distance scales, or whether it begins to increase to $D_S(0) = 2$ as expected from renormalization group predictions [31, 32]. Due to the current absence of such further investigations a definitive comparison between renormalization group and CDT predictions of the short distance spectral dimension is currently incomplete. However, this work is in progress.

Acknowledgments

D.N.C is especially grateful to J. Laiho for suggestive early discussions on this work. We thank R. Loll for carefully reading a draft version and providing useful comments. We also thank A. Gorlich, J. Gizbert-Studnicki, F. Saueressig, J. Cooperman and J. Mielczarek for useful discussions. D.N.C acknowledges the support of the grant DEC-2012/06/A/ST2/00389 from the National Science Centre Poland.
