

Development of Silk based Bio-polymeric Porous Matrices for Tissue Engineering Applications

A THESIS SUBMITTED

FOR THE AWARD OF THE DEGREE

OF

DOCTOR OF PHILOSOPHY

IN

BIOTECHNOLOGY AND MEDICAL ENGINEERING

BY

MAHESH KUMAR SAH

(ROLL NO. 507BM002)

NATIONAL INSTITUTE OF TECHNOLOGY
ROURKELA - 769008, INDIA

2013

National Institute of Technology, Rourkela

CERTIFICATE

This to certify that the thesis entitled “**Development and Characterization of Silk based Bio-polymeric Porous Matrices for Tissue Engineering Applications**” being submitted by **Mr. Mahesh Kumar Sah** for the award of the degree of Doctor of Philosophy in Biotechnology & Medical Engineering of NIT Rourkela, is a record of bonafide research work carried out by him under my supervision and guidance. Mr. Mahesh Kumar Sah has worked for more than five years on the above problem in the Department of Biotechnology & Medical Engineering, National Institute of Technology Rourkela and his work has reached the standard for fulfilling the requirements and the regulation relating to the degree. The contents of this thesis, in full or part, have not been submitted to any other University or Institution for the award of any degree or diploma.

(Dr. Krishna Pramanik)

Professor & Head
Deptt. of Biotechnology & Medical Engineering,
NIT Rourkela

Place: Rourkela

Date:

Dedicated To

God & My Parents

ACKNOWLEDGEMENTS

At this moment of accomplishment, first of all I pay homage to my guide, Dr. (Mrs.) K. Pramanik. This work would not have been possible without her guidance, support and unflinching encouragement from the very early stage of this research. Under her guidance, I successfully overcame many difficulties and learned a lot. I can't forget her hard times to review my thesis progress, providing valuable suggestions and necessary corrections. Her unflinching courage and conviction will always inspire me, and I hope to continue to work with her noble thoughts. I can only say a proper thanks to her through my future work. I am indebted to her more than she knows.

I gratefully thank Doctoral Research Committee (DSC) members, Prof. Amit Biswas, Prof. Mukesh Gupta, Prof. Subhankar Paul and Prof. Kunal Pal of the department and Prof. Surojit Das from the department of Life Sciences for their constructive comments to improve the quality of this thesis. I am thankful that in the midst of all their activity, they accepted to be members of the committee.

Collective and individual acknowledgments are also owed to research group members, I belong to, Bhism Narayan Singh, Chinmaya Mohapatra, Akalabya Bissoyi, Sadanand Jinna, Rajdeep Kaur, Partha Sarthi Majhi, Nadeem Siddiqui, Varshini Viswanath, Rukmini Roy, Manalee Survey and Supriya Patil whose presence somehow perpetually refreshed, helpful, and memorable. Many thanks go in particular to Prof. Sirsendu Ray, Prof. Indranil Banerjee, Prof. Amitesh Kumar and Prof. B. P. Nayak, for giving me such a pleasant time since I knew them in NIT Rourkela. I forward my special gratitude for Prof. Arvind Kumar from Department of Chemical Engineering who has helped me a lot while my stay in NIT Rourkela

Words fail me to express my appreciation to my special friends whose dedication, love and persistent confidence in me, has taken the load off my shoulder.

Finally, I would like to thank everybody who was important to the successful realization of this thesis, as well as expressing my apology that I could not mention personally one by one. This thesis has been kept on track and been seen through to completion with the support and

encouragement of numerous people including my well wishers, my friends, colleagues and various institutions. At the end of my thesis I would like to thank all those people who made this thesis possible and an unforgettable experience for me. At the end of my thesis, it is a pleasant task to express my thanks to all those who contributed in many ways to the success of this study and made it an unforgettable experience for me.

Mahesh Kumar Sah

ABSTRACT

Development and Characterization of Silk based Bio-polymeric Porous Matrices for Tissue Engineering Applications

Tissue engineering has emerged as a promising approach for the development of artificial body organs, repair, recover or improve tissue structures and functionality. 3D porous scaffolds possessing biomimicking properties are needed to support the neogenesis of tissues and mass transport of cells, nutrients and metabolic waste. Keeping this in view, the present dissertation work was undertaken for the development of SF based scaffolds with improved surface, mechanical and biological properties that can be used as artificial extracellular matrices for tissue regeneration. The silk fibroin was extracted from *B. mori* silk cocoon and the process was optimized by Response surface methodology using Box-Behnken Design. Porous SF and SF/PVA) blend scaffolds were prepared by salt leaching process and characterized for morphological (SEM), structural (XRD and FTIR), thermal (DSC and TGA) and mechanical (compressive strength) behaviour. The SF scaffolds were further modified with soluble eggshell membrane protein (SEP) with the aim of improving cell affinity for tissue regeneration. The pore size of the prepared SEP-SF and SEP-(SF/PVA) scaffold were in the range of 250-350 μ m and porosity of 90-93%. The measured compressive strength of SF and SF/PVA (50:50) scaffold were 279.8 ± 36.2 KPa and 235 ± 67.1 KPa respectively. The existence of soluble eggshell membrane protein on the scaffold surface, structural and thermal stability was confirmed by EDX, XRD, FTIR, DSC and TGA analysis. An increase in compressive strength of the prepared SF scaffolds was achieved by modification with SEP (321.5 ± 42.2 KPa for SEP-SF and 247.5 ± 23.7 KPa for SEP-(SF/PVA) scaffolds). The cell culture study has indicated the significant improvement in cell adhesion and proliferation observed with hMSCs cultured on SF and SF/PVA scaffolds modified with SEP. The cyto-compatibility of the SEP conjugated SF scaffolds was confirmed by *in-vivo* animal model testing. This study has demonstrated that the biomimic property of SF scaffold can be enhanced by surface modification with SEP. Finally, it is concluded that the SEP conjugated SF/PVA (50:50) has the potential for use as artificial extra cellular matrix particularly for soft and other non-load bearing tissue engineering applications.

Key Words: Biopolymer, Silk Fibroin, Tissue Engineering, Eggshell Membrane Protein, Surface Modification, PVA, Biocompatibility

CHAPTER 1

General Introduction

GENERAL INTRODUCTION

1.1. Background

Millions of patients worldwide suffer from tissue or organ failures because of the consequence of trauma, injury, systemic disorders, infection or other conditions that include transplantation, surgical repair and chemotherapy in few cases [Langer and Vacanti, 1993; Vacanti, 2006]. Tissue and organ failure accounts for approximately fifty percentage of total annual expenditure in health care in US [Lanza et al., 1993] and much lesser in India despite of the great need of expenditure that ultimately results in more number of patients death [Deolalikar et al., 2008]. Moreover, the current clinical treatment methods such as autologous or allogenic grafting suffer from several drawbacks including immune-rejection, disease transmission and lack of sufficient donor organs [Fuchs et al., 2001; Lanza et al., 2000; Saltzman et al., 2004]. As a result, none of these techniques can fully recover the structure and function of damaged and/or diseased tissue [Asnaghi et al., 2009]. In recent years, tissue engineering is considered as most promising approach to overcome these limitations through the development of an artificial functional tissue construct. It has been reported that tissue engineering transplant having autologous cells can effectively surmount the limitations of direct transplantation including the graft rejection and disease transmission. Most importantly such approach reduces the requirement of donors [Minas et al., 1999; Dorfman et al., 1998]. However, the main challenges lie in engineering a suitable polymeric matrix, cell with their regenerative potential and delivery of signalling molecules. In this context, the design and fabrication of three dimensional scaffolds from biocompatible and biodegradable materials with tailor properties is an essential component to regulate vital cellular function such as morphogenesis, differentiation, proliferation, adhesion and migration. The material properties of the scaffolds and its structural characteristics are time factors that can affect cellular behaviour and ultimately determine the performance of a tissue engineered construct [Sundelacruz et al., 2009]. It is further evident that a single biomaterial may not possess all the desired properties and hence the development of a suitable polymer blend or composite material with appropriate composition [Cai et al., 2002] is prime requirement.

1.2. General strategies for tissue regeneration

Tissue engineering (TE) applies the principles and methods of interdisciplinary engineering and life sciences to fundamentally understand the tissue structure/function and their replacement. This medical approach offers remedy to existing problems through delivery of stem cells and bioactive molecules onto three dimensional (3D) artificial extracellular matrix [Langer and Vacanti, 1993]. During past two decades, most of the development in guided TE techniques has been based on either cells or matrices only. However, present trend in TE deals with a combination of both in addition to active macromolecules to achieve the target tissue. Thus, TE approaches can be classified on the basis of these three phenomena, either studied individually or in combination [Langer and Vacanti, 1993; Fuchs et al., 2001]:

1.2.1. *Cell and cell based therapies:* Isolated cells are directly injected intravenous or into specific host organ in cell based TE approach. Injected cells in such approach utilize blood stream as source of nutrients and bioactive molecules while the host tissue matrix as cell support system for adherence, recognition and proliferation [Matas et al., 1976]. Pros of injection approach includes the cell specificity that is needed to be supplied, and avoids any kind of surgery complications. This approach has find application in restoring lost organ metabolic function. However, the application in replacement of organ structure/function is limited. The cell based *in vivo* repair can be enhanced by *in vitro* production of specific tissues.

1.2.2. *Inducing tissue regeneration by soluble bioactive factors:* Bioactive signaling molecules such as low-molecular-weight (LMW) drugs, oligonucleotides and proteins (cytokines, chemokines, hormones, growth factors) that are capable of regulating specific cellular metabolism inside host. Such specific cellular response includes cell survival, growth, migration and differentiation of a specific subset of cells by triggering specific activation reaction in metabolic pathway [Chen et al., 2009]. Based on their cellular response, these signaling molecules can find place in overlapping classes of mitogens (stimulating cell division), growth factors (proliferation-inducing) and morphogens (controlling cell differentiation). Precise regulation of bioactivity of such signaling molecules at the damaged site may effectively control regeneration process. ECM (natural/synthetic) contains a wide range of adhesive molecules on interfacial surface to bind and modulate the bioactivity of signaling molecules [Discher et al., 2005; Ramirez et al., 2003].

1.2.3. *Employing artificial support system (scaffold)*: In this approach, cellular or acellular scaffold system consisting of natural or synthetic biomaterial is implanted into the host. In cell culture study it has been found that detached adult cells tend to reform their original structures in different set of micro-environmental conditions [Folkman et al., 1980]. Isolated donor cells also have the potential for morphogenesis but limited when injected as a suspension into the host. This is primarily due to absence of 3D support system immersed in a pool of bioactive molecules that provide *in vivo* microenvironment. In addition, implantation of larger tissue volume faces limited interaction with host environment for nutrients uptake, gas exchange and waste elimination. Such findings have lead to developing artificial tissue construct by attaching cells on scaffold templates.

1.3. Overview of potential Tissue Engineering applications

Tissue engineering aims at regenerating the diseased tissues (and organs as a future perspective) *in vitro* or through a combination of *in vitro* and *in vivo* processes and implanting the product at the diseased site to achieve full functionality. Improved healing processes and a higher quality of life are expected results, probably leading to lower costs of treatment in the long term. It offers the potential of a paradigm shift in medicine: new forms of therapy can be envisioned which allow the repair or regeneration of cells, tissues and organs which have lost their function due to disease, injury or congenital defects. Potential applications of tissue engineering are envisioned in the following fields:

- i. Skin,
- ii. Cartilage,
- iii. Bone,
- iv. Cardiovascular diseases,
- v. Organs,
- vi. Central nervous system,
- vii. Miscellaneous e.g. ligaments, tendon, skeletal muscle etc.

Although tissue engineering research is being carried out in all these fields, only a very few products have already entered the market, and the present state of the art in science and technology does not allow a precise assessment which of these developments will finally yield new therapeutic options and commercially viable products. Therefore, a broad variety of information sources and methods has to be used for potential tissue engineering.

1.4. Tissue Engineering challenges and future prospects

1.4.1. TE Research & Development

The field challenge concerns acquiring a **fundamental understanding of tissue differentiation mechanisms** that might be harnessed for the development of tissue-engineered products. One product that the tissue engineering industry is pursuing is “bone-on-demand,” to be used in cases where new bone formation is needed. One component is the availability of **biomaterials that act as scaffolds** for tissue repair and reconstruction, or for the deposition of engineered tissues and cells preceding implantation. Recent research is directed towards addressing these scaffolds with the goal of creating materials that have the desired functional properties for tissue engineering applications. For example, so-called blended-polymer scaffolds have an extended lifetime in the body that is more suitable for orthopedic applications than non-blended scaffolds [Spain et al., 1998]. Development of new materials of this type that enable different applications of tissue engineering is likely to be the focus of considerable future research. For the biological component of tissue engineering, rapid advances are being made in **identifying new cell types** for use in tissue regeneration. For example, undifferentiated stem cells are attracting intense interest because of their capacity to be transformed into almost any cell type that may be needed.

1.4.2. TE Clinical Barriers

The ultimate goal of tissue engineering is to produce tissues that will function successfully for the lifetime of the recipient. According to Griffith and Naughton [Griffith et al., 2003] specific methods are needed to assess quantitatively the long-term outcome of engineered connective tissues, such as cartilage, tendon and blood vessels. Failure of these engineered tissues may be fatal. To date, tissue engineering has been successful in producing simple vascular tissues, such as skin and cartilage which are sufficiently thin to receive oxygen and other nutrients by passive diffusion [Malda et al., 2003]. Molecular diffusion is only relevant at very small length-scales, and thus found inadequate to support mass transfer in a thick tissues. A major obstacle in tissue engineering is the inability to maintain large masses of living cells upon transfer from the in vitro culture conditions into the host in vivo [Mooney et al., 1999]. In order to achieve complex-engineered tissues and organs, vascularization of the regenerating tissue is essential. Vasculature and in particular capillaries, are required to supply essential nutrients to the cells, supplying oxygen, removing waste and providing a biochemical communication “highway” [Koet al.,

2007; Cassell et al., 2002; Eiselt et al., 1998; Nerem et al., 1998; Nguyen et al., 2001a; Nguyen et al., 2001b]. All tissues and organs (with the exception of a minority of tissues such as cartilage) need to be vascularized to be able to survive.

1.4.3. Industrial Challenges

Quality control of the materials used in various surgical applications is a key challenge for the tissue engineering industry. For example, living human cells are being used in scaffolds to repair structural tissue damage. These materials need to be produced and cultured under good manufacturing practice (GMP) conditions to meet FDA standards especially the cells that are grown *ex vivo*. As a result, the tissue engineering industry is striving to create appropriate quality control standards and evaluate them.

1.4.4. Future Prospective of Tissue Engineering

With the advancement of the concept of “regenerative medicine” and in particular the field of tissue engineering a completely new form of medical treatment can be envisaged with the potential to change medical practice profoundly. Tissue engineering is emerging as a vibrant industry with a huge potential market. The biomaterials, scaffolds, artificial organs, and differentiating cells that are combined to create a tissue engineering product address significant medical needs, such as major tissue and organ damage or failure. The industry still faces numerous technical challenges including the establishment of a consensus quality control program that ensure the functionality and safety of tissue engineering products. Efforts to address these issues are underway, and if past success is any indication, this technology is certainly one that will have major impact in future health care practice.

Tissue engineering has significant market potential and financial investment continues apace. The positive results regarding specific products and processes in clinical settings will support the R&D scenario of field. Technical advances in the various components of the industry will contribute to market growth. In future, efforts will likely increasingly focus on the development of tissue-engineered products under consensus safety and efficacy standards, including potential source of cells and tissues, characterization and testing of materials, quality assurance and control, preclinical and clinical evaluation [Omstead et al., 1998]. The FDA has already provided some regulatory guidance concerning specific materials, such as certain marketed artificial skin products; in the next few years, these guidelines will likely be increasingly formalized and

structured, ensuring that tissue engineering products not only work but are also safe. Significant future developments will include the continued development of artificial organs that use cells embedded into appropriate support structures. The range of human tissue that can be engineered will also increase dramatically in the future, so in addition to the traditional targets, such as skin and liver, other tissues and organs will see their day. A great deal of excitement in clinical circles is that of developing artificial human thyroid tissues which are capable of producing T cells, and this will be a major area for continued R&D [Martin et al.,2000]. Finally, stem cells and their manipulation for therapeutic purposes will continue to be a major area of development, because of the pluripotency of these cells.

1.5. Silk as Ideal Biopolymer for Tissue Engineering

In general, silks are defined as protein polymers that are produced by *Lepidoptera* larvae undergoing complete metamorphosis or adult forms eg. silkworms, spiders, scorpions, mites and flies [Altman et al., 2003] which differ at the molecular level. Silk has been of interest since its discovery in china in around 5000 years back and is being manufactured through sericulture across Asia and Europe. India is the second largest producer and largest consumer in the world [Giridhar et al., 2010]. The commercial interest of silk is not only for its textile properties such as texture, tenacity and dyeing but also for its application in cosmetic products and pharmaceuticals [Brooks et al., 1989]. The wide application of silk as biomedical sutures over decades have shown path to their utilization as bio-polymeric scaffolds in tissue engineering. Besides the biocompatibility with host tissue, the mechanical strength of a biomaterial plays important role in scaffold designing [Li et al., 2002; Ko et al., 1998; Ko et al., 1999]. The viscoelastic nature of biological tissues confines the application of synthetic polymers since it has been observed that increase in strength compromises with toughness of synthetic polymers. Silk finds the ideal candidature for biomedical applications because of combined strength and toughness, primarily due to its antiparallel β pleated molecular structure. Among varieties of silk sources, those from silkworm silk (*Bombyx mori*) and spider silk (*Nephila clavipes*) are most extensively used for various applications. While the availability of *Bombyx mori* silk is abundant due to farming, the practice is almost impossible with *Nephila clavipes* because of their predatory nature. The progress in biotechnology have made possible to produce recombinant type spidroin in a variety of host organisms. This chapter deals with the silk protein from most common silkworm species, *Bombyx mori* and its application in bio-scaffold development for tissue regeneration.

1.5.1. Structure and composition

Silkworm silk is commonly produced from the cocoons of domestic moths, *Bombyx mori*. Silk fibers are 10-25 μm in diameter. Each fiber consists of core protein covered by a coating of hydrophilic proteins called sericins (20–310 kDa) that glues core fibers together [Sinohara et al., 1979; Kaplan et al., 1998; Zhou et al., 2000; Inoue et al., 2000]. The fibers are not circular in cross section but appear triangular as shown in Figure 1.1. Twenty-five to thirty percent of the silk cocoon mass is sericin, which is removed during the de-gumming process. The core protein consists of three chains: heavy chain (~390 kDa), light chain (~26 kDa) and a glycoprotein, P25 (25 kDa) [Inoue et al., 2000]. The disulfide linkage between the Cys-c20 (twentieth residue from the carboxyl terminus) of the heavy chain and Cys-172 of the light chain holds the fibroin together and a 25 kDa glycoprotein, named P25, is non-covalently linked to these proteins [Tanaka et al., 1999]. Light chain is necessary for the secretion of protein from the silk glands. P25 is connected to both heavy and light chains by noncovalent interactions. P25 is necessary for the assembly of heavy and light chains [Inoue et al., 2000]. Heavy chain is fiber forming protein and its structure determines properties of silk fiber. Heavy chain is commonly referred as fibroin protein. Electrophoretic analyses of silk cocoons have revealed the presence of several minor proteins of unknown function. These low molecular weight proteins are classified as non-structural silk proteins [Kodrik et al., 1992].

- The gene for the fibroin protein (*H-fib* gene) is located on 25th chromosome of *Bombyx mori* silkworm and consists of two exons and one intron [Zhou et al., 2000, Zhou et al., 2001]. A number of silk polymorphs have been reported, including the glandular state prior to crystallization (silk I), the spun silk state which consists of the β -sheet secondary structure (silk II), and an air/water assembled interfacial silk (silk III, with a helical structure) [Kaplan et al., 1998; Jin et al., 2003; Motta et al., 2002]. The silk I structure is the water-soluble state and upon exposure to heat or physical spinning easily converts to a silk II structure. The silk fibroin obtained from silkworm cocoon exists in silk II structure consisting of 5263 residues with molecular weight of 39.1kDa. The primary structure of heavy chain consists of 12 repetitive regions called crystalline regions and 11 non-repetitive interspaced regions called amorphous regions [Zhou et al., 2001].

- The crystalline regions make up 94% of the sequence and each repetitive region in an average 413 residues in length and consist of Gly-X repeats (X=Ala/ Ser/Thr/Val) [Zhou et al., 2001] forming hexapeptides sub-domain including: GAGAGS, GAGAGY, GAGAGA and GAGYGA as shown in table 1.1. These sub domains end with tetrapeptides such as GAAS or GAGS [Zhou et al., 2000; Zhou et al., 2001; Gage et al., 1980]. The repeat GAGAGS is the most frequently (70%) occurring hexapeptide repeat sequence. The crystalline repetitive region is responsible for the secondary structure (antiparallel β -pleated sheets) of the protein. Each crystal is on an average made up of 4 individual β strands each 11 amino acids long. The β strands are connected to one another by β turn made up of GAAS amino acids. The full form of abbreviations used for amino acids is given in **appendix A**.
- The β -sheet structures are asymmetrical with one side occupied with hydrogen side chains from glycine and the other occupied with the methyl side chains from the alanines that populate the hydrophobic domains. The β -sheets are arranged in such a way that the methyl groups and hydrogen groups of opposing sheets interact to form the inter-sheet stacking in the crystals. Strong hydrogen bonds and van der Waals forces generate a structure that is thermodynamically stable [Kaplan et al., 1998]. The inter and intra-chain hydrogen bonds form between amino acids perpendicular to the axis of the chains and the fiber [Kaplan et al., 1998].

Table 1.1: Amino acid content of *B. mori* silk fibroin [Kaplan et al., 1998; Gandhi M.R., 2007]

AAs content		Hexapeptide repeats content	
Gly	45.9%	GAGAGS	70%
Ala	30.3%	GAGAGY	20%
Ser	12.1%	GAGYGA	6%
Tyr	5.3%	GAGAGA	4%
Val	1.8%		
Other AAs	4.7%		

- The amorphous regions consist of 42-43 residues and are linkers between repetitive domains [Zhou et al., 2001]. The less crystalline forming regions of the fibroin heavy chain, also known as linkers, are between 42–44 amino acid residues in length. All the linkers have an

identical 25 amino acid residue (non-repetitive sequence) which is composed of charged amino acids not found in the crystalline regions [Zhou et al., 2001]. The primary sequence results in a hydrophobic protein with a natural co-block polymer design.

1.5.2. Bio-relevant Properties

1.5.2.1. Physical properties

- Silk fibres from the *Bombyx mori* silkworm have a triangular cross section with rounded corners, 5-10 μm wide. The fibroin-heavy chain is composed mostly of beta-sheets, due to a 59 aminoacid repeat sequence with some variations [Lewin et al., 2006]. The flat surfaces of the fibrils reflect light at many angles, giving silk a natural shine. Silkworm fibres are naturally extruded from two silkworm glands as a pair of primary filaments (brin), which are stuck together, with sericin proteins that act like glue, to form a bave (Fig 1.1A. SEM photographs).
- Silk has a smooth, soft texture that is not slippery, unlike many synthetic fibers.
- Silk is one of the strongest natural fibres but loses up to 20% of its strength when wet. It has a good moisture regain of 11%. Its elasticity is moderate to poor if elongated even a small amount, it remains stretched.
- Silk is a poor conductor of electricity and thus susceptible to static cling.
- Natural and synthetic silk is known to manifest piezoelectric properties in proteins, probably due to its molecular structure [Fukada et al., 1983].
- An important feature of silk as a biomaterial, compared with other fibrous proteins such as collagen, is the versatility of options for **sterilization** [Sugihara et al., 2000]. Sterilization of silk fibroin scaffolds by autoclaving does not change morphology [Meinel et al., 2004a] or β -sheet structure when heated to 120°C [Furuzono et al., 2004]. Comparatively, collagen denatures at these temperatures [McClain et al., 1972]. Silk fibroin scaffolds can also be sterilized using ethylene oxide [Altman et al., 2003], γ -radiation, or 70% ethanol [Karageorgiou et al., 2004; Li et al., 2006].

1.5.2.2. Chemical properties

- The high proportion (50%) of glycine, which is a small amino acid, allows tight packing and the fibers are strong and resistant to breaking. The tensile strength is due to the existence of

many inter seeded hydrogen bonds that works when fibres are stretched, resisting breakage due to the applied force.

- Silk is resistant to most mineral acids, except sulfuric acid. Silk becomes yellow in colour by perspiration.
- The silk I structure is observed in vitro in aqueous conditions and converts to a β -sheet structure when exposed to methanol or potassium chloride [Huemmerich et al., 2006].
- The silk II structure excludes water and is insoluble in several solvents including mild acid and alkaline conditions, and several chaotropes. Silk is insoluble in most solvents, including water, dilute acid or dilute alkaline solutions.

1.5.2.3. Mechanical Properties

The properties of silk are due to the extensive hydrogen bonding, hydrophobic nature of protein, and significant crystallinity. The elastic modulus of *Bombyx mori* silk is 15-17 GPa and has a tensile strength of 610-690 MPa [Altman et al., 2003]. While spider silk has strength as high as 1.75 GPa with a breaking elongation of over 26%. The geometry and mechanical properties are important design criteria for Tissue engineering scaffolds. The study conducted by Altman G.H. et al [Altman et al., 2003] is summarized in table 1.2. It indicates that the tensile strength of silk is much higher than polylactic acid (PLA) which is most commonly used biomaterial. PLA has the tensile strength of 28-50 MPa. In tissue engineering, scaffolds provide initial framework for the cells to grow and attach. The strength should be high enough to withstand initial loading conditions. Tendon and bone has the tensile strength of 150 and 160 MPa respectively. PLA with the low tensile strength is not able to provide strong support for the tendon or bone cells to proliferate. Cross linked collagen with the tensile strength of 47-72 MPa is also not strong enough. Silk which is much stronger than PLA and cross linked collagen, will provide enough support.

Figure 1.1: (A) SEM image showing cross section of *Bombyx mori* silk fiber (B) structure of silk fibre and (C, D) the schematic of structure of *Bombyx mori* silk fibroin protein. The primary structure consists of 12 repetitive regions interspaced by 11 non-repetitive regions. The repetitive region is responsible for the formation of β -sheets crystals while the non-repetitive region forms the amorphous part of the protein.

Table 1.2: Comparison of mechanical property of *B. mori* silk fiber with other biomaterial fibers and tissues [Gosline et al., 1999; Cunniff et al., 1994]

Fibre	UTS (MPa)	Elastic Modulus(GPa)	% Strain at break
B. mori silk	740	10	20
Spider silk	875-972	11-13	17-18
Tendon (comprised of mainly collagen)	150	1.5	12
Bone	160	20	3
Kevlar 49 fiber	3600	130	2.7
Synthetic Rubber	50	0.001	850

1.5.2.4. Biological Properties

Apart from the geometry and mechanical properties; biocompatibility and biodegradation are important considerations for the fabrication of scaffolds. Silk materials are of considerable interest due to their structural properties and superior biocompatibility.

1.5.2.4.1. Biocompatibility

There were several concerns regarding the biocompatibility of silk from *Bombyx mori*. Sutures made from virgin silk compared with sutures from de-gummed silk showed differences in hypersensitivity [Altman et al., 2003]. The inflammatory response of de-gummed silk fibroin *in vitro* compared with polystyrene and poly(2-hydroxyethyl methacrylate) showed less adhesion of immuno-competent cells [Santin et al., 1999]. Virgin silk (fibroin containing sericin gum) is potential allergen but degummed silk in which sericin is removed is biocompatible. Sericin, a glue-like protein that holds the fibroin fibres together, has been identified as the source of immunogenic reactions [Soong et al., 1984, Panilaitis et al., 2003]. Numerous *in vitro* studies have demonstrated that once sericin is extracted, fibroin supports cell attachment and proliferation for a variety of cell types [Gupta et al., 2007; Roh et al., 2006; Servoli et al., 2005; Minoura et al., 1995; Jin et al., 2004; Inouye et al., 1998]. *In vitro* evaluation of degummed fibroin demonstrates that the interactions of fibroin with the humoral components of the inflammatory system are comparable with those of polystyrene and poly (2-hydroxyethyl methacrylate), the two materials used extensively for biomedical applications [Santin et al., 1999]. Silk films implanted *in vivo* induced a lower inflammatory response than collagen films and PLA films [Meinel et al., 2005]. Silk fibroin non-woven mats implanted subcutaneously in

rats induced a weak foreign body response and no occurrence of fibrosis. There was little upregulation of inflammatory pathways at the implantation site and no invasion by lymphocytes after six months *in vivo* [Dal et al., 2005].

1.5.2.4.2. Biodegradation

The degradation of biomaterials is important in terms of restoring whole tissue structure and function *in vivo*. Control over the rate of degradation is an important feature of functional tissue design, such that the rate of scaffold degradation matches the rate of tissue growth [Lanza et al., 2000]. Silk fibroin fibers retain more than 50% of their mechanical properties after two months of implantation *in vivo*; thus, they are defined as a non-degradable biomaterial by the United States Pharmacopeia [Horan et al., 2005]. Natural polymers like collagen and silks degrade via the action of proteases. The rate of silk fibroin degradation depends upon the structure, morphology, mechanical and biological conditions at the location of implantation. Degradation studies involving the systematic exposure of silkworm silk to enzymes have found that silk will degrade as a result of proteolysis [Taddei et al., 2006], with protease being reported to have the greatest effect [Arai et al., 2004; Horan et al., 2005; Li et al., 2003]. A correlation between *in vitro* and *in vivo* rates of degradation of silk fibroin fibers has also been established [Horan et al., unpublished]. Arai *et al.* [Arai et al., 2004] compared degradation of silk fibers with silk films when exposed to different amounts and types of enzymes. Silk fibroin porous sponges from regenerated *B. mori* fibers degraded differently with different processing conditions [Kim et al., 2005c]. Silk fibroin degradation could be regulated by changing crystallinity [Minoura et al., 1990a], pore size, porosity, and molecular weight distribution (MWD) of the silk fibroin. A change in MWD can be achieved by treating silk fibroin under alkaline conditions and heat. A decrease in MWD may disrupt ordered structures and reduce cross-links, potentially resulting in faster degradation. It will be useful to understand the mechanism and correlation of silk fibroin degradation with mechanical properties. The degradation of silk fibroin material also depends on the processing method for biomaterial development. The degumming process may cause unwanted degradation of fibroin [Jiang et al., 2006] while methanol treatment may significantly reduce the rate of degradation [Minoura et al., 1990b; Uebersax et al., 2006]. Fibroin films are reported to experience more significant degradation than fibres [Arai et al., 2004] and aqueous-derived silk fibroin scaffolds degrade more rapidly than hexa-fluoro isopropanol (HFIP) derived scaffolds [Kim et al., 2005c], possibly due to increased surface area. The potential to

manipulate the rate of degradation is important for tissue engineering applications, and control over the physical form and post-treatment of a silk biomaterial may allow tailoring of the degradation. In the case of bone, for example, the ability of a scaffold to maintain structural integrity over an extended period of time is crucial as it allows mass transport of nutrients and waste products while bone ingrowth, matrix deposition and remodelling occurs and a vascular network is formed. In other situations, such as wound healing, more rapid degradation may be desirable. Silkworm silks have similar structural characteristics to amyloid [Li et al., 2001] and dissolved fibroin has been reported to accelerate amyloid accumulation in mice [Lundmark et al., 2005]. The presence of amyloids in the body has been linked with neuro-degenerative diseases including Alzheimer's and Parkinson's.

1.5.3. Control of morphology of silk biomaterials

Several different material morphologies can be formed from aqueous or solvent formulations of the natural fiber form of silk for utilization as biomaterials in biomedical applications. The fibers must first be dissolved in aqueous systems, followed by reprocessing into desired material formats. The processibility of silk into a number of forms provides flexibility in their application for different kinds of tissue engineering. The commonly applied forms of native silk may be classified as below:

1.5.3.1. Silk fibers—Silk fibers can be obtained by reeling from silkworm cocoons [Kaplan et al., 1998]. Sutures braided from silk fibers have been used for centuries in gummed (virgin) and de-gummed (black braided silk) forms as sutures for surgical options [Altman et al., 2003]. A thorough review of the utilization of virgin and black braided silk (coated with silicone or wax to prevent fraying) and associated immune responses has been previously described [Altman et al., 2003]. Silk sutures have been used for tendon tissue engineering [Kardestuncer et al., 2006]. Sutures modified with immobilized Arg-Gly-Asp (RGD) peptide to increase cell attachment, were cultured with human tenocytes and supported increased adhesion after 3 days when compared with unmodified silk fiber and tissue cultured plastic [Kardestuncer et al., 2006]. An increase in collagen type I and decorin transcript levels was observed on the RGD-modified sutures compared with unmodified silk and tissue culture plastic at six weeks [Kardestuncer et al., 2006].

1.5.3.2. Non-woven silk fibroin mats—Non-woven mats are of interest due to the increased surface area and rougher topography for cell attachment. Silk fibroin has been used to generate non-woven silk mats from reprocessed native silk fibers or by electrospinning. Electrospun fibers can be produced in a wide range of diameters, ranging from a few nanometers to a few microns depending on the mode of processing [Reneker et al., 1996]. Electrospinning of aqueous silk fibroin solution mixed with poly(ethylene oxide) (PEO) was established and fiber morphology based on scanning electron microscopy (SEM) analysis showed uniform fibers less than 0.8 μm in diameter [Jin et al., 2002]. hMSCs cultured on these mats showed attachment and spreading [Jin et al., 2004]. Silk fibroin mats prepared from formic acid with fiber diameters averaging 100 nm showed a Young's modulus of 515 MPa, ultimate tensile strength (UTS) of 7.25 MPa and strain of 3% [Ayutsede et al., 2005]. Electrospun non-woven meshes can be prepared as predominately random coil structure from which β -sheet structures can be formed via methanol treatment [Min et al., 2004].

1.5.3.3. Silk fibroin films—Silk fibroin films have been cast from aqueous or organic solvent systems, as well as after blending with other polymers. Silk films prepared from aqueous silk fibroin solution had oxygen and water vapor permeability dependent on the content of silk I and silk II structures [Minoura et al., 1990a, 1990b]. Alteration of silk structure was induced by treatment with 50% methanol for varying times. Changes in silk structure resulted in differing mechanical and degradability properties of the films [Minoura et al., 1990b]. Nanoscale silk fibroin films can also be formed from aqueous solution using a layer-by-layer technique [Wang et al., 2005]. These ultrathin films were stable due to hydrophobic interactions and predictable film thickness could be obtained based on control of solution conditions.

1.5.3.4. Silk fibroin hydrogels—Hydrogels are three-dimensional polymer networks which are physically durable to swelling in aqueous solutions but do not dissolve in these solutions. Hydrogel biomaterials provide important options for the delivery of cells and cytokines. Silk fibroin hydrogels have been prepared from aqueous silk fibroin solution and are formed from β -sheet structures [Kim et al., 2004; Ayub et al., 1993]. An increase in silk fibroin concentration, increase in temperature, decrease in pH, and an increase in Ca^{++} concentration decreased the time of silk fibroin gelation. Hydrogel pore size was controllable based on silk fibroin concentration and temperature [Kim et al., 2004].

1.5.3.5. Silk fibroin porous sponges—Porous sponge scaffolds are important for tissue engineering applications for cell attachment, proliferation, and migration, as well as for nutrient and waste transport. Regenerated silk fibroin solutions, both aqueous and solvent, have been utilized in the preparation of porous sponges. Sponges have been formed using porogens, gas foaming, and lyophilization [Nazarov et al., 2004]. Solvent-based sponges were prepared using salt or sugar as porogen. Solvents like 1,1,1,3,3,3-hexafluoroisopropanol (HFIP) do not solubilize salt or sugar; so pores sizes in the sponges reflect the size of the porogen used in the process [Nazarov et al., 2004].

1.6. Scope and Objective

It is fact that there is urgent need of alternative treatment for tissue diseases, tissue injuries and organ failure because of having several limitations associated with the current clinical methods including insufficient tissue regeneration because of poor cell retention and survival, immunorejection, significant donor site morbidity leading to loss of functional tissue. In this situation, recently, tissue engineering has been emerged as an attractive alternative technique for the clinical treatment of damaged and/or diseased tissue through the generation of functional tissue. In this context, the design and fabrication of a suitable three dimensional (3D) artificial extra cellular matrix from biocompatible and biodegradable materials with tailor properties is the main challenge. Among the various polymeric biomaterials, silk fibroin obtained from silk cocoon has been reported to be a potential candidate for the tissue engineering application. It is ultimately demonstrated that a combination of different polymers and/or their composites with other bioactive substances are essential to meet the desired properties of the scaffold for clinical tissue engineering application. In this strategy, in the present work 3-D matrices with desired surface, structural and biological properties will be fabricated from silk fibroin protein and PVA polymers by applying salt leaching method.

The objectives of the thesis work are:

- i. Optimization of process conditions for extraction of silk fibroin from *B. mori* silk cocoon
- ii. To prepare silk fibroin based porous scaffold by salt leaching method
- iii. To modify the surface properties of scaffold for enhanced cell adhesion and proliferation
- iv. To characterize the prepared scaffolds
- v. To study the biocompatibility of scaffolds by *in vitro* cell culture and *in vivo* animal model

1.7. Thesis Outline

The whole thesis work has been organized in 5 chapters as follows: **Chapter 1-** includes the introduction and significance of the research work, **Chapter 2-** presents the literature review including concepts and fundamental understanding of recent advancement in silk based tissue engineering and possible improvement in potency of current implantable silk fibroin biopolymers in tissue repair. It has also been discussed, the need and possible ways to improve their bio-relevant properties of SF scaffold to make it more effective to be used as tissue engineering scaffold materials, **Chapter 3-**presents the materials and methods employed for the preparation of silk fibroin matrices and their physical, chemical and biological characterisation, **Chapter 4-** deals with the results and discussion of experimental work which is subdivided into the following parts: **Part I** reports the optimization of process conditions to regenerate native silk into silk fibroin solution and its characterization. The objective of **Part II** is to examine the processability of concentrated aqueous silk fibroin solutions into highly porous gel sponges and study of their various properties for possible tissue engineering applications. **Part III** deals with the development and characterization of salt leached silk fibroin scaffolds and their comparative study after cross-linking with eggshell membrane (ESM) protein. **Part IV** demonstrates the green process for the fabrication of SF/PVA scaffolds of various pore sizes and their modification with SEP with an aim to study their bio-relevant properties, **Chapter 5-** includes a brief summary and conclusion of the thesis work along with suggested future study.

CHAPTER 2

Literature Review

LITERATURE REVIEW

2.1. Biomaterials for scaffold development

According to the European Society for Biomaterials (ESB), the definition of ‘Biomaterial’ is material intended to interface with biological systems to evaluate, treat, augment or replace any tissue, organ or function of the body [Williams et al., 1999]. In general, a biomaterial is a non-living substance used as a medical device that is designed to regulate the cellular behavior in biological microenvironment [Davis et al., 2005]. Biomaterial-based 3D porous systems present an ideal substrate for cell–cell and cell–material communications both in culture and inside the body, and their properties can be modified to induce differentiation of cells into specific lineages [Sundelacruz et al., 2009]. In recent years, wide range of natural and synthetic biomaterials have been developed and designed for this purpose. Typically, three main classes of biomaterials, such as ceramics, synthetic polymers and natural polymers, are used for scaffolds fabrication in tissue engineering.

2.1.1. Natural polymers

The use of natural polymers as scaffold materials is most promising for tissue engineering and other biomedical applications because of their excellent biocompatibility and biodegradability. In the last decade natural materials, such as collagen, silk fibroin, various proteoglycans, alginate based substrates and chitosan, have drawn much attention in the field of tissue engineering [Pati et al., 2013; Bhat et.al. 2013; Liu et al., 2010; Gomathi et al., 2003]. The scaffolds made up of natural polymers are biologically active and promote cell proliferation and adhesion. In addition, they are biodegradable and replaced by biological ECM over time. However, such scaffolds face challenges being homogenous, reproducibility of structure and load bearing strength for orthopedic applications. Therefore, it is reported that these polymers must be further modified with improved form [Das et al., 2012] and property that is desirable for tissue engineering applications [Jayasinghe et al., 2010]. Polymers from natural sources such as proteins, polysaccharides and polyesters are considered to be potential candidates for scaffold preparation.

2.1.1.1. Protein-derived polymers

The most important protein derived polymers used for scaffold preparation are collagen and silk fibroin proteins. Type I Collagen is the most abundant and widely investigated for tissue

engineering applications [Hayashi, 1994]. Heat treatments and/or chemical glycation procedures are used to fabricate matrices with adequate mechanical properties. Collagen microsponges into synthetic polymeric scaffolds increase their mechanical performance [Chen et al., 2004]. Collagen-based scaffolds, combined with active agents like growth factors have more therapeutic influence on tissue engineering approaches [Wallace and Rosenblatt, 2003]. Another important polymer is silk protein that has robust mechanical properties due to presence of highly repetitive primary sequence of simple amino acids leading to formation of β -sheets. Research have shown the utilisation of silk fibroin in tissue engineering applications, particularly where high mechanical strength and slow biodegradation is required [Altman et al., 2003]. Experimental studies of MSCs seeded highly porous silk scaffolds for in vitro cartilage [Wang et al., 2005] and bone [Kim et al., 2005] regeneration have shown promising results.

2.1.1.2. Polysaccharides

Polysaccharides have wide applications in tissue engineering particularly for the enhancement of desired mechanical properties. These biopolymers can broadly be divided into four major groups according to the sources from which these are obtained. The polysaccharides are subdivided, based on their chemical structure. Starch and cellulose are the most important plant saccharides having tissue engineering application particularly for bone regeneration [Wan et al., 2006; Salgado et al., 2002]. The cohesive and hydrogen-bonded structure of cellulose fibres makes it exceptionally water insoluble with great strength exhibiting poor degradation in vivo. Alginate, an algal polysaccharide has potential to combine with calcium [Percival and McDowell, 1990] and this property is reported to have mineralisation effect in orthopaedic tissue engineering. Chitin and its derivative chitosan obtained from animal exoskeleton have been studied for bone regeneration and have been found with excellent biodegradability and cell-adhesive property [Venkatesan and Kim, 2010]. Hyaluronic acid, an important GAG component has been used for finishing the scaffold surface for improving its biocompatibility [Mao et al., 2003]. Non-toxicity of Pullulan and unique rheological properties of xantan gum from microbial culture also finds application in vivo. Bacterial cellulose (BC) has high water- holding capacity, crystallinity, biocompatibility and shows high tensile strength in wet state [Mano et al., 2007].

2.1.1.3. Naturally derived polyesters

Polyhydroxyalkanoates (PHAs) obtained from micro-organisms are thermoplastic polyesters with good biodegradability and biocompatibility. Among various PHAs, PH (Butyrate) and PH (Butyrate- co-Valerate) are commonly used for tissue engineering applications. More flexible, less crystalline and easy to process scaffold materials can be produced by copolymerization of pure PHB. These materials can be used as support material for tissue engineering application [Masaeli et al., 2013].

2.1.2. Synthetic Polymers

Various synthetic polymers have been employed for scaffolds development including poly-L-lactic acid (PLLA), polyglycolic acid (PGA) and their copolymer poly-DL-lactic-co-glycolic acid (PLGA). These materials have been much successful towards cartilage, bone, skin, bladder, and liver TE since their architecture and degradation can be well controlled by varying individual polymer composition [Lu et al., 2000; Oh et al., 2003; Rowlands et al., 2007]. However, limitations of these polymers include the risk of implant rejection due to less bioactivity and the degradation byproduct (CO₂ gas) that lowers the local pH finally responsible for cell and tissue necrosis [Liu et al., 2006].

2.1.3. Ceramics

Ceramic scaffolds, such as hydroxyapatite (HA) and tri-calcium phosphate (TCP) can be used for bone regeneration and generally not used for soft tissue regeneration. Such scaffolds are characterized by high mechanical strength, low elasticity, and a hard brittle surface. In bone tissue engineering, they exhibit chemical and structural similarity to the mineral phase of native bone and enhance osteoblast differentiation and proliferation [Hench et al., 1998; Ambrosio et al., 2001]. The application of ceramics is common in dental and orthopedic surgery for filling and coating implant surface of host bone. However, due to their brittleness and difficulty in remodeling check their clinical application of scaffold based bone regeneration [Wang et al., 2003]. In addition, with ceramic scaffolds, difficulty has been reported to control their biodegradation rate [Tancred et al., 1998].

2.1.4. Polymer/Polymer blend and Polymer/Ceramic Composite

Each of the individual biomaterial groups mentioned above has some pros and cons, so the development of composite scaffolds comprising a number of phases is becoming increasingly important. For example, different research groups have attempted to integrate ceramics into polymeric scaffolds [Kim et al., 2006; Huang et al., 2008] while many others have combined natural polymers with other natural [Cai et al., 2002] or synthetic polymers [Wu et al., 2007] in order to improve their biological activity. Composite or blend materials, combining natural and synthetic polymers, have been developed to combine the desired characteristics of both polymer to overcome the drawbacks of organic material classes. Such scaffolds show some promise towards successful implantation, at least one phase cause problem associated with biocompatibility, biodegradability or both. Most of the biomaterials in scaffolds can be improved by modifying their surfaces chemically or physically, and a variety of such surface modified scaffolds have been used for investigating cells behaviour [Mano et al., 2007]. Modification of biomaterials and understanding of cell behavior have made it clinically possible to replace or reconstruct damaged host cells and tissues [Beckstead et al., 2006]. Development of cell-material microarrays has allowed rapid testing of biomaterial interactions with cells [Peters et al., 2009]. Considerable research work has been done to develop, design and demonstrate the increasing advantages of polymer based cell system in tissue regeneration [Chen et al., 2004; Chen et al. 2002]. As far as there is advancement in biomaterial research, new biomaterials and novelty in their usage will continue to emerge.

2.2. Scaffold Fabrication Methods

A variety of well-known fabrication techniques are used in scaffold design for TE applications. A well-designed three-dimensional scaffold is one of the fundamental requirements that guide tissue formation *in vitro* and *in vivo*. Frontiers areas in medicine is changing rapidly from utilizing synthetic implants and tissue grafts to a tissue engineering approach that uses degradable porous scaffolds integrated with biological cells or molecules to regenerate tissues [Hollister et al., 2005]. Therefore, the selection of scaffold is important to enable the cells to behave in the desired manner to generate tissues and organs of the desired shape and size. In the body, cells and tissue are organized into three-dimensional architecture. To engineer these functional tissue and organs, scaffolds have to be fabricated by different methodology to

facilitate the cell distribution and guide their growth into three-dimensional space. The main techniques for scaffolds fabrication are summarized below:

2.2.1. Solvent casting

Solvent casting is a very simple, easy and inexpensive method for scaffold fabrication. It does not require any large equipment; it is totally based upon the evaporation of some solvent in order to form scaffolds by one of the two routes. One method is to dip the mold into polymeric solution and allow sufficient time to draw off the solution; as a result a layer of polymeric membrane is created. Other method is to add the polymeric solution into a mold and provide the sufficient time to evaporate the solvent that create a layer of polymeric membrane, which adhere to the mold [Mikos et al., 2004]. One of the main drawbacks of this technique is the use of toxic solvent that denatures the protein and may affect other solvents. There is a possibility that the scaffolds designed by these techniques may also retain some of the toxicity. To overcome these problems scaffolds are fully dried by vacuum process to remove toxic solvent. However, this is very time consuming technique and to overcome these problems some researchers have combined it with particulate leaching techniques [Mikos et al., 1993a; 1993b; 1996] for the fabrication of scaffolds.

2.2.2. Particulate-leaching techniques

Particulate leaching is one of the most common methods that are widely used for preparation of scaffolds with controlled porosity [Ma & Langer, 1999; Lu et al, 2000]. Salt, wax or sugars as porogens are used to create the pores or channels. In this method, salt is grounded into small particles and those particles that have desired size are poured into a mold and filled with the porogen. A polymer solution is then cast into the salt-filled mold. After the evaporation of the solvent, the salt crystals are leached away using water to form the pores of the scaffold. The process is easy to carry out. The pore size can be controlled by controlling the amount, size and shape of the porogen [Plikk et al., 2009]. The particulate leached scaffold with porosity up to 93 % and pore diameter up to 500 micrometers can be prepared [Mikos et al., 1993a; 1993b]. Main advantage of this technique is its simplicity, versatility and easy to control the pore size and geometry. Pore geometry is controlled by the selection of the shape for specific porogen agent, where as pore size is controlled by sieving the porogen particle to the specific dimensional range [Mano et al., 2007]. However, certain critical variables such as pore shape and inter-pore

openings are not controlled [Moore et al., 2004]. To overcome these drawbacks advanced fabrication technologies have been developed as described below.

2.2.3. Gas foaming

Many of the fabrication techniques require use of organic solvents and high temperature. The residues that remain after completion of process can damage cells and nearby tissues. This may also denature the biologically active molecules incorporated within the scaffolds. The gas foaming technique does not require the use of organic solvents and high temperature. This technique uses high pressure soluble inert gas, e.g. CO₂ or N₂, in the supercritical region as blowing agent for the fabrication of highly porous scaffolds [Harris et al., 1998; Singh et al., 2004; Wang et al., 2006]. The porosity and porous structure of the scaffolds depend upon the amount of gas dissolved in the polymer. Instead of using a single polymer, this method is also applicable for composites of polymer and (bio) ceramic to employ in hard TE constructs [Kim et al., 2006]. The advantage is the elimination of solvent, thus avoid the risk of remaining solvent residue, and the low processing temperatures preventing degradation of the polymer during processing. The scaffolds often have a closed surface (skin) and mainly non-percolated pores which can be a serious problem as these characteristics limit nutrient transport through the scaffold. The porosity of the scaffolds is controlled by combining the method with particulate leaching [Ikada et al., 2006]. The mix polymer and porogen are exposed to high pressure until they have completed its saturation with carbon dioxide, followed by the removal of porogen by foaming process and thereby a highly interconnected pore structure is formed [Huang & Mooney, 2005].

2.2.4. Freeze drying

Freeze drying technique is used for the fabrication of porous scaffolds [Whang et al., 1995; Schoof et al., 2001]. This technique is based upon the principle of sublimation. Polymer is first dissolved in a solvent to form a solution of desired concentration. The solution is frozen and solvent is removed by lyophilization under high vacuum that fabricate the scaffold with high porosity and inter connectivity [Mandal & Kundu, 2009 a, b]. This techniques were applied to a number of different polymers including silk proteins [Vepari & Kaplan, 2007, Altman et al., 2003], PGA, PLLA, PLGA, PLGA/PPF blends. The pore size can be controlled by the freezing rate and pH, however a fast freezing rate produces smaller pores. Controlled solidification in a

single direction has been used to create a homogenous 3D-pore structure [Schoof et al., 2001]. The main advantage of this technique is that, it neither requires high temperature nor separate leaching step. The main drawback of this technique is smaller pore size and long processing time [Boland et al., 2004].

In **emulsion freeze-drying**, homogenization of a polymer–solvent system and water leads to formation of an emulsion [Ho et al., 2004; Whang et al., 1995]. An emulsion exists of two phases, a continuous phase and a dispersed phase. The continuous phase consists of the polymer-rich phase, whereas water is the dispersed phase. The emulsion is cooled quickly to freeze the solvent and water, resulting in solidification of the polymer directly from the liquid state and the creation of a porous polymer structure. Subsequently, the frozen solvent and water are removed by freeze-drying. Emulsion freeze-drying is attractive for creation of relatively thick scaffolds with large pores. Additionally, incorporation of proteins is enabled during the fabrication of the scaffold. The obtained morphology is mainly non-percolated (solid-wall like pores), which is the major drawback of freeze drying as this often limits cell in-growth and nutrient transport through the scaffold.

2.2.5. Phase separation

Phase separation technique for scaffolds designing requires temperature change that separates the polymeric solution in two phases, one having low polymer concentration (polymer lean phase) and other having the high polymer concentration (polymer rich phase). Methods often used for phase separation are e.g. liquid induced phase separation (LIPS, immersion precipitation) [Kim et al., 2004; Liu et al., 2004; Zoppi et al., 1999] and thermally induced phase separation (TIPS) [Guan et al., 2005; Hua et al., 2002; Li et al., 2004; Nam et al., 1999]. Polymer is dissolved in phenol or naphthalene, followed by dispersion of biologically active molecule in these solutions. By lowering the temperature liquid-liquid phase is separated and quenched to form a two phase solid and the solvent is removed by extraction, evaporation and sublimation [Mikos et al., 2004] to give porous scaffolds with bioactive molecules integrated in to the structure [Sachlos & Czernuszka, 2003; Hua et al., 2002]. An appropriate liquid-liquid phase separation is critical for the preparation of nanofibers and does not occur in all solvents which involves the selection of solvent. Furthermore, the phase separation temperature is crucial for the formation of nanofibers. Advantage of the phase separation technique is that, it can easily combine with other fabrication technology (Particulate leaching) to design three dimensional structures with controlled pore

morphology. It can also be combined with rapid prototyping to create nano fibrous scaffolds for tissue engineering applications [Smith et al., 2006]. These methods allow processing of pure polymers as well as composites of polymer–(bio) ceramic for application in hard TE [Causa et al., 2006].

2.2.6. Electrospinning

Electrospinning (ESP) technique for the scaffolds designing is based upon the charging of a polymer solution utilizes the electrostatic force and subsequent ejection of polymer solution through a capillary tip or needle for the production of polymeric fiber ranging from nanoscale to microscale [Bhattacharai et al., 2006; Riboldi et al., 2005]. This process is controlled by high intensity electric field between two electrodes having electric charges of opposite polarity. To obtain continuous fibers, the method requires solutions containing relatively high polymer concentrations usually in the range of 10-15 wt%. Varying the process parameters, e.g. distance between needle and collector, strength of the electric field and polymer concentration allows tuning of the fiber diameter [Moroni et al., 2006; Boudriot et al., 2006]. More than 200 polymers are used for electrospinning like silk fibroin [Zarkoob et al., 2004; Sukigara et al., 2003; Jin et al., 2004], collagen [Matthews et al., 2002], chitosan [Ohkawa et al., 2004], gelatin [Ma et al., 2005] etc. The process is very versatile in terms of use of polymers, non-invasive and does not require the use of coagulation chemistry or high temperature for fiber generation. One of the main advantages of this technique is the high flexibility and fiber resolution of the obtained scaffold suitable for growth of the cell and subsequent tissue organization [Li & Tuan, 2009; Liang et al., 2007; Leong et al., 2008]. Additionally, alignment of the electrospun fibers is enabled to induce cell and tissue alignment [Buttafoco et al., 2006] favorable for better cellular growth for *in vitro* and *in vivo*. A drawback of electrospinning is the risk of breaking fibers during fabrication, which might lead to inferior quality of the scaffold.

2.2.7. Fiber mesh

Fiber mesh technique for scaffold fabrication consists of individual fiber either woven or interweave into three dimensional pattern of variable pore size [Martins et al., 2009]. The method is developed by Mikos and his coworkers [Mikos et al., 1993a]. PGA is the first biocompatible and biodegradable polymer to spun into the fiber and used as a synthetic suture thread. It is prepared by the deposition of polymer solution over a nonwoven mesh of another

polymer PLLA [Chen et al., 2002] or collagen [Eberli et al., 2009] matrix followed by subsequent evaporation [Ikada et al., 2006]. At a temperature above the melting temperature of PGA, fiber bonding occurs and subsequently, the PLLA matrix of the composite is removed by dissolving in methylene chloride agent [Sachlos and Czernuszka, 2003] utilizing the fact that PGA is insoluble in this solvent. This process yields the scaffolds of PGA fiber that is bonded together by heat treatment. PGA mesh provides the high porosity and surface area to polymer mass ratio [Mooney et al., 1996]. This provides the mechanical stability and allows the tissue ingrowths. Main advantage of this technique is to provide the large surface area for cell attachment and rapid diffusion of nutrient that is favorable for cell survival and growth [Chen et al., 2002].

2.2.8. Self assembly

Self assembly is the spontaneous organization of the molecule into well defines acheiving an ordered structure required for specific function [Zhang et al., 2003]. Self assembly of natural or synthetic molecule produced nanoscale fibers known as nanofibers. Amphiphilic peptide sequence is a common method for the fabrication of 3D nanofibrous structure for tissue engineering. In aqueous solution, the hydrophobic and hydrophilic domains within these peptides interact together with the help of weak non covalent bonds [Joshi et al., 2009; Zhang et al., 2006] such as hydrogen bond, Van der Waals interactions, ionic bond and hydrophobic interaction. This produces distinct fast recovering hydrogel, with the hydrophobic interactions as the molecules come together. The di- and tri-block peptide ampholites (PAs) are designed that are self-assembled into a rod-like architecture. So a new technique for the self-assembly of PAs into nanofibers by controlling pH and by engineering the peptide head group of the PAs is developed [Hartgerink et al., 2002]. The fabricated nanofibers have amino acid residues that may be chemically modified by the addition of bioactive moieties. Other advantage of this technique is to avoid the use of organic solvent and reduce the cytotoxicity because it is carried out in aqueous salt solution or physiological media [Ma et al., 2005]. Main disadvantage of this technique is its complicated and elaborated process.

2.2.9. Melt molding/ Sintering

Melt molding generally referred to the processing of polymeric powders at high temperature while the term “sintering” is for ceramics, metals, glasses and their composites to make the

particles adhere to each other. Melt molding process involves the filling of teflon mould with PLGA powder and gelatin microspheres of specific diameter followed by heating the mould above the glass transition temperature of PLGA while applying pressure to the mixture [Thompson et al., 1995a, 1995b]. This action causes the PLGA particle to attach together. Once the mould is removed, gelatin microspheres are dissolved by immersing the mixture into water and scaffolds are then dried. Scaffolds produced by this technique assume the shape of the mould. Melt molding process can be modified to incorporate short fiber of hydroxyapatite (HA). Uniform distribution of HA fiber throughout the PLGA scaffolds could only be achieved by using the solvent casting technique to prepare the composite material of HA fiber, PLGA matrix and gelatin or salt porogen, which are used in melt molding process [Hou et al., 2003]. Scaffolds fabricated by sintering are mainly for hard TE constructs. The possibility of creating controlled and graded porosity is the main advantage of sintering. The major disadvantage is the possible risk of low interconnectivity of the pores and the brittleness of the fabricated scaffold in case of using certain biomaterials.

2.2.10. Rapid prototyping (RP)

RP is also called as solid free-form technique. This technique is more advanced technique for scaffold fabrication. It can rapidly produce 3D object by using layer by layer manufacturing method. RP technique generally comprises the design of scaffold model by using the computer aided design (CAD) software, which is then expressed as a series of cross section [Lin et al., 2008, Woodfield et al., 2009]. Corresponding to each cross section RP machine lays down a layer of material starting from the bottom and moving up a layer at a time to create the scaffolds. In typical example, image of bone defect in a patient can be taken and develop 3D CAD model. The computer then can reduce the model to slice or layers. The 3D objects are constructed layer by layer by using RP techniques such as fused deposition modeling (FDM), selective laser sintering (SLS), 3D printing (3D-P) or stereolithography. Now-a-days, RP is an efficient way for generating the scaffolds of desired property. Other advantage of this technique is to produce the parts with highly reproducible architecture (size, shape, inter connectivity, branching, geometry and orientation) and compositional variations yielding biomimetic structure, that varying in design and material composition. The method is able to control the mechanical property, biological effects and degradation kinetics of scaffolds [Kai et al., 2009; Hutmacher et al., 2000;

2001]. One of the main drawbacks of this technique is achieved low resolution by current systems and types of polymeric materials that are used for this technique.

2.2.11. Membrane lamination

Membrane lamination is another SFF-like technique used for constructing three-dimensional biodegradable polymeric foam scaffolds with precise anatomical shapes. Membrane lamination is prepared by solvent casting and particle leaching and introducing peptide and proteins layer by layer during the fabrication process. The membranes with appropriate shape are soaked with solvent, and then stacked up in three-dimensional assemblies with continuous pore structure and morphology [Maquet & Jerome, 1997]. The bulk properties of the final 3D scaffolds are identical to those of the individual membrane. This method generates the porous 3D polymer foams with defined anatomical shape, since it is possible to use the computer assisted modeling to design the template with desired implant shape. The disadvantage of this technique is that layering of porous sheets, result in lesser pore interconnectivity [Hutmacher et al., 2000; 2001] and that it is a time consuming process.

2.3. Silk biomaterial as TE matrices

Silk from *B. mori* has been utilized as universal biomaterial with a wide range of processability and applications as demonstrated through figure 2.1 and table 2.1.

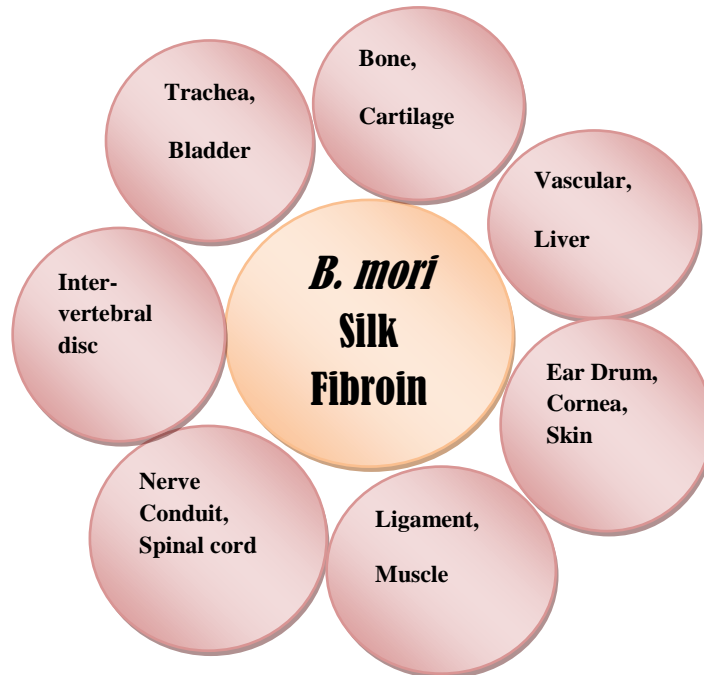

Figure 2.1: Silk for different tissue engineering application [Kasaju and Bora, 2012]

2.4. Surface modification and Composite/blend development

The brittleness of pure SF scaffold restricts their application and thus their physical properties are enhanced by mixing with other synthetic or natural polymers and other biomaterials [[Gobin et al., 2005](#); [Kweon et al., 2003](#); [Du et al., 2006](#)]. The cross-linking of such blended system may results into different degradation under physiological conditions [[Ma et al., 2003](#)] in addition to improved mechanical strength [[Sabato et al., 2001](#)]. The interaction of such composite scaffolds towards host cells have not been explored much. The improvement in tissue engineering biopolymers can be achieved by utilizing polymers of natural or synthetic origin, separately or in

blended form, with grafted or cross-linked networks. Mixing of glycerin (a commonly used plasticizer) has been reported to improve the mechanical properties of silk film [Lu et al., 2010] and also to reduce phase separation between silk and PVA in the blend [Dai et al., 1999]. After mixing with silk, glycerin molecules interact with silk chains via intermolecular hydrogen bond formation between -OH groups of glycerin and -NH groups of silk [Dai et al., 1999]. Chen et al. successfully fabricated electrospun silk fibroin [SF]/chitosan [CS] composite nanofibers [NFs] that could both support the proliferation (SF component) and osteogenic differentiation (CS component) of human fetal osteoblastic [hFOB] cells [Chen et al., 2012a]. Silk-CNT composite scaffolds developed by Chen et al. showed improved neuron differentiation efficiency from hESCs [Chen et al., 2012b].

Surface modification via physical adsorption or chemical immobilization of a protein or ligand improves biomaterial properties towards cellular behaviour [Jayasinghe et al., 2010; Chrzanowski et al., 2012]. Silk surfaces are hydrophobic, and can be functionalized using the AA side chain chemistry. The surface of silk fibroin biomaterials is modified using carbodiimide chemistry, which uses amine or carboxyl groups on silk. For example, arginine residues of silk fibroin were modified by 1,2-cyclohexanedione resulted into improved cell attachment and proliferation [Gotoh et al., 1998]. SF surface coupled with poly(ethylene glycol) (PEG) showed decreased attachment of fibroblasts [Gotoh et al., 1997] and also showed protein adsorption and hMSC attachment related to the amount of PEG on the surface [Vepari et al., 2010]. Surface properties of SF biomaterials for improved cell adhesion and proliferation can be modulated by conjugation with integrin recognition RGD sequence via carbodiimide coupling [Ruoslahti et al., 1987]. The RGD peptide plays vital role in cellular adhesion by engaging integrins present over surface of many cell types [Hersel et al., 2003]. The remarkable improvement in cellular attachment and differentiation promotes ligament, [Chenet et al., 2003] bone, [Meinel et al., 2004b] and dental [Petrini et al., 2013; Karageorgiou et al., 2004] tissue engineering [Xu et al., 2008]. It's fascinating to know that some wild type of silkworms like *Antheraea pernyi* have RGD in their silk fibroin sequence [Minoura et al., 1995]. Sofia et al. reported the covalent attachment of RGD to silk fibroin films resulting in increased number of mineral modules formed by Saos-2 cells in osteogenic media [Sofia et al., 2001]. T.Damrongrungruang fabricated RGD-modified electrospun Thai silk fibroin nanofibers to compare adhesion of human fibroblast cell line between RGD- and non-RGD modified electrospun nanofibers and observed a

significantly higher cell number in RGD modified silk fibre compared to conventional ones [Damrongrungruang, 2010].

Cell differentiation occurs in response of gradients of morphogens during embryogenesis and is repeated during adult tissue regeneration [Teixeira and Urist, 1998]. These signaling cues required for tissue development would be useful in biomaterial designing. Protein-based growth factors covalently attached to SF scaffolds has also been promising to promote cell differentiation cultured within scaffolds. One of the most common growth factor for bone tissue engineering is bone morphogenic protein (BMP-2) that can be directly immobilized on SF films, [Karageorgiou et al., 2004], scaffolds [Karageorgiou et al., 2006; Kirker et al., 2007] and electrospun mats [Li et al., 2006] via carbodiimide coupling. Gradients of BMP-2 were covalently immobilized and adsorbed over three-dimensional silk fibroin sponges and studied with hMSCs results into significantly higher expression of osteogenic markers [Vepari et al., 2010].

Several chemical modification methods to improve SF blood compatibility have been reported. Many of them have been modeled after the structure of commonly used anticoagulant, heparin the highly sulfated polysaccharide. Strategies have been employed to incorporate sulfate groups into SF in order to mimic the heparin structure. SF derivatives produced through the reaction with chlorosulfonic acid [Tamada et al., 2004] and sulfonated silk blends [Ma et al., 2006] or grafting of 2-methacryloyloxyethyl phosphorylcholine (MPC) onto silk fabric [Furuzono et al., 2000] were shown to be effective approaches in SF modification for applications where these materials will be in blood contact. Sulfated SF derivatives have also shown Anti-HIV activity [Gotoh et al., 2000]. Similarly, incorporation of phosphorylcholine (PC) into silk reduces inflammatory reactions to these materials *in vivo* by significantly reducing platelet adhesion [Furuzono et al., 2000]. Liu et al. reported the improved mechanical properties and lower inflammatory response of modified silk fibre with gelatin in place of sericin using NDGA as a cross-linking agent for ligament tissue engineering applications [Liu et al., 2007].

2.5. PVA as traditional biomaterial for SF scaffold development

PVA, a synthetic polymer has excellent hydrophilicity, biocompatibility, biodegradability and processability with ability to form high strength fibres suitable for medical applications [Mansur

and Costa, 2008; Mansur et al., 2004]. In addition, the published literature has indicated that no significant difference is found in quantitative or qualitative cytotoxicity evaluation of PVA. It is also shown that the amount of PVA accumulated in organs is too small to affect the biological fate, which suggested that PVA is excreted to the same extent as for example PEG, supporting the cytocompatibility of PVA [Yamaoka et al., 1995]. Furthermore, due to its solubility at room (25°C) or body temperature (37°C), it doesn't easily leach out into water or cell culture medium. A wide range of natural/synthetic polymers blended with PVA have been investigated for tissue engineering applications [Choi et al., 2013]. Development of scaffolds from PVA and PVA blends with other biopolymers, involves the crosslinking of PVA either chemically (with difunctional gluteraldehyde in presence of sulfuric acid, acetic acid or methanol) [Dai et al., 1999; Kim et al., 1993] or physically (with electron beam or gamma irradiation [Mathew et al., 2013; Wang et al., 1998], heat-treatment). Recently PVA gels have been prepared without crosslinking agents as a cell adhesive surface [Gupta et al., 2011]. Furthermore, a number of natural/synthetic polymer blended with PVA [Choi et al., 2013] and Poly(vinylidene fluoride) [Dikshit and Nandi, 2001] have been investigated for TE applications. Incorporation of PVA solution in chitosan has shown improvement in biocompatibility of the blend system [Huang et al., 2005]. Silk fibroin and PVA have been separately investigated as materials for tissue engineered constructs [Meinel et al., 2004a; Hofmann et al., 2007] and many research groups have studied the preparation method and properties of SF/PVA blends for improved stiffness of SF [Li et al., 2002; Dai et al., 2002; Li et al., 2001; Tanaka et al., 1998; Tanaka et al., 1997; Tsukada et al., 1994]. However, silk fibroin/PVA scaffolds have not yet been explored much for cytocompatibility and potential bone tissue engineering application.

2.6. Utility of SF based matrices in Tissue Regeneration

An ideal scaffold for tissue engineering application must have the property of biocompatibility with host tissue, biodegradability and non immunogenic in nature. Therefore much of the research is being done on natural polymer which fulfills these criteria. Silk, which is a naturally derived polymer, has been in use for medical application such as suture material due to its high mechanical and compressive strength. It proves to be an ideal polymer for tissue engineering application owing to its better bioactive properties as compared to synthetic polymers which is an important prerequisite for a polymer for the development of construct. They can be easily

modified in combination with other materials to achieve required mechanical and surface properties of scaffold. Therefore silk is considered as a promising biomaterial for tissue engineering application.

2.6.1. Skin wound healing

Research groups [Chiarini et al., 2003; Dal et al., 2003] have reported the in-vitro dermal fibroblasts spreading and proliferation on fibroin substrate without secretion of pro-inflammatory interleukins accountable for host response against foreign body. In vitro study of oral keratinocytes on woven fibroin meshes have shown promising proliferation [Min et al., 2004]. In another study, fibroin-alginate sponges [Roh et al., 2006] and fibroin-chitosan blend [Gobin et al., 2006] have been found to enhance skin wound healing compared to currently used clinical materials. The effects of the transparent fibroin film (silk film) and dressing were compared with an objective to regenerate the epidermis and dermis of the wound and reported the superiority of silk films with additional advantages of cost effectiveness, ease of availability, sterilizability, and easy observation of tissue recovery due to transparent nature [Sugihara et al., 2000]. Naksupan et al. studied the healing effect and toxicity of silk fibroin gel in skin wound of animal model and observed the accelerated epidermal (keratinocytes) cell proliferation, migration to wound and remodeling of wound site without any trace of cytotoxicity anatomical change. This study indicates the potential use of silk fibroin gel for wound dressing application in clinical trial [Naksupan et al., 2012].

2.6.2. Skeletal tissues

2.6.2.1. Cartilage

Major research on the application of silk fibroin based 3D scaffolds for cartilage tissue engineering were reported by D. L. Kaplan group, most often fabricated by salt-leaching [Wang et al., 2006; Marolt et al., 2006; Meinel et al., 2004a; Hofmann et al., 2007]. In vitro human articular chondrocytes [Wang et al., 2006] and mesenchymal stem cells (MSCs) [Marolt et al., 2006; Meinel et al., 2004a; Hofmann et al., 2006] cultured on these scaffolds have demonstrated chondrogenesis as elevated amount of collagen type II and GAG both in static [Meinel et al., 2004a, 2004c] and dynamic [Marolt et al., 2006] cultures. Hofmann et al. studied the effect of serum in culture media in terms of support to chondrogenesis on silk and collagen scaffolds and reported that cartilage synthesis on silk scaffolds in serum-free conditions is highly significant.

In the absence of serum, the GAG level was significantly higher on the fibroin scaffolds as compared to collagen controls but lower in presence of serum, indicating the promotion of chondrogenesis due to surface properties of the silk scaffolds and its potential clinical applications where the use of serum is avoided [Hofmann et al., 2006]. However, the engineered cartilage tissue had inferior mechanical properties to those of native cartilage [Hofmann et al., 2006; Marolt et al., 2006] and lower GAG content produced by differentiated MSCs than by chondrocytes [Marolt et al., 2006], indicating further need to optimize the culture conditions with respect to scaffold properties, cell differentiation and mechanical stimulation. Silk fibroin sponges developed by thermally induced phase separation (TIPS) method showed support to chondrocyte proliferation for up to 28 days [Morita et al., 2002] with inferior mechanical properties as of native tissue due to the inferior expression of synthesized extracellular matrix. Alteration in cell culture protocol using the same scaffolds resulted in higher expression of type II collagen, GAG and extracellular matrix throughout the culture period of 28 days, signifying the application in hyaline cartilage tissue engineering [Aoki et al., 2003].

2.6.2.2. Bone

Tissue engineering approach for the repair of bones with different morphologies using silk fibroin scaffolds in various forms have been reported [Fini et al., 2005; Kim et al., 2005a; Kirker-Head et al., 2007; Hofmann et al., 2007; Marolt et al., 2006; Meinel et al., 2004b; Kim et al., 2005b; Meinel et al., 2005]. Initial efforts deal with silk fibroin hydrogels [Fini et al., 2005] and membranes/nets [Kim et al., 2005b] without pre-seeded cells for guided bone regeneration. While in this decade, techniques have been developed to use 3D porous silk fibroin scaffolds seeded with MSCs for the repair of bone defects with complex dimension mostly done by D. L. Kaplan group [Meinel et al., 2006a; Kim et al., 2005a; Meinel et al., 2005; Kim et al., 2005b]. In their study, regenerated silk fibroin solution (RSF) was processed into films [Sofia et al., 2001, Wang et al., 2005], electrospun to form scaffolds [Li et al., 2006] or a 3-D porous scaffold by salt-leaching [Kirker-Head et al., 2007; Hofmann et al., 2007; Marolt et al., 2006; Meinel et al., 2006a; Kim et al., 2005c; Meinel et al., 2005]. The addition of RGD functionality [Meinel et al., 2005; Meinel et al., 2004b] or growth factors [Kirker-Head et al., 2007; Karageorgiou et al., 2006; Li et al., 2006] was reported to enhance surface properties for cellular activities. Fibroin films coupled with RGD peptides incubated with osteoblast-like cells were found to produce mineralized matrix [Sofia et al., 2001]. Silk fibroin films and scaffolds immobilized with bone

morphogenic protein-2 (BMP-2) have been demonstrated to induce osteogenesis *in vitro* [Meinel et al., 2006b; Karageorgiou et al., 2004] and bone formation when implanted with or without seeded pre-differentiated and undifferentiated MSCs in non-load bearing [Karageorgiou et al., 2006] and load-bearing [Meinel et al., 2006a] bone defect sites *in vivo*. Bone formation at the site of implantation with fibroin scaffolds seeded with undifferentiated cells *in vitro* induces early osteogenesis than scaffolds without preseeded cells. SF scaffolds cultured with cells before implantation also has shown better mechanical properties [Meinel et al., 2006a]. SF based hydrogels have been reported to outperform *in vivo* bone ingrowth than commercially available synthetic polymers [Fini et al., 2005]. For the bone regeneration at bone defect site with complex dimension meant that several smaller scaffolds have to be stacked together instead of using a larger one. Larger scaffolds though can support bone formation with better mechanical properties but problem of mass transport limits their use [Meinel et al., 2006b]. Most reports demonstrate the culture medium supplementation when BMP-2 is involved; however, Meinel et al. successfully differentiated MSCs along osteogenic lineages with BMP-2 applied via viral transfection [Meinel et al., 2006b]. Reports demonstrate the successful differentiation of MSCs into osteogenic lineages grown over Fibroin–nano-hydroxyapatite composite films [Tanaka et al., 2007] and have been observed to promote osteogenesis at both non-load bearing [Kim et al., 2005b; Meinel et al., 2005] and load-bearing [Meinel et al., 2006a] sites implanted in rodent models.

2.6.2.3. Ligament/tendon

The adaptability of silk biomaterial into controllable physical and mechanical properties makes it promising for ligament and tendon tissue engineering. The natural twisted and wire-rope geometrical configuration of silk fibers provide better mechanical properties and larger surface area for cell attachment and ECM deposition in a pattern similar to collagen fibers present in ligaments and tendons. Silk fibroin fibers devoid of sericin, has been investigated for proliferation and differentiation of MSCs towards ligament tissue, expression of ligament-specific markers (collagen type I, collagen type III, tenascin-C) and cellular response for mechanical stimulus [Altman et al., 2002]. Gelatin coated fibroin fibers have been demonstrated to restore the mechanical properties that are reduced by sericin removal without influencing *in vitro* cytotoxic effects and *in vivo* inflammatory response for ligament tissue engineering [Liu et al., 2007; Takezawa et al., 2007]. RGD coated silk fibroin matrix showed enhanced ECM

production by both MSCs and anterior cruciate ligament (ACL) fibroblasts [Chen et al., 2003] and increased expression of Collagen type I (the main constituent of ligaments) as compared to unmodified silk fibroin controls. Investigations also reported the mechanical stimulation of MSCs seeded in RGD-coated matrices. MSCs remained attached and aligned in the direction of the stimulus and shown further improvement by addition of growth factors for ligament tissue engineering [Moreau et al., 2005]. Ligament tissue engineering has been better supported by silk-based scaffolds and sponges as demonstrated by better proliferation of ACL fibroblasts seeded with MSCs [Liu et al., 2008; Seo et al., 2007]. Research report have demonstrated the maximum load of 2337 ± 72 N, an elastic modulus of 354 ± 26 N/mm and a strain at failure of $38.6 \pm 2.4\%$ the silk fibroin matrices, which are similar to ACL [Laurencin et al., 2005]. In a similar study silk fibroin scaffolds showed support for adherence, spreading, proliferation and differentiation of adult human MSCs towards ligament neogenesis [Altman et al., 2002]. The mechanical strength of scaffold was retained during three weeks of culture with expression of ligament-related transcripts (tenascin-C, collagen type III (Col-III) and Col-I) from second week. The expression of bone or cartilage related transcripts were not significantly affected suggesting the silk fibroin scaffolds promoted the ligament-specific hMSCs differentiation [Altman et al., 2002]. Studies on cabled yarns have shown that they are suitable for load-bearing applications, whereas braided and textured yarns were found suitable for non-load-bearing tissues with enhanced cell seeding and tissue ingrowth but with limitation of mass transport and mechanical fixation observed *in vivo* [Altman et al., 2002]. The group led by Vunjak-Navakovic designed a 6-cord silk fiber matrix with decreased scaffold stiffness and more void space (>90%) while maintaining the tensile strength which contribute to an enhanced tissue support and infiltration for neotissue formation [Vunjak-Novakovic et al., 2004]. Type-I collagen and mRNA levels for decorin (the most abundant proteoglycan in tendon tissue) were found to be highest on silk-RGD followed by silk films than on the control [Kardestuncer et al., 2006].

2.6.2.4. Vascular tissues

Silk fibroin scaffolds are a possible alternative for vascular grafts due to combination of their unique mechanical properties to withstand vascular pulsating pressure and biocompatibility towards endothelial cells and smooth muscle cells [Zhang et al., 2008; Soffer et al., 2008]. Soffer et al. fabricated electrospun nanofibrous tubular structures from silk fibroin with an objective to bioengineer small diameter vascular grafts. Human endothelial cells and smooth muscle cells

were successfully proliferated on substratum indicating their potential use as scaffolds for vascular grafts [Soffer et al., 2008]. Scaffold porosity of 80% and above is reported ideal for endothelialization of vascular grafts [Zhou et al., 2009]. Tubular silk scaffolds electrospun out of formic acid can resist up to 575 mmHg, which is much higher than physiological pressure of 120 mmHg [Marelli et al., 2010]. Drawback of using organic solvents, such as formic acid and HFIP, is that traces remained after processing may affect cyto-compatibility. Sulphonated and heparinized silk fibroin films have shown suitable mechanical properties for use as artificial blood vessels in addition to anticoagulant activity and support to endothelial cell culture [Ma et al., 2005]. Reports demonstrate that the blood compatibility of silk fibroin is enhanced by the grafting of hydrophilic polymers such as 2-methacryloyloxyethyl phosphoryl choline (MPC) [Furuzono et al., 2000], or blending with S-carboxymethyl keratine [Lee et al., 1998], or coating with fibronectin or collagen [Unger et al., 2004; Fuchs et al., 2006]. Couet et al. have developed collagen-silk filament composites for vascular tissue engineering [Couet et al., 2007]. For the successful engineering of bone and other tissues, it is mandatory for silk fibroin to promote vascularization process in the regenerating tissue [Mooney and Mikos, 1999].

2.6.2.5. Other tissues

Studies have shown that collagen-fibroin blends [Hu et al., 2006; Cirillo et al., 2004] and lactose-silk fibroin conjugates [Gotoh et al., 2004] support the attachment and proliferation of hepatocytes. It is also been reported that cells cultured on SF-containing films are able to eliminate ammonia and synthesize urea [Cirillo et al., 2004], suggesting potential applications for liver tissue engineering. Silk fibroin has also been demonstrated to support the growth and proliferation of rat dorsal root ganglia (DRG) and Schwann cells on the substrate made up of purified silk fibroin fibers [Yang et al., 2007] and has, therefore, been proposed as a potential candidate for nerve tissue engineering.

2.7. Conclusions

In recent years, a wide range of biomaterials have been developed and designed by the scientists for tissue engineering includes various types of synthetic and natural polymers and their composites. The main limitation of using synthetic polymers is the risk of implant rejection due to lowering of local pH by their degradation byproduct (CO₂ gas) and thus lead to cell and tissue necrosis. Whereas, the matrices of natural polymers are biodegradable, biologically active and

these promote cellular ingrowth for ECM formation. Gelation of naturally derived polymers is reported to be less controllable, although the hydrogels formed are more compatible for hosting cell and bioactive molecules. The properties of biopolymer can, further, be modified to induce differentiation of cells into specific lineages. The improvement in tissue engineering biopolymers can be achieved by utilizing polymers of natural or synthetic origin, separately or in blend form, and grafted or cross-linked networks. Surface modification via physical adsorption or chemical immobilization of a protein or ligand improves the material properties towards cellular behavior. The addition of RGD functionality or growth factors is reported to enhance surface properties of the scaffold.

Among the biopolymers, silk fibroin is reported to be the most attractive candidate for developing matrices for tissue regeneration and cell based therapy. *In vivo* and *ex vivo* experiments have demonstrated that silk based biomaterials show a wide range of advantages related to physical, chemical, mechanical, thermal and biological properties that help in regaining function at cell-adhesion sites. However, many problems still to be solved to use them for actual clinical application. There is a need to study and develop different silk based hybrid scaffolds that could efficiently replace the organ structure and function. The detailed study of cell attachment, cell infiltration and vascularization can help in efficient integration of the implants into the patient's body, avoiding the generation of fibrosis around the implants. Moreover, silk fibroin based hybrid scaffolds should be analyzed for their biodegradation properties. Finally, before using silk fibroin based tissue engineering products in medicine, the biocompatibility and the possible generation of heterologous amyloid must be tested *in vivo*, with the purpose of assuring their biosafety.

CHAPTER 3

Materials & Methods

3.1. Materials

Bombyx mori silk cocoons were obtained from silkworms reared in controlled conditions at the mulberry farms in Chittoor district, Hyderabad (Andhra Pradesh, India). Analytical grade Na₂CO₃ (S. D. Fine chemicals, India) and LiBr (>99% purity, Sigma Aldrich, Germany) and chemicals for Bradford Assay were used as such without further purification. Poly (vinyl alcohol) (Himedia, RM 6170) were used as blend polymeric materials for scaffold preparation and NaCl (Himedia, RM 583) as porogen. Freshly broken double membrane bound eggshells were collected from the canteen of National Institute of Technology, Rourkela, India for the preparation of soluble eggshell membrane protein (SEP). Standard stainless steel sieves (Fisher Scientific) (100 µm, 200 µm, 300 µm, 500 µm) were used for sorting NaCl particles into various particle size ranges. Clinical grade of laboratory chemicals and Milli-Q water were utilized in processing of scaffold fabrication and cell culture studies.

3.2. Preparation and Characterization of Polymer(s) solutions

3.2.1. Preparation of regenerated silk fibroin aqueous solution

Dried *B. mori* silk cocoon shells were cut into small pieces and treated with boiling aqueous solution of sodium carbonate of varying concentration for 20 min with stirring. The whole mass was washed with Milli-Q water repeatedly to remove the glue-like sericin protein and then dried in hot air oven. Before further use, the silk was dried in vacuum drying oven at 80°C for 6h. The degummed silks were completely dissolved in 9.3M LiBr aqueous solution at 70°C for 2½ h with stirring. The fibroin solution was dialyzed in a cellulose membrane based dialysis cassette (molecular cutoff 12,400) against deionized water for 3 days with changing of water every 6 h in order to remove LiBr. The dialysed regenerated silk fibroin (RSF) solution was centrifuged at 5-10°C and 9000 rpm for 20 min and stored at 4°C for further study. The concentration of silk fibroin aqueous solution was calculated by measuring the volume of solution and weighing the remaining solid after drying. The concentration of SF solution was calculated using the formula:

$$V_2 = V_1 \times \frac{C_1}{C_2}$$

Where, V₁ and V₂ are the volume of fibroin solution before and after evaporation, C₁ is the concentration of the fibroin solution before evaporation and C₂ is the concentration that is required in the experiment.

The concentration of SF solution was measured as 12% (w/v). Finally, the SF solution with concentration 4-6% (w/v) was prepared by dilution. The sequential experimental procedure for protein extraction from *B. mori* silk cocoon has been shown in [Figure 3.1](#).

Figure 3.1. Schematic diagramme for extraction of fibroin protein from *Bombyx mori* silk cocoon

3.2.2. Process optimization of SF extraction

3.2.2.1. Measurement of protein concentration

The concentration of fibroin protein was measured by the Bradford protein assay method [[Bradford, 1976](#)]. The fibroin solution was added to the Bradford reagent and incubated at 30°C for 5 min. The absorbance of resultant solution was measured at 595nm. The Bradford assay relies on the binding of the dye Coomassie Blue G-250 to protein. Thus, the quantity of protein is estimated by determining the amount of dye in the blue ionic form, usually achieved by measuring the absorbance of solution at 595 nm. Bovine serum albumin was used as a standard protein.

3.2.2.2. *Degumming loss*

Degumming loss, a quantitative evaluation of the degumming efficiency, is represented by the weight loss of the fabric (expressed as a percentage of the initial weight) after degumming. Before the measurement of weight loss, the samples were kept at 37°C in hot air oven for 24 h. The degumming loss was calculated as,

$$D(\%) = \left(\frac{W_i - W}{W_i} \right) \times 100$$

Where, D is Degumming loss, W_i is initial wt. of silk cocoon and W is wt. of silk fibroin recovered after degumming.

3.2.2.3. *Experimental design for response surface methodology*

Box-Behnken rotatable design (BBRD) for three independent variables each at three levels was adopted in this study. A total of 17 experiments were necessary for the estimation of the various coefficients of the model. The quadratic response surface model was fitted to the following equation [Evans et al., 2003; Guaracho et al., 2009]:

$$Y = \beta_0 + \sum_{i=1}^k \beta_i X_i + \sum_{i=1}^k \beta_{ii} X_i^2 + \sum_{j=1}^k \beta_{ij} X_i X_j + \varepsilon \quad (1)$$

Where, X_1, X_2, \dots, X_k are the input variables, which influence on the response Y ; $\beta_i (i = 1, 2, \dots, k)$, $\beta_{ij} (i = 1, 2, \dots, k; j = 1, 2, \dots, k)$ the unknown parameters and ε is a random error [Guvenc et al., 2007]. Actual values of independent variables in Box-Behnken design for the protein extraction using silk cocoon is shown in Table 3.1.

Table 3.1: Experimental range and levels of independent variables for extraction

X_i	Range and levels		
	-1	0	+1
X_1 : Na_2CO_3 concentration (mg/l)	0.01	0.02	0.03
X_2 : LiBr concentration (mg/l)	9.10	9.30	9.50
X_3 : Temperature (°C)	55	70	85

It is important to include the second order model to provide good prediction throughout the region of interest. The second order response surface design is rotatable; this means that the variance of the predicted response is the same at all points. Rotatability is a reasonable basis for the selection of response surface design. Because the purpose of response surface methodology (RSM) is optimization and as the location of the optimum is unknown prior to running the experiment, it makes sense to use design that provides equal precisions of estimation in all directions [Kumar et al., 2008]. For Model Fitting and Statistical Analysis, a three-dimensional response surface and contour plots of the independent variables and their interactions were generated using the statistical software, Design Expert software version 6.0.6 (STAT-EASE Inc., Minneapolis, US). The main aim of the optimization of protein extraction process was to establish the maxima levels within the independent variables such as Na_2CO_3 concentration (X_1), $LiBr$ concentration (X_2) and temperature (X_3).

3.2.3. Characterization of RSF solution

3.2.3.1. Rheological properties

The rheological property of the prepared silk fibroin solution was assessed by measuring the viscosity by a cone and plate viscometer (BOHLIN VISCO-88, Malvern, U.K.). The cone angle is 5.4° and diameter 30mm. A gap of 0.15mm was maintained between the cone and plate for all the measurements. The temperature was maintained using an external water circulator as 30°C , 35°C , 40°C , 45°C , $50^\circ\text{C} \pm 1^\circ\text{C}$. The experiment was done in triplicate ($n=3$).

3.2.3.2. Measurement of molecular weight

The molecular weight of the regenerated silk fibroin was determined by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) according to the method described in published literature [Laemmli, 1970]. The running gel was prepared using 12% acrylamide gel and 5% condensing gel. The gel was stained with the Easy Stain Commassie Blue Kit (Invitrogen, Carlsbad, CA).

3.2.3.3. Particle size analysis

The average particle size of the prepared regenerated SF solution was determined by Zetasizer Nano ZS (Malvern, U.K) particle analyzer based on laser beam scattering technique. The measurement was done at 30°C after discarding the precipitated impurities of the solution centrifuged at 9000 rpm for 10 min at 10°C . The optic unit contained a 4 mW He-Ne (633 nm) laser.

3.2.4. Preparation of Soluble Egg Shell Membrane Protein (SEP)

Freshly broken double membrane bound eggshells, collected from our institute canteen were immediately stored in chilled water. The raw eggshell was washed properly and then peeled off manually from the membrane. The sample was kept in aqueous acetic acid (70%) for two days to dissolve residual eggshell followed by rinsing with Milli-Q water repeatedly to remove acidity and then dried in hot air oven (50°C) for two days [Tsai et al., 2006]. Finally, the SEP was obtained by reductive cleavage of disulfide bonds present in ESM with aqueous 3-mercaptopropionic acid (3-MPA) at 90°C in presence of 10% acetic acid, following the method published earlier [Yi et al, 2003; Yi et al., 2004]. The average particle size of the prepared SEP solution was determined by same method as mentioned above for the RSF solution.

3.2.5. Preparation of SF/PVA blend solution

Aqueous PVA solution (10% w/v) was prepared by dissolving PVA powder under continuous magnetic stirring at 80°C for 4 h. The hot polymeric solution was cooled to ambient temperature and stored for further study. The aqueous SF (12% w/v) and PVA (10% w/v) solutions were blended with varying ratios of SF to PVA in the range 75/25 to 25/75, under magnetic stirring at 40°C for 48 h. Glycerin (4% (w/v), Himedia, RM 018) was added to the SF/PVA blend solution for minimizing phase difference. SF/PVA solution was cooled to room temperature and the pH of the blend was adjusted to 2.00 with 0.1 N HCl (Merck, India).

3.3. Preparation and Characterization of SF and SF based matrices

3.3.1. Preparation of Silk Fibroin Hydrogels and Sponges

The prepared regenerated silk fibroin was kept at 20°C for 3 days under humid environment to form translucent silk fibroin hydrogels (thermgels). The hydrogels were then kept at -20°C for 24 h and lyophilized for 24 h to prepare fibroin sponges.

3.3.2. Fabrication of silk fibroin porous scaffold

Porous scaffolds were prepared from silk fibroin solution by salt leaching method using NaCl as porogen. The silk fibroin was diluted to 8% (w/v) with Milli-Q water and poured into a circular mould (15mm dia.) either before or after NaCl was added as a porogen. Samples were then left covered in the mould for 24 h and placed in methanol for 30 min followed by the transfer into deionized water for salt leaching for 48 h. The salt leached samples were kept in vacuum dryer for 24 h at 40°C and stored in a dessicator [Kim et al., 2005c].

3.3.3. Preparation of SEP-SF Scaffolds

The SF scaffolds were steam sterilized and dried in ethanol ambience. The scaffolds were then soaked in SEP solution 2% (w/v) and incubated in hot air oven at 37 °C for 24 h for drying. The dried samples were cross-linked by pouring onto it a few drops of 1-ethyl-3-(3-[dimethylamino]propyl) carbodiimide (EDC) solution (10 mg/ml) mixed with N-hydroxysuccinimide (NHS) solution (10 mg/ml) (50:50), and then incubated at 37°C for 12 h [Hafemann et al., 2001]. The cross-linked samples were desalted with 70% ethanol and dehydrated with 99.5% ethanol, before drying under an air stream at 37°C for 24 h. The cross-linked SF-SEP scaffolds were kept in desiccator for further study.

3.3.4. Preparation of SF/PVA Scaffold

A series of scaffold samples with varying SF/PVA blend ratio were prepared in triplicate using porogen of different particle size (100-200, 200-300 and 300-500 µm). 4g of granular NaCl (air-dried) was kept in autoclavable teflon moulds and 2ml of different blend solutions were poured into it. Sample container was covered and kept at 40-50°C in hot air oven for 24 h. Few drops of methanol were added into the samples and kept for 30min for the conformational transition to occur and then dried in vacuum drying oven. The dried samples were kept in deionized water for 48 h for leaching of NaCl from the samples. These final product samples are dried in vacuum drying oven for 48 h and stored in desiccator for further study.

3.3.5. Preparation of SEP-(SF/PVA) scaffolds

The prepared SF-PVA scaffold was steam sterilized and dried in ethanol ambience. The scaffolds were then soaked in 2% (w/v) SEP solution and dried in hot air oven at 37 °C for 24 h. The dried scaffolds were cross-linked by pouring onto it few drops of 1-ethyl-3-(3-[dimethylamino]propyl) carbodiimide (EDC) solution (10 mg/ml) mixed with N-hydroxysuccinimide (NHS) solution (10 mg/ml) (50:50), and incubated at 37 °C for 12 h in 4-morpholinoethanesulfonic acid (MES) reaction buffer [Hafemann et al., 2001; Hermanson et al., 1996]. The cross-linked sample was desalted (with 70% ethanol) and dehydrated (with 99.5% ethanol), before being dried under an air stream at 37 °C for 24 h. The cross-linked SEP-(SF/PVA) scaffolds were kept in desiccator for further study.

3.3.6. Physico-chemical and Thermal characterization

3.3.6.1. Porosity and Pore size distribution

The porosity of the scaffolds were measured by liquid displacement method following the procedure discussed in published literature [Kim et al., 2005] using hexane as the displacement liquid since it is a

nonsolvent for silk and is able to permeate easily through the scaffold without causing swelling or shrinkage. In brief, a sample of weight W was immersed in a known volume (V_1) of hexane in a graduated cylinder. The sample was left covered in hexane for 5 min. During this time, the contents in the cylinder underwent an evacuation- repressurization cycle to force the hexane to pass through the pores. The total volume of the hexane and the hexane impregnated scaffold was V_2 . The volume difference ($V_2 - V_1$) is the volume of the polymer scaffold. The hexane impregnated scaffold is then removed from the cylinder and the residual hexane volume is recorded as V_3 . The quantity ($V_1 - V_3$), volume of hexane within the scaffold, was determined as the void volume of the scaffold. All measurements were carried out in duplicate.

The total volume (V) of the scaffold was,

$$V = (V_2 - V_1) + (V_1 - V_3)$$

and the porosity of the scaffold (π) was obtained by,

$$\pi = \frac{(V_1 - V_3)}{(V_2 - V_3)}$$

Mercury intrusion porosimetry was used to measure pore size distribution of scaffolds.

3.3.6.2. Phase Contrast and Scanning Electron Microscopy

The morphology of raw and regenerated samples was observed under phase contrast microscope (Carl Zeiss, Axiovert 40 C) equipped with a cannon 3 CCD color video camera. The surface morphology of degummed silk fibre, raw ESM,SF scaffolds and SEP conjugated SF scaffolds were examined by SEM (JEOL JSM -6480LV SEM) observation at different magnification. Scaffold samples were air-dried while ESM was kept in 2.8% gluteraldehyde solution overnight before SEM analysis. The samples were affixed via carbon tape to the SEM sample holders and vacuum-coated with a 20-nm layer of platinum. SEM was performed at a voltage of 15 kV and room temperature. To measure the aperture of the porous structure, the SEM analysis was done using image analysis software (JEOL SMileView) and the average pore size was calculated. The elemental composition of soluble egg shell membrane protein was also determined by EDX analysis.

3.3.6.3. X-ray diffraction

The diffraction pattern of samples was recorded by an X-ray diffractometer (Phillips PW-1830) with Ni-filtered Cu-K α radiation operating at 35 kV and 30mA. The samples were scanned from 20° (2θ) to 70° (2θ) at a scanning rate of 3.0/min. Crystallinity was determined by integration using KaleidaGraph (Synergy Software).

3.3.6.4. *Fourier transform infrared (FTIR) spectroscopy*

The FTIR analysis was performed using a FTIR spectrometer (model system IRPrestige-21, Shimadzu) interfaced with IR microscope operated in absorbance mode. The spectrum was measured and recorded solid samples in KBr pellets in the 500–4000 cm^{-1} region with a resolution of 4.0 cm^{-1} . The spectra were smoothed with constant smooth factor for comparison.

3.3.6.5. *Differential scanning calorimetry*

The thermal behavior of scaffolds was determined by differential scanning calorimetry (DSC) (Mettler Toledo DSC822e). 10-15 mg of each sample was scanned between the range of 30-300°C at a rate of 20°C / min under nitrogen atmosphere.

3.3.6.6. *Thermal gravimetric Analysis*

The thermal stability of scaffolds samples were investigated by TGA using a DTG-6H (Simadzu). The amount of samples for each measurement were about 1 mg, and all the measurements were carried out with a heating rate of 10°C min^{-1} in flowing N_2 heated up to 500 °C.

3.3.7. **Mechanical Property**

Compressive tests were performed to determine compressive modulus of the scaffolds (dry state) by using a Universal Testing Machine (H10 KS TINIUS OLSEN) with a 1 kN load cell at room temperature. The size of the tested specimens was measured with a micrometer. The lengths and diameters of the tested specimens for SF scaffolds were 11.94 ± 0.22 mm and 5.64 ± 0.26 mm, respectively. The cross-head speed was set at 2 mm min^{-1} and compressive moduli of scaffolds ($n = 4$) were calculated from the slopes of compressive stress–strain curves.

3.3.8. **Swelling assay and Biodegradability**

3.3.8.1. *Swelling property of silk hydrogel*

The swelling properties of the hydrogels were studied using conventional gravimetric method [Vazquez et al., 1997]. The swelling behavior of dried (60°C for 24 h) and pre-weighed hydrogels (disc-shaped) was determined by immersing in double-distilled water at 37°C. Swollen gels were weighed by an electronic balance at pre-determined time intervals after wiping excess surface liquid by filter paper [Gupta and Shivakumar, 2010]. The swelling index (SI) was calculated from the following equation:

$$SI = \frac{M_t - M_o}{M_o} \times 100$$

Where M_t is the mass of the swollen gel at time t , and M_o is the mass of the dry gel at time 0.

3.3.8.2. Swelling property and biodegradability of scaffolds

The preliminary cytocompatibility of the scaffold was investigated using a protein-free acellular simulated body fluid medium (SBF or Kokubo solution) of pH 7.40 and ionic composition- Na⁺ 142.0, K⁺ 5.0, Ca²⁺ 2.5, Mg²⁺ 1.5, Cl⁻ 147.8, HCO³⁻ 4.2, HPO₄²⁻ 1.0, SO₄²⁻ 0.5 mM [Kim et al., 1999]. The SF based scaffold were cut into 5.0mm×5.0 mm square pieces with initial weight measured as W₀ and soaked in SBF at 37°C and pH 7.4. The samples were soaked in SBF for different time period (30 min., 2 h, 4 h, 24 h, 96 h and 192 h). After soaking, the remaining solution were carefully removed from the medium, excess water on the surface was removed using lint-free tissue paper and weights (W₁) were determined. Samples were then dried at 40°C in an oven for 24 h and the weights of dried samples were measured as W₂. The initial change in weight refers to fluid-uptake measurements (swelling) while the final weight difference after sample drying indicates the biodegradability of samples in SBF. Each experiment was performed in triplicate. Swelling index (S) is calculated as,

$$S = \frac{W_1 - W_0}{W_0} \times 100$$

Whereas the biodegradation (B) in SBF is calculated as,

$$B = \frac{W_2 - W_0}{W_0} \times 100$$

3.3.9. Contact angle measurement

The hydrophilicity of developed scaffolds was evaluated in terms of contact angle measurement using a sessile drop technique with a Digital Contact Angle Measurement System fitted with a CCD camera (KGV-5000) [Kim et al., 2003]. First of all, scaffolds were attached smoothly to the silicon wafer surface by gradual evaporation of small water droplets placed along each edge of scaffold (2×2 cm²). A 5 µl droplet of pure water (Milli-Q-water) was pipetted onto the scaffold surface and temporal images were automatically taken. Using the computer simulation software, the contact angles were calculated from these images. The experiment was performed at 25°C and about 60% humidity. The measured contact angle value reflects the hydrophilicity of scaffold with respect to the pure water (Milli-Q-water) as lower the contact angle more is the hydrophilicity of scaffold.

3.3.10. In vitro Cell Study

3.3.10.1. Preparation of matrices for cell study

The scaffolds were soaked in 10% NH₄OH to neutralize any acidity, and rinsed 3 times with sterilized distilled water. The samples were then sterilized by exposure to saturated steam and then immersed in

70% ethanol for 24 h for sterilization followed by rinsing with sterile PBS 3–4 times. After drying, samples were kept in UV radiation for 6 h on each side. Sterilized samples were then soaked in PBS overnight on a shaker (25 rpm) and immersed in the culture medium for 4–10 h to result in a more hydrophilic surface for optimal cell adhesion.

3.3.10.2. Isolation and culture of hMNCs on silk hydrogels

Mononuclear cells (MNCs) were isolated from fresh peripheral blood of healthy, middle aged human using Ficoll-paque separation technique as described previously [Neagu et al., 2005]. The work was approved by Institutional Ethical Committee. The hMNCs culture was expanded in growth media containing 90% DMEM-F12, 10% foetal bovine serum (FBS), 100 U/mL penicillin, 1000 U/mL streptomycin and 0.2% fungizone antimycotic. After passaging of culture 3 times, the cells were cultured to obtain a cell density of 3×10^7 cells/ml. Autoclaved 15 ml of sterilized SF solution (12% w/v) were supplemented with powder DMEM-F12 and NaHCO_3 . For the induction of gelation, solutions were sonicated for 20 min in a laminar hood. After sonication, solution was cooled to room temperature. A volume of 50 μL cell suspension was added and well mixed with SF solution to make the final concentration of 1×10^5 cells/ml. The solution was put into 5 culture petridishes (Tarson, 32 mm) and incubated at 37°C and 5% CO_2 . At the end of day 3 & 7, small plugs were punched out of the gels, washed 2-3 times with PBS, cut into two halves and incubated in Trypan blue for 15 min at 37°C .

3.3.10.3. Isolation and culture of hMSCs

Human umbilical cord blood (UCB) was collected from nearby Ispat General Hospital, Rourkela, India from 37year old delivery patient with informed consent and due approval from the Institutional Ethics Committee. Mononuclear cells (MNCs) were isolated from UCB by Ficoll gradient centrifugation technique and cultured in Dulbecco's modified Eagle's medium (DMEM), supplemented with 10% fetal calf serum (FCS), 1% non essential amino acids, L-ascorbic acid (0.150 g/l), 1% of 200 mM L-glutamine, 2% of 1 M HEPES, penicillin (100 U/ml) and streptomycin (0.1 mg/ml) at 37°C , under 5% CO_2 and 80% RH environment with the medium being replaced every 2–3 days. hMSCs were selected due to their property of short-term adherence to tissue culture flasks when incubated under standard conditions (37°C , 5% CO_2 and 80% RH). After 24 h, non-adherent cells were discarded and adherent cells were further cultured, with the medium being replaced every 2–3 days. When culture flasks became semiconfluent after about 7 days, the cells were detached and serially subcultured [Kamihira et al., 2007]. hMSCs harvested at third to four cycles of passaging at viable cells/ml were used for seeding into scaffolds.

3.3.10.4. Phenotypic characterization of hMSCs by Flowcytometry

Phenotypic analysis of cultured hMSCs was performed by flow cytometry study. The fourth passage of cultured hMSCs were detached and properly washed with PBS followed by incubation for 20 min in 5% FBS (Foetal bovine serum) in PBS. The cells (1×10^5 cells per antibody) were resuspended in 100 μ l PBS after washing with PBS. 1 μ l of phycoerythrin (PE) or fluorescein isothiocyanate (FITC) conjugated mouse monoclonal antibodies against human CD34, CD45, CD90 (BD Biosciences, San Jose, CA) and CD105 (Invitrogen, Carlsbad, CA, USA) were added and incubated for 60 min in the dark at 4°C. After thorough washing cells three times with PBS, cells were resuspended in 400 μ l PBS and analysed by BD LSR Fortessa and FACS Diva software (Becton Dickinson, San Jose, USA).

3.3.10.5. Cell seeding and culture

The sterilized scaffolds were placed in a 6 well plate. MSCs were seeded with 1×10^5 cells/ml into the scaffold by static method and cultured in CO₂ incubator at 37°C, 5% CO₂ and 80% RH. The cultural medium was replaced every 2-3 days. The MSCs-seeded scaffolds were grown *in vitro*. MSCs seeded-scaffold was then assessed for cell attachment, proliferation and viability at various time points over the 14 days period of culture.

3.3.10.6. Cell Morphology

The photomicrographs of cells were observed under phase contrast microscope (Carl Zeiss, Axiovert 40 C) equipped with CCD camera. The surface morphology of MSCs on the scaffolds was examined by SEM (JEOL JSM -6480LV SEM) observation at different magnification. Adhered hMSCs in culture plate and cell seeded scaffolds were kept in 2.8% glutaraldehyde solution overnight before SEM analysis. The samples were affixed via carbon tape to the SEM sample holders and vacuum-coated with a 20-nm layer of platinum. SEM was performed at a voltage of 15 kV and room temperature.

3.3.10.7. Cell seeding efficiency and cell proliferation assay

For the study of cytocompatibility of salt leached SF scaffolds, (3-[4,5-dimethyltriazol-2-yl]-2,5-diphenyl tetrazolium) (Sigma, St Louis, MO, USA) assay was performed as reported in the published literature [Cory et al., 1991; Wilson et al., 2000]. This colorimetric assay is based on the ability of live cells to reduce yellow MTT reagent to a purple formazan product [Mosmann et al., 1983]. In brief, 5×10^4 cells were seeded on scaffolds in a 96-well plate. The cells were incubated at 37°C in humidified atmosphere containing 5% CO₂. After 24 h incubation, supernatant of each well was replaced with MTT

diluted in serum free medium and the plates incubated at 37°C for 4 h. After that, 10%SDS/ 0.04 N HCl solution was added to supernatant and plates were re-incubated for 24 h, 200µl was transferred to a clean 96-well plate and absorbance was measured at 595 nm using ASYS EXPERT PLUS spectrometric microplate reader. For analysis, all data were expressed as average \pm standard deviation for number of 3 replicates (n=3).

Figure 3.2: Stepwise representation of cell based bone regeneration. MSCs isolated and characterized from adult tissues, incorporated into scaffold, cultured, proliferated and differentiated, finally implanted into defective site.

3.3.10.8. Alkaline phosphatase (ALP) Assay

ALP assay is based on measuring the change in colorimetric absorbance of colourless para-nitrophenol phosphate (pNPP) cleaved to yellowish (paranitrophenol + phosphate) by membrane bound alkaline phosphatase enzyme. The alkaline phosphatase (ALP) activity of hMSCs grown on the scaffold was estimated to investigate the osteogenic differentiation following the method described in literature [Mauney et al., 2005]. In brief, the hMSCs seeded scaffolds were cultured in osteogenic differentiation medium for 1, 7 and 14 days. At each time interval, the scaffold were thoroughly washed with PBS to remove the residual serum and then 1 ml of 0.02% Triton® X-100 was added to dissolve the cells. The

solutions were centrifuged at 14,000 rpm at 4°C for 15 min. 100 µl 1 mol/l Tris-HCl, 20 µl 5 mmol/l MgCl₂ and 20 µl 5 mmol/l p-nitrophenylphosphate were added to the supernatant and incubated for 30 min at 37°C. The reaction was stopped with 50 µl of 1N NaOH and the absorbance was measured at 410 nm using a UV-VIS spectrophotometer (Systronics-117). The standard curve was prepared using p-Nitrophenol of known concentrations [Sun et al., 2008]. All solutions were components of the Alkaline Phosphatase Assay Kit (Abcam, Cambridge, MA, ab83369-500).

3.3.10.9. Histology

Samples were fixed in 10% neutral buffered formalin (4% formaldehyde in phosphate buffered saline), embedded in paraffin, sectioned (5 µm thick) and observed histologically by hematoxylin and eosin (H&E). The cross-sections of the grafts were analyzed after 3, 7 and 14 days of *in vitro* culture. A general assessment of histology was performed using light microscopy.

3.3.11. *In vivo* biocompatibility test in animal model

The developed scaffolds were transplanted under the skin of 4- to 6-week-old ICR recipient mice as per procedure described previously [Jung et al., 2008] with a slight modification. In brief, Intra-peritoneal injection of avertin (Tri-bromoethanol, 0.25 mg/g of body weight; 2-methyl-2-butanol, 0.16 ml/g) was performed to anesthetize the mice and the skin was sterilized with 70% (v/v) ethanol. Approximately ~1 cm linear incision was made on the dorsolateral side of the skin and a small pouch was created in the subcutaneous layer. Scaffolds of dimension 5 x 5mm² were transplanted into the surgically-created subcutaneous pouch and the incision was closed using nylon suture. The mice were monitored routinely for the skin and systemic diseases, if any. After one month, they were sacrificed by cervical dislocation and the scaffolds were explanted. Histological analysis was done with the skin around the site of transplantation. The skin samples were fixed in 10% (v/v) neutral buffered formalin and dehydrated in ascending grades of 40%, 60%, 80%, 95% and 100% ethanol and embedded in the paraffin wax. 5µm thick slices of specimens were made by microtome sectioning and were examined histologically after hematoxylin and eosin staining. All testing were performed under the aseptic conditions in compliance with the Guide for the Care and Use of Animals in Research and Teaching, published by the Federation of Animal Science Societies (3rd Edition, 2000) in Bio-Organ Research Centre, Konkun University, South Korea, and were approved by the Institutional Biosafety and Ethical Committee. Efforts have been given to ameliorate the suffering of animals.

3.3.12. Statistical analysis

Statistical significance was determined for all groups of scaffold samples for a number of 3 replicates and P values were generated by ANOVA using the Dunnett Test for multiple comparisons to one control ($p < 0.05$, $n \geq 3$ assays). This method relies on assumptions of normality and homogeneity of the variances of the distributions.

CHAPTER 4

Result & Discussion

PART I

Extraction of silk fibroin protein extraction from *B. mori* silk cocoon and its characterization

Silk fibroin (SF), a natural macromolecule derived from domestic silkworm (*Bombyx mori*), has attracted the interest of scientists of various disciplines for a long time. It has a long history of use in medicine, for example, as sutures and artificial ligaments. Recently it has been considered as a promising biomaterial that offers a wide range of biomedical applications because of its excellent mechanical properties, environmental stability, biocompatibility and biodegradability [Ning et al., 1999; Altman et al., 2003]. These properties make SF as most attractive and promising biomaterial for bone, cartilage and ligament tissue engineering [Altman et al., 2003]. Silk consists of two different proteins: sericin and fibroin [Perez-Rigueiro et al., 1998]. Silk must be regenerated into a desirable form to meet a specific biomedical application. Removal of sericin from silk fibre traditionally known as degumming requires a thermo-chemical treatment [Perez-Rigueiro et al., 2002]. The detail procedure and reason for degumming of the silk has been reported earlier [Kadhar et al., 2008]. The weakening of non-covalent bonds with fibroin and involvement of hydrophilic bond with ionic solution leads to removal of sericine. The fibroin has highly oriented crystalline domain and it is insoluble. The fibroin content of naturally spun silk fibers can be separated from sericin *in vitro* [Rui et al., 1998]. Degummed silk fibers is soluble in certain high ionic-strength aqueous solutions of chaotropic salts namely CaCl_2 , LiBr and so on, which destabilize proteins in solution and increase their solubility [Kweon et al., 2001a], leading to a transparent solution [Ayub et al., 1993; Sashina et al., 2006]. To date many researchers have attempted to find suitable solvents for preparing SF solutions, which may be subsequently spun into fibers. However, very few published reports are available that can provide complete processing of silk, optimization of process conditions and the characterization of silk solution. In this chapter, effort has been given to study the effect of various key process parameters to maximize the yield of SF from silkworm cocoon. The study uses Box–Behnken design for the optimization purpose using RSM to understand the effect of important process variables and their interactions on SF extraction process.

4.1.1. Degumming of *B. mori* silk cocoon

Degumming is a method of removing sericine from silk cocoon. The mechanism of sericin removal in chemical degumming is a combination of various effects such as: dispersion/solubilization and hydrolysis of different sericin polypeptides [Freddi et al., 1996]. Hydrolysis prevails when strong alkaline compounds are added to the degumming bath. Therefore, it was investigated the effects of key process parameters, such as temperature, time, and salt concentration on sericin removal

without triggering the hydrolytic degradation of fibres, that is easily induced by the presence of harsh chemicals in the treatment bath.

4.1.1.1. Effect of Na₂CO₃ salt concentration

To study the effect of salt concentration on the extent of sericin removal, the chopped silk cocoons were treated with varying concentration of aq. Na₂CO₃ in the range 0.01 to 0.04M. The degumming temperature and treatment time were kept constant at 70°C and 60 min. The effect of salt concentration on the formation of degummed silk fibers is shown in Figure 4.1.1. It is observed that the amount of silk fiber sharply decreased with increase in salt concentration from 0.01M to 0.02M which may be due to the loss of most of sericine from the silk fibre into the solution. The degumming loss was found to be increased from 19.9 % to 24.4 % with increase in concentration from 0.01 to 0.02M Na₂CO₃ solution and no significant increase in degumming loss with further increase in concentration of Na₂CO₃ is observed. However, the maximum degumming loss of 25.4 % was achieved at the concentration of 0.04M (Fig. 4.1.1). Therefore 0.02M Na₂CO₃ has been established as the most favourable salt concentration for degumming achieving maximum sericine removal. The minimum salt concentration also offers the silk fibre to be intact as high concentration of harse chemical may cause hydrolytic degradation of silk fibroin. Furthermore, at 0.02M, the silk surface was found smoother as compared to higher concentration as revealed by SEM (Fig. 4.1.4).

Figure 4.1.1: Effect of aq. Na₂CO₃ concentration on degumming of silk at 70°C and 60 min, The degumming loss is increasing with increase in Na₂CO₃ concentration. However most of the degumming loss representing maximum sericine removal is acheived with 0.02M Na₂CO₃.

4.1.1.2. Effect of degumming time

The treatment time has a significant influence on the degumming of silk [Kadhar et al., 2008]. To study the effect of the treatment time on the extent of sericin removal, the silk cocoon were treated with 0.02M aq. NaCO₃ solution at 70°C at a varying time period in the range 20-80 min. At 20 min., degumming loss was calculated as only 11% recovery of 8.9 g of silk fibre as shown in Fig. 4.1.2. At 40 min the loss increases to 18.8 % and the amount of silk recovered was 8.12 g. A loss of degumming 25.1 % was achieved after 60 min. Though a slightly increase in degumming loss (25.6 %) was observed with 80 min treatment time, the recovery of silk fibroin was found to be less (Fig. 4.1.2). This reduction in recovery of silk fibre with longer treatment time may be due to increased hydrolysis of interlinking bond between sericine and fibroin and more solubility of sericin into the solution. Moreover, the increase in treatment time probably exposes sericin to the action of hydrolysis by salt. Therefore, it has been established that 60 min is the most favourable degumming time.

Figure 4.1.2: Effect of treatment time on degumming process performed at 0.02M NaCO₃ and 70°C. Degumming loss is increased steadily with increase in treatment time and reached maximum at 60 min.

4.1.1.3. Effect of degumming temperature

It is evident that sericin can be removed using water alone, but high temperature is required to attain complete degumming (110–120°C, under pressure) [Freddi et al., 1996]. The effect of degumming temperature on the sericin removal was studied by conducting degumming experiment at varying temperature range 60–90°C. Below 60°C no significant degumming is achieved as reported earlier [Sukigara et al., 2003]. The concentration of Na₂CO₃ and treatment time were kept constant at 0.02M and 60 min respectively. The degumming temperature of 60°C probably contributed to enhance the solubility of partially hydrolyzed sericin fractions adhering to the fibrous core of the silk as depicted in Fig. 4.1.3. The rise in temperature from 60 to 70°C resulted in the loss of most of the sericin achieving 24.4% degumming loss. A slight increase in degumming loss was observed at 80°C and 90°C. The corresponding degumming loss is 25.1% and 25.5% (Fig. 4.1.3). Thus, degumming temperature of 70°C is established as optimum temperature. The rise in temperature not

only provides the activation energy for the breakdown of interlinking bonds but also increases the solubility of sericin into solution [Kadhar et al., 2008].

Figure 4.1.3: Effect of temperature on degumming process. The graph showing an increase in degumming loss with temperature and most of the degumming is achieved between 60-70°C.

4.1.1.4. SEM study with degummed silk fiber

The SEM observation of silk fibers obtained by the treatment with different concentration of Na_2CO_3 salt is shown in Fig.4.1.4. It is observed that the removal of sericin resulted in the separation of the individual silk filaments, which were glued together by sericin and sizing agents in the raw silk. This conferred on the fabric the denser texture and rough surface typical of light weight silk fibres. The dull appearance and stiff handle of the raw silk fibre disappeared, and the degummed silk became shiny, soft, and scroopy. Fig. 4.1.4(a) clearly confirms the presence of sericin stick as white spots to the surface of silk fiber. The presence of sericin in silk fiber is more when treated with 0.01M salt concentration showing non-uniform removal of gum from interlacing regions of fibers compared to the use of 0.03M salt concentration. So it is concluded that increase in concentration of Na_2CO_3 decreases the sericin content of silk fiber. The closer observation of SEM images of the silk fibroin fibre showed that the individual silk filaments split off and their surface

was clean and free of sericin. On the other hand, the presence of sericin on the fibre was observed when silk degummed with lower salt concentration. Furthermore, it is interesting to note that the deposits were mainly located at the cross over points between silk fibers making it stick together. The diameter of silk fibre was analysed and measured as 10-12 μm using SEM JEOL software.

4.1.2. Preparation of regenerated aqueous SF solution

The solubility of silk fibroin in ionic liquids depends on the identity of both the cation and anion, with the anion having a much larger effect. It is reported that more the cation and anion are able to participate in hydrogen bonding, the greater the solubility of the silk fibroin [Phillips et al., 1989]. Presumably, the ionic liquid disrupts hydrogen bonding present in the β -sheets. The solubility depends on various factors like temperature, salt concentration and exposure time. Therefore, the effect of these parameters on solubilisation of degummed silk fibre was investigated in this study.

4.1.2.1. Effect of temperature on solubilization

The effect of temperature on solubility of protein is shown in figure 4.1.5. It is observed that the solubility is steadily increased with increases in temperature from 50 to 70°C and then becomes almost constant with further increase in temperature. However, the complete dissolution of silk fibre occurs at 70°C and higher temperature. Furthermore, though a reasonable solubilisation was obtained at 60°C, it was very difficult to separate SF solution. Thus, it is established that 70°C is the optimal temperature for dissolving degummed silk fibre.

Figure 4.1.4: SEM micrographs illustrating morphology of degummed silk fibre with (a) 0.01M Na_2CO_3 , shows comparatively incomplete removal of sericin. (b) 0.02M Na_2CO_3 , shows relatively smooth and individual longitudinal strands and (c) 0.03M Na_2CO_3 , shows individual longitudinal strands.

Figure 4.1.5: Effect of temperature on solubility of SF protein. A steady increase in solubility of silk fibroin is observed with temperature upto 70 °C

4.1.2.2. Effect of LiBr concentration on solubilization

The effect of LiBr concentration on solubility of protein is shown in Fig.4.1.6. LiBr is selected among other chaotropic reagents viz. CaCl_2 and NaSCN due to its higher dissolving ability as reported earlier [Addis and Raina, 2013]. The amount of protein present is more at 9.3M than obtained with other salt concentrations. So as the concentration of LiBr increases, the solubility of protein also increases. At concentration of 9.1M, protein concentration is 1.4 mg/ml that increases to 1.7 mg/ml at 9.3M concentration. There is no further increase in protein concentration beyond 9.3M. An increase in solubility is observed upto 9.3M that may be due to enhanced breaking of disulfide bonds between the heavy and light chains of silk fibroin [Kweon et al., 2001]. A comparable protein concentration is also obtained with LiBr concentration of 9.4M and 9.5M. However, the maximum protein concentration is obtained with 9.3M LiBr concentration. The slight decrease in protein concentration may be due to increased partial molar concentration of salt in solution.

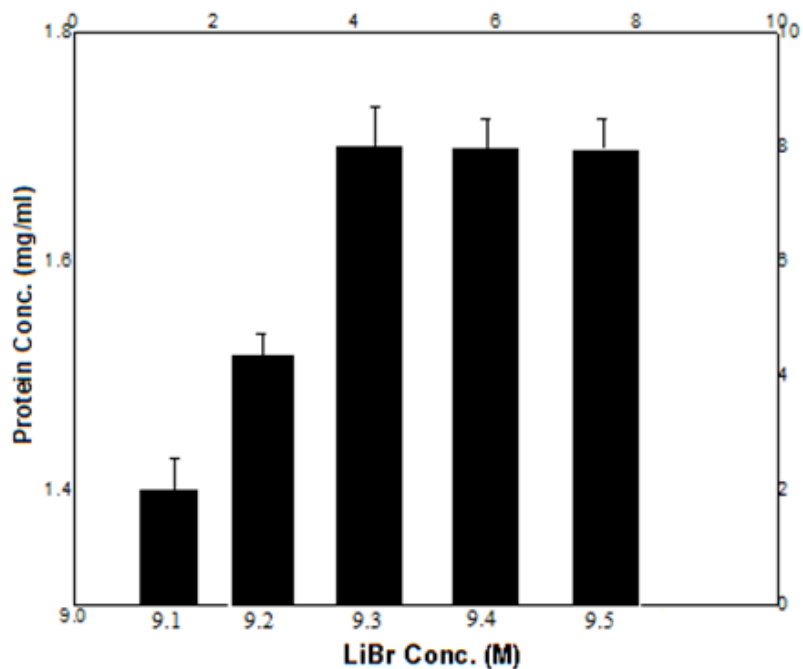

Figure 4.1.6: Effect of LiBr concentration on the solubility of protein. Protein concentration increases with increase in concentration of LiBr upto 9.3M and then a decline in trend is observed.

Figure 4.1.7: Effect of exposure time on dissolution of silk fibroin. Figure shows a steady increase in dissolution of SF with treatment time 1-3 h achieving maximum dissolution and no significant change is observed beyond 3h.

4.1.2.3. *Effect of exposure time on solubilization*

The exposure time facilitates the solute with thermal energy to break bonds that binds molecules together. More is the exposure time, more of the heat energy accumulates to break inter and intra-chain covalent bonds in silk fibroin. Therefore, the effect of exposure time on solubilization of degummed silk fiber was studied with 9.3M LiBr solution at 70 °C. As it is indicated in Fig. 4.1.7, the SF concentration found to increase with increase in exposure time from 1-3 h. There is no further increase in SF concentration observed beyond 3 h of exposure.

4.1.3. **Characterization of regenerated aqueous SF solution**

During dissolution of degummed silk fiber in LiBr, the amide bonds of fibroin molecular chain is reported to cleave to a different extent resulting in easy solubilization in water. This regenerated silk fibroin is easily denatured and gelled by various factors [Zhang et al., 2005]. Besides temperature and pH, the stability of silk fibroin solution largely depends on its molecular weight [Zhang et al., 2005]. The particle size measurement of polymeric materials confirms the structural stability in solution and provides a high degree of control over processed material performance [Horiba Scientific Inc., 2012]. The prepared SF aqueous solutions were kept at 4°C and characterized by SDS-PAGE and particle size analysis within a month. Fig. 4.1.8a (SDS-PAGE) shows a smear band of silk fibroin corresponding to molecular marker ranging between 200 kDa to 30 kDa. As the result indicates that the regenerated protein solution are composed of a mixture of polypeptides with different molecular weights. A broad dull band at 200 to 35 kDa and dense band at 25 kDa are observed in Fig. 4.1.8a. The former band may be attributed to the degradation products of heavy chain (350 kDa) formed by the cleavage of amide bonds of raw silk protein, while the band at 25 kDa corresponds to light chain of raw silk protein. The result is further confirmed by particle size analysis of silk fibroin solution as shown in Fig. 4.1.8b. The particle size distribution profile is observed to be binodal, with peaks at around 100nm and 5µm. Since particle size of the starting SF solution is disintegrated due to extraction process with salts, the result shows the presence of light chain (25 kDa) with disintegrated heavy chain(350 kDa) [Horan et al., 2005].

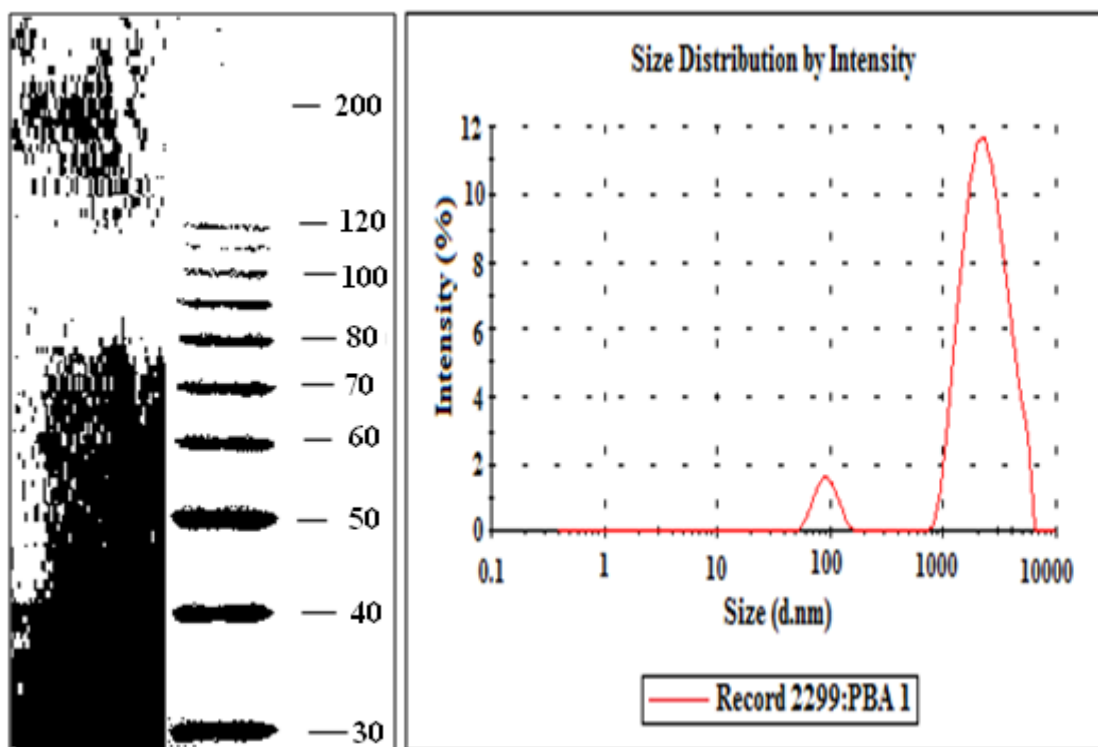

Figure 4.1.8: (a) SDS-PAGE (12% gel) of silk fibroin protein. Marker and fibroin lanes mean the standard protein ladder from 10 to 200 kDa (Gibco Co., USA) and molecular mass range of silk fibroin, respectively and (b) Particle size distribution of silk fibroin.

4.1.4. Optimization of SF extraction by RSM

The optimization of any process using response surface methodology (RSM) is more advantageous than the traditional single parameter optimization in terms of saving time, working space and raw material. Therefore, an attempt has been made in the present study to establish the optimum conditions of key variables for maximum SF protein extraction. The process variables used are the Na_2CO_3 concentration (X_1), LiBr concentration (X_2) and temperature for dissolution (X_3). All the experiments were conducted for optimizing the three individual parameters using Box–Behnken design (Table 4.1.1). The results were analyzed by multiple regression analysis. Table 4.1.2 shows the experimental conditions and results of extracted SF yield based on the factorial design. Maximum yield of protein (2.10 mg/ml) was recorded under the experimental conditions of Na_2CO_3 concentration 0.01 M, LiBr concentration 9.10 M, and temperature 70°C .

To decide about the adequacy of the model for SF yield, three different tests such as Sequential Model Sum of Squares, Lack of Fit Tests and Model Summary Statistics were carried out and p values for all the regressions were found to be lower than 0.01 (see Tab. 4.1.2). This means that at least one of the terms in the regression equation had a significant correlation with the response variable. The model summary statistic showed the highest regression coefficient as $R^2 = 0.9761$ for the quadratic model with minimum standard deviation of 0.041. ANOVA analysis confirmed that

the form of the model chosen to explain the relationship between the factors and response is validated [Tarangini et al., 2009].

Table 4.1.2: Box–Behnken design matrix of the three variables in coded units along with the experimental and predicted values of protein yield

In order to determine the significance of quadratic model, ANOVA analysis was done. The p -values were used as a tool to verify the significance of each coefficient, which also indicates the interaction strength of each parameter. The smaller the p -values are, the bigger is the significance of the corresponding coefficient [Zhao et al., 2009]. Here, the p -value of the model is found to be smaller than 0.0001, which indicates that the model is suitable for use in this experiment. The P -value of “lack of fit” is 0.64 ($p > 0.01$), which indicates that “lack of fit” is not significant relative to the pure error. The coefficient of determination (R^2) and adjust coefficient of determination

($Adj.R^2$) are shown in Table 4.1.3. The values indicate that the accuracy and general availability of the polynomial model are adequate [Tarangini et al., 2009]. The regression coefficients and the corresponding p -values are presented in Table 4.1.4. From the p -values of each model term, it is concluded that three linear coefficients (X_1, X_2, X_3), three quadratic coefficients (X_1^2, X_2^2, X_3^2), and three cross-product coefficients (X_1X_3) are significant. Using the designed experimental data (Table 4.1.1), the polynomial model for the protein extraction was regressed as follows (in terms of actual factors):

$$Y = -132.13 - 16.70X_1 + 29.08X_2 - 0.02X_3 + 1130X_1^2 - 1.62X_2^2 - 4.32E - 004X_3^2 + 0.01X_1X_3 \quad (3)$$

Table 4.1.3: Analysis of variance for the fitted quadratic polynomial model for protein yield

A normal probability and a dot plot of residuals are shown in Fig. 4.1.9. The data points on this plot lie reasonably close to a straight line, indicating that X_1 , X_2 , X_3 , X_1^2 , X_2^2 , X_3^2 , and X_1X_3 are the only significant effects and that the underlying assumptions of the analysis are satisfied. Fig. 4.1.10 shows the relationship between the actual and predicted values of Y for protein extraction from *Bombyx mori* silk cocoon. It is observed from Fig. 4.1.9 that the developed models are adequate as indicated by the residuals for the prediction of each response are minimum.

Figure 4.1.9: Normal % probability versus residual error

Figure 4.1.10: Scatter diagram of predicted versus actual response for silk fibroin extraction

Many parameters can influence the extraction of protein. Eq. (3) shows that the yield of SF protein has a complex relationship with independent variables that encompass both first and second-order polynomials and may have more than one maximum point. Fig. 4.1.11 represents the effects of Na_2CO_3 concentration, temperature and their reciprocal interactions on protein yield. The degumming SF yield is shown to increase with increase in temperature at constant Na_2CO_3 concentration. However, the maximal SF protein yield is obtained at of $85^\circ C$. Fig. 4.1.12 shows the effects of $LiBr$ concentration, temperature and their reciprocal interactions on protein yield. At a high temperature, the SF yield is increased with increase in temperature.

Figure 4.1.11: Response surface plots representing the effect of Na_2CO_3 concentration and temperature and their reciprocal interaction on SF yield

Figure 4.1.12: Response surface plots representing the effect of LiBr concentration, temperature and their reciprocal interaction on SF yield

4.1.5. Validation of the model

The optimal values of the selected variables were determined by solving the regression equation (Eq. 3) using Design-Expert 6 software. The optimal conditions for SF protein yield estimated by the model equation are as follows: Na_2CO_3 concentration, $X_1= 0.01$ M, LiBr concentration, $X_2= 9.23$ M and temperature, $X_3= 85^\circ\text{C}$. The theoretical protein yield (Y) predicted under the above conditions is 2.09 mg/ml. In order to verify the prediction of the model, the optimal reaction conditions were applied to three independent replicates for protein yield. The average protein yield is measured as 2.1 ± 0.01 mg/ml which is quite matching with the estimated value using model equation. This demonstrated the validation of *RSM* model. The good correlation between these results confirmed that the response model is adequate for reflecting the expected optimization. The results also suggest that the models of Eq. (3) are satisfactory and accurate.

PART II

Preparation, characterization and *in vitro* biocompatibility study of silk fibroin hydrogel

Hydrogels are three-dimensional polymeric networks that are prepared by physical or chemical crosslinking and resist swelling in aqueous solution without dissolving in it [Vepari et al., 2007; Lee et al., 2001]. Since hydrogels are highly hydrated hydrophilic polymer networks that contain pores and void spaces between the polymer chains, it can be implanted for tissue restoration or local release of therapeutic factors. Such hydrogels are biocompatible and provide many advantages over the conventional solid scaffold materials, including an enhanced supply of nutrients and oxygen for the cells and space to cells for proliferation and expansion. Due to their high water content, hydrogels have similarities to some tissues and extracellular matrices (ECM) [Park et al., 1992]. Because of this property, hydrogel has been considered as an attractive biomaterial and widespread research is under way on using hydrogels as scaffold materials for possible application in tissue engineering. Hydrogels prepared from a variety of polymers such as alginates, chitosan, and collagen have been studied for use as scaffold material [Lee et al., 2001; Drury et al., 2003]. Hydrogels made from synthetic polymers offer the benefit of gelation and gel properties that are controllable and reproducible through the use of specific molecular weights, block structures, and modes of crosslinking. However, the less biocompatibility and use of toxic reagents for their preparation limit their applications. Generally, gelation of naturally derived polymers is reported to be less controllable, although their hydrogel forms are reported to be more compatible for hosting cell and bioactive molecules [Lee et al., 2001; Smidsrod et al., 1990]. Injectable biomaterials for tissue engineering are defined as cell seeded engineered scaffolds that directly injected at the site of defect. Such fluidly material takes the complex shape of site, fixes it and exchanged with body fluid while the seeded cells proliferate and differentiate to form tissues. Such approach in tissue engineering has been reported to reduce surgical operations [Balakrishnan et al., 2005; Kretlow et al., 2007]. Therefore, in this part of thesis work, efforts have been given to examine the processability of concentrated aqueous silk fibroin solutions into highly porous gel sponges and study their properties for possible tissue engineering applications.

4.2.1. Morphological Study

Morphologically, the hydrogels shows a sponge-like cross-linked structure formed by physical entanglement as well as chemical hydrogen and covalent bindings. Water-stable hydrogels were formed from SF aqueous solutions after 24 h of incubation that leads to the formation of porous matrices. The formation of porous matrices is due to the induction of a sol-gel transition in concentrated solution sample [Garg et al., 2012].

Figure 4.2.1: (a) Simple vertical view and (b,c,d) microscopic images of SF hydrogel obtained from 12% (w/v) aq. SF solution, when kept at 20°C for 3 days observed at magnification (b) 5X, (c) 10X and (d) 20X

Figure 4.2.2: SEM images of (a) porous lyophilized hydrogel with leaf-like structure prepared from 4 wt % SF and (b) hydrogel sponge prepared from >12 wt % SF solutions.

Regenerated silk fibroin solution when kept at 20°C in humid environment for more than 72 h, the solution was converted into gel and ultimately hydrogel (thermgel) formed. The process was induced by adding a few drops of methanol as crystallinity inducing solvent. The silk hydrogel intact in shape is formed and stabilized due to inter-networking. The gel doesn't lose its integrity when kept vertically as shown in Fig. 4.2.1(a). Fig. 4.2.1(b, c, d) is a representative optical micrograph of prepared silk fibroin hydrogel sample. Morphological study of silk fibroin porous matrices are observed by SEM (Fig. 4.2.2(a, b)) after lyophilizing the hydrogel samples at -80° C. Lyophilized hydrogels prepared from silk fibroin solutions of 4-12 wt% concentration showed leaf-like morphologies while sponge-like structures were observed with concentration more than 12 wt%. This is in good agreement with the observation reported earlier [Kim et al., 2004]. The sponge-like structure is more liable to be applicable for tissue regeneration as it provides better niche and channel for cellular activities.

4.2.2. Swelling Property

The swelling state of the polymer is reported to be important for its bioadhesive property [Smart et al., 1984; Smart et al., 2005]. It is also reported that the molecular structure of fibroin doesn't change by change in water content of the gel, while the physical properties of the gel changes significantly [Ayub et al., 1993]. Therefore, the swelling behavior of the prepared hydrogel was studied and the experimental data is tabulated in Table 4.2.1. It is observed that water uptake by hydrogels increased with time until equilibrium is reached at 24 h. The swelling was found to occur uniformly in all direction with increase in volume and change in physical appearance from translucent to opaque and semi-fluid was observed (Fig. 4.2.3).

Figure 4.2.3: Pictorial view of (a) dehydrated and (b) swollen SF hydrogel

The dehydrated gel is found to be non-brittle representing the presence of water molecule to maintain equilibrium with respect to physical properties of the gel. The gel became brittle when it was dehydrated in oven. The higher swelling rate at the initial stage indicates the sucking of water molecules into the collapsed gel and adsorption of water over the dried surface of gel. Though the swelling ratio increased with increase in time of soaking, a decline in rate is observed beyond 16 h and the rate becomes constant with further increase in time. Therefore, the maximum swelling index of 286.7 is obtained at 16 h (Table 4.2.1). No further change was observed beyond 24 h of soaking which may be due to the entry of water molecule at a slower rate to the collapsed gel network.

Table 4.2.1: Swelling behaviour of dehydrated SF hydrogel in water at different time period

Time (h)	Weight of gel (mg)	Swelling Index (%)
0	77.19	0
2	135.12	75.05
4	244.14	216.28
16	298.54	286.76
24	301.12	290.1
28	301.15	290.14
32	301.155	290.15
36	301.155	290.15

4.2.3. Thermo-rheological Behavior

The thermorheological behavior of prepared SF hydrogel was examined by measuring shear stress and viscosity at 5 degrees interval. Fig.4.2.4 shows the changes in viscosity with temperature. Thermal behavior of SF samples recently studied through differential scanning calorimetry (DSC) depicts a broad endotherm with a peak near 45°C indicating gradual structural change with increase in temperature and a new structure is formed above 45°C. This thermal behavior shows consistency with the viscoelastic behaviour of SF hydrogel. Preliminary ATR FT-IR studies have indicated that the fraction of antiparallel β -sheet conformation appreciably increased at 45°C [Ochi et al., 2002]. Irreversible structural change could be considered as a reason to the observed thermoreheological behavior.

Figure 4.2.4: Thermo-rheological behavior of SF hydrogel

Fig. 4.2.4 shows the linear proportionality between viscosity and temperature at the low shear rate region less than 100 s^{-1} . It has been reported that the rheopectic fluids increase their viscosity over time with application of shear forces, while thixotropic fluids have a reversible time-dependent loss of viscosity accompanying the application of shear force [Miller et al., 1960]. If the time-dependent

loss of viscosity is nonreversible, the fluid is considered to have rheodestructive properties. The present study shows that the prepared gel exhibits rheopectic and either thixotropic or rheodestructive properties. Furthermore, repeated observation reveals that continuous swirling of the mixture leads to an irreversible decrease in the viscosity. Therefore, the time-dependent reduction in viscosity of gel is rheodestructive rather than thixotropic.

4.2.4. Structural Analysis

Structural characterization of silk fibroin fibre and lyophilized hydrogels were performed by X-ray diffraction and FTIR analysis. The XRD patterns and FTIR peaks of degummed silk fiber and lyophilized RSF hydrogel are shown in Fig. 4.2.5 & 4.2.7 respectively.

4.2.4.1. XRD Analysis

X-ray profiles of lyophilized hydrogels prepared from aqueous SF solutions are shown in Fig. 4.2.5. It has been reported that when silk fibroin solutions freeze, below the glass transition temperature between -34°C & -20°C , the protein structure doesn't change significantly [Li et al., 2001]. The amorphous structure of lyophilized SF hydrogel samples are indicated by the exhibition of a broad peak at around 20° [Magoshi et al., 1996]. Silk fibroin hydrogels showed a distinct peak at 20.6° and two minor peaks at around 9° and 24° , that is very similar to β -sheet crystalline SF structure (Silk I) [Ayub et al., 1993; Asakura et al., 1985]. X-ray diffraction result shows that the gelation of silk fibroin solutions induced a transition from random coil to β -sheet conformation (Fig. 4.2.6) which is also reported in published literature [Hanawa et al., 1995; Ayub et al., 1993; Kang et al., 2000].

Furthermore, the regenerated silk fibroin (RSF) hydrogel (line b in Fig. 4.2.5) shows more amorphous state, while the degummed silk fiber (line a in Fig. 4.2.5) shows a typical X-ray diffractogram of β -sheet crystalline structure, depicting four diffraction peaks at 18.9° , 20.6° , 24.3° and 28.1° , corresponding to β -sheet crystalline spacing of 4.69° , 4.31° , 3.66° and 3.17 \AA , respectively [Ayub et al., 1993; Asakura et al., 1985]. While the lyophilized fibroin hydrogel shows the characteristic peak at 20.6° . Other peaks corresponding to degummed silk fibre is not visible indicating the more α -helical secondary structure. In conclusion, the processing of silk fibroin results in a loss of β -sheet structure thus making it more biodegradable and lower mechanical strength.

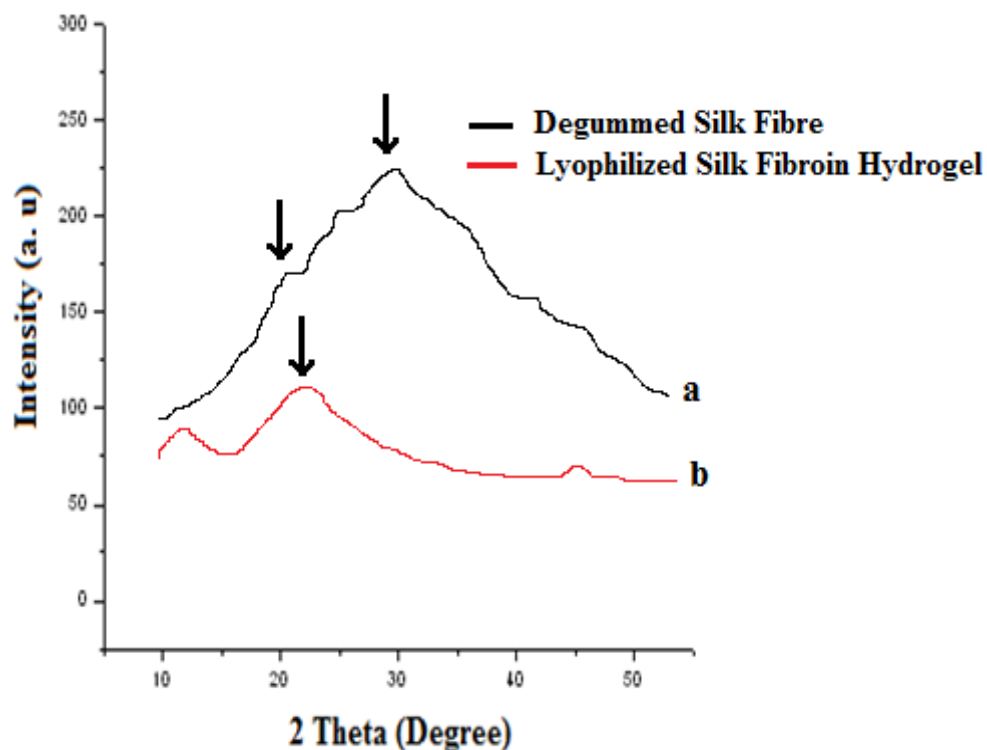

Figure 4.2.5: X-ray diffraction of (a) degummed silk fiber and (b) lyophilized SF hydrogel. RSF hydrogel (line b; 18.9°, 20.6°, 24.3° and 28.1°) shows more amorphous state, while degummed silk fiber (line a; 4.69°, 4.31°, 3.66° and 3.17 Å) shows a typical X-ray diffractogram of β -sheet crystalline structure.

Figure 4.2.6: Sol-gel transition of silk fibroin. Figure depicts the formation of silk fibroin hydrogel with a stable and irreversible intermolecular β -sheet structure.

4.2.4.2. FTIR study

IR spectrum represents typical absorption bands sensitive to the molecular conformation of SF. Therefore, in order to confirm the conformational changes of SF, FTIR spectroscopy of degummed silk fibroin and lyophilized silk fibroin hydrogel was performed and the results are shown in Fig. 4.2.8. Silk protein exists in three conformations, namely, random coil, silk I (R form), and silk II (β -sheet) [Um et al., 2001]. The absorption bands at 1657, 1525, 1245 and 651 cm^{-1} which correspond to amide I, amide II, amide III & amide V bands, respectively, confirm that the degummed silk fiber is mainly in β -sheet conformation similar to the native silk fibre [Mandal et al., 2008a; Mandal et al., 2008b]. The corresponding peaks of silk fibroin lyophilized hydrogel are observed at 1625, 1509, 1245, 667 cm^{-1} respectively indicating the β -sheet conformation at the end of processing through regeneration, gelation and lyophilization. Besides, few more peaks were found in lyophilized fibroin powder at frequencies corresponding to 1327-1393 cm^{-1} indicating stretched C-O bonding and thus relatively unstable state. All the peaks observed in three amide band regions varied in their width and intensities.

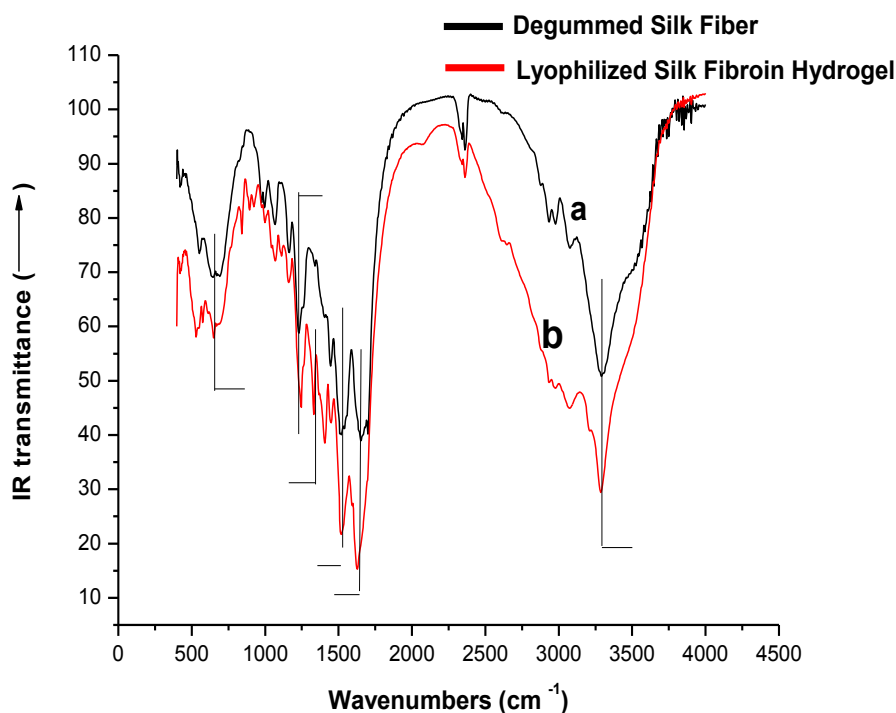

Figure 4.2.7: FT-IR spectra of (a) degummed silk fibers and (b) lyophilized SF hydrogel

4.2.5. Thermal Analysis

The thermal behavior of degummed silk fibre and fibroin hydrogel were assessed by TGA and DSC. Degummed *B. mori* silk fibre and lyophilized fibroin hydrogel showed different thermogravimetric curves. As indicated in Fig. 4.2.8, the initial weight loss below 100 °C may be due to the water evaporation [Um et al., 2001]. At temperature above 200°C, the weight loss is observed to occur again. However, silk fiber did not completely decompose even at 700°C. It is evident from result that silk fibre underwent at least three thermal decomposition stages in the temperature range 200-300°C, 300-350°C and 350-400°C. A similar decomposition pattern is also observed with lyophilized hydrogel. However, the rate of degradation is comparatively faster in case of SF hydrogel.

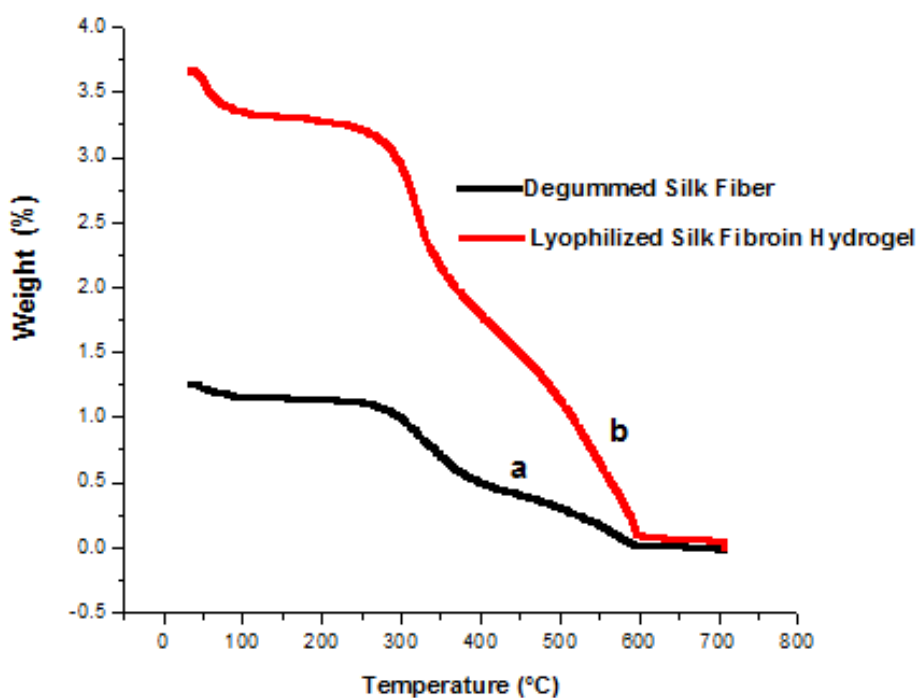

Figure 4.2.8: TGA curves of (a) degummed silk fibers and (b) lyophilized SF hydrogel

The decomposition at approximately 300°C may be attributed to a disintegration of the intermolecular side chains during the crystalline melting process, while that at around 400 °C due to a main chain disintegration, coupled with simultaneous carbon atom rearrangements [Hirabayashi et al., 1974]. It has been reported that the decomposition at 300°C indicates the low crystallinity of the unoriented β -type configuration and, thus it can be concluded that there is less possibility of obtaining a crystalline β -structure, which occurs in the temperature range 325-330 °C. Furthermore,

the low weight loss at 400°C observed with gels may be due to its low water content. This suggests that the fibroin molecules come to close contact with each other during lyophilization process and form a dense aggregate which could mechanically resist the carbon atom rearrangements, thus resulting in low weight losses. This phenomenon of the fibroin molecules could be a possible reason for the lyophilized fibroin gel.

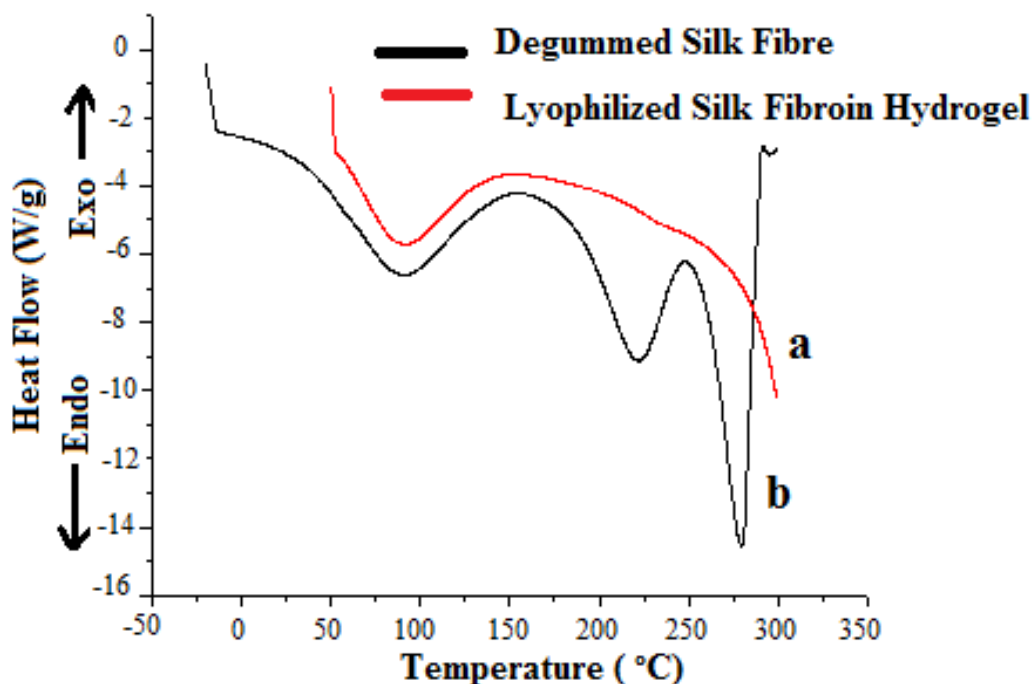

Figure 4.2.9: DSC curves of (a) degummed silk fiber and (b) lyophilized SF hydrogel

Thermal analysis of degummed silk fibroin and lyophilized fibroin hydrogel has shown different thermal calorimetric curves (Fig. 4.2.9). In the DSC curve of degummed silk fiber, an endothermic peak is observed to start at 56.8 °C and reached maximum at 76.3 °C without any trace of exothermic transition which may be due to β -sheet structure of the sample. Whereas the DSC curve for lyophilized fibroin hydrogel starts at 35.4 °C and reached maximum at 67.7 °C. This difference in results may be attributed to the change in β -sheet conformation. A conformational change through the crystallization of SF from random coil to β -sheet causes an exotherm curve to exist [Chen et al., 2012]. As indicated from DSC curves, two exothermic peaks are observed at around 166 °C and 255 °C which can be attributed to the conformational change to β -form, while two endothermic peaks observed around 220 °C and 286 °C may be because of the conformational

change of β -form into random coils. The exotherm at 220°C indicates the crystallization of the fibroin random coils to α -form of crystals. The decomposition peaks of all the regenerated fibroins (endotherms around 290 °C) are lower in comparison to the original silk fiber [Warwicker et al., 1954], indicating the lower thermal stability of regenerated samples. The low thermal stability may be due to lower crystallinity as well as decrease in molecular weight during the degumming process of the regenerated SF.

4.2.6. *In vitro* Biocompatibility Study

Human mononuclear cells (hMNCs) have been successfully encapsulated in various hydrogel systems due to the potential regeneration of damaged tissue and prolonged drug release [Liang et al., 2011]. In this work hMNCs were isolated for the study of cytocompatibility of SF hydrogels. Due to physical limitation of silk hydrogel prepared from SF with low concentration (< 4% (w/v)), the hMNCs were encapsulated in hydrogel system with higher concentration (prepared from SF aq. solution of concentration >4 % (w/v)).

The success of tissue engineering biomaterials not only relies on the non-toxic supportive structure for cell adhesion but also on facilitating cell proliferation. The microscopic images (Fig. 4.2.10) of cells proliferated on hydrogel were taken on consecutive days. Cell size and number were observed to increase with culture period while maintaining the round shape. Fig. 4.2.11 shows the uniform adherence and spreading of mononuclear cells over fibroin hydrogel. The cells are found to be embedded in SF gel matrix. Detachment of cells from the substratum is observed to be minimal after 2 days *in vitro* cultivation. The morphology of monocytes during *in vitro* cultivation was observed by phase-contrast microscopy. The cells are found to retain round shape and homogenous distribution at day 1 (Fig. 4.2.10a & 4.2.10b) and the cells retained their original round shape (Fig. 4.2.10c) at day 3. Initially, the monocytes were found to be small (7-9 μ m) [Birmingham et al., 1980] and rounded with cytoplasmic spreading.

A progressive enlargement of monocytes occurs in culture with increasing granulation and vascularization of the cytoplasm. After 1 week of cultivation, the monocytes are observed approximately twice the size of freshly isolated monocytes (Fig. 4.2.10d). With 4% gel, cell numbers are observed to be stopped increasing after 7 days which may be due to limiting spatial and nutrition, indicating that maximal level of cell proliferation is reached (Fig. 4.2.11). The SEM

of hMNCs laden SF hydrogel is depicted in Fig. 4.2.12. Similar observations are found with hydrogel systems such as alginate and PEGs reported earlier [Ramdi et al., 1993; Nuttelman et al., 2006]. However, the morphology of hMNCs encapsulated in $> 4\%$ gel is found to change drastically leading to cell death, aggregated and/or dissolved, as evident from the empty cavities in histological images (Fig. 4.2.13). The loss of cellular activity with higher gel concentration is most likely due to mechanical restrictions and mass transport limitations.

Figure 4.2.10: Microscopic images of hMNCs encapsulated and cultured in SF hydrogels prepared from aqueous SF solution at concentration 4% (w/v) after day 1 (a,b), 3 (c), and 7 (d). hMNCs retained round shape morphology and nonaggregated in the gel as compared to floating cell clusters in day 1 (Fig. a). Bar = 100 μm in all images. The viable cells can be seen as bubbles rounded with trypan stain indicated by arrows.

Figure 4.2.11: Micrographs of hMNCs adhered on the hydrogel surface observed by phase contrast microscope at different magnification (5X, 10X, 20X)

Figure 4.2.12: SEM Morphology of cell encapsulated in SF hydrogel

Figure 4.2.13: Micrograph of hMNCs seeded fibroin hydrogel (prepared from >4% (w/v) SF solution) cultured over 2 weeks. Empty cavities are clearly visible indicating non-supportive behavior towards cell proliferation.

PART III

**Development of porous SF scaffolds with and without SEP
conjugation**

A number of surface modification methods that involve the use of radiation [Mathew et al.; 2013] or a variety of bioactive molecules [Son et al., 2008; Mann et al., 2002; Yang et al., 2001; Lee et al., 2000] have been the choice of many researchers to improve scaffold material characteristics. Different bioactive molecules (RGDs and other short repetitive peptide chains) have been immobilized physically or chemically on polymeric scaffolds [Mann et al., 2002; Yang et al., 2001], and amphiphilic block polymers as additives [Lee et al., 2000]. In this study, we used soluble form of egg shell membrane protein (SEP) for surface modification of the developed SF scaffold. To the best of our knowledge, this is the first report of modifying the surface of porous SF scaffold with SEP. The reason behind the selection of eggshell membrane (ESM) biopolymer is the long history of SEP used in Chinese medicine prescribed as, Bencao Gangmu for injuries. Eggshell membrane (ESM) is a double layered insoluble and semipermeable sheet located between the eggshell and egg white [Carrino et al., 1996], and is functionally behave as scaffold for biomineralization to develop egg shell and chick embryo [Nakano et al., 2003; Tsai et al., 2006; Rose and Hincke 2009]. ESM consists of 70% organic, 10% inorganic and 20% water. The major organic components includes insoluble proteins, such as collagens (type I, V, and X), osteopontin, and sialoprotein [Nys et al., 2001], alongwith a small amount of carbohydrates and lipids [Suyama et al., 1977; Baker et al., 1962]. Previous studies have developed SF scaffolds with defined small pore sizes with limited inter connections [Nazarov et al., 2004], or large (>500 μ m) with well connected pores [Kim et al., 2005c]. Attempt has been made in the present study to fabricate 3-D SF scaffolds with improved surface characteristics using SEP as bioactive molecule. The SEP conjugated SF scaffolds were further evaluated to assess the improvement in their physico-chemical and biochemical characteristics in terms of biodegradability, thermal stability, compressive strength, cell adhesion and proliferation property. Thus it is expected to obtain a novel scaffold with improved bioactivity for its potential use in tissue engineering.

4.3.1. Morphological Study

The light milky white colored fibroin solution (12% w/v), observed under phase contrast microscope shows a porous wet matrix and that of ESM membrane as a bed of granular particles as shown in Fig. 4.3.1a and 4.3.1b. The SEM images of degummed silk fibroin (Fig. 4.3.1c) reveal the fibrous nature of starting material, while ESM (Fig. 4.3.1d) structure as membrane fiber embedded in white collagen-like matrix. ESM fibers come out from the tubular gland cells present in oviduct and wrap

the surface of rotating egg white protein followed by the deposition of mineralized shell as reported earlier [Burley et al. 1989; Kodali et al., 2011]. Thus after peeling off the eggshell from the membrane, it doesn't contain any CaCO_3 as observed in Fig. 4.3.1d. This is further confirmed by elemental (Table 4.3.1) and XRD (Fig. 4.3.5) analysis.

Figure 4.3.1: Microscope images of (a, b) SF hydrogel and (c,d) ESM by (a,c) phase contrast microscope and (b,d) SEM

4.3.2. Pore size and Porosity

SF scaffolds with varying pore size and porosity were prepared using NaCl as porogen from 4-6% SF solution by salt leaching method following the procedure published earlier [Lee et al., 2000]. Table 1 show the pore size and porosity of the scaffolds prepared under study. The pore size was measured from SEM images as shown in Fig. 4.3.2. The particle size of porogen is shown to have a great influence on the pore size and porosity of scaffolds. Scaffolds with pore size in the range of 30 to 350 μm were obtained using porogen of size < 100 μm (Fig. 4.3.2a), 100-200 μm (Fig. 4.3.2b), 200-300 μm (Fig. 4.3.2c) and 300-500 μm (Fig. 4.3.2d). The porosity and pore size of scaffolds were obtained in the range of 81-93% and 30-350 μm respectively using porogen of the size range 100-500 μm . Particle size below 100 μm and above 500 μm (data not shown) is not found

to be favorable for scaffold due to the limitation in pore interconnectivity [Hulbert et al., 1970]. The pore size of the scaffolds is 10–20% smaller than the particle size of NaCl used which may be due to the partial dissolution of the crystal surface. The recommended pore size for a scaffold system based on cell size and migration is minimum 100 μm as reported earlier [Hulbert et al., 1970]. However, subsequent studies have shown better vascularization and cell migration in implants with pore size $>300 \mu\text{m}$ [Karageorgiou et al., 2005; Murphy et al., 2010; deGroot et al., 1996]. In previous studies, aqueous-derived SF scaffolds prepared with different particle size range of NaCl resulted in similar trend in pore size and supported cell migration and enhanced vascularization during tissue regeneration [Zhou et al., 2009; Kim et al., 2005; Altman et al., 2003].

Figure 4.3.2: SEM of SF scaffold prepared by salt leaching method using NaCl as porogen of different particle size range: (a) $< 100 \mu\text{m}$ (b) $100\text{-}200 \mu\text{m}$ (c) $200\text{-}300 \mu\text{m}$ (d) $300\text{-}500 \mu\text{m}$

Table 4.3.1: Pore size and porosity of SF and SEP-SF scaffolds prepared with RSF 4-6% (w/v) using NaCl as porogen (n=3)

Sample	NaCl particle size	Pore Size	Porosity	Remarks
SF	<100 μm	30-70 μm	85-88 %	Not interconnected
SF	100-200 μm	90-150 μm	81-86 %	Interconnected and suitable for skin TE [Yang et al., 2002]
SF	200-300 μm	140-230 μm	87-89%	Interconnected but moderate applicable for osteogenesis [Murphy et al., 2010]
SF	300-500 μm	225-350 μm	90-93%	Interconnected and more applicable for osteogenesis and chondrogenesis [Murphy et al., 2010; deGroot et al., 1996]
SEP-SF	300-500 μm	200-300 μm	85-90%	Interconnected and more applicable for osteogenesis and chondrogenesis [Murphy et al., 2010; deGroot et al., 1996]

4.3.3. SEP conjugated SF scaffold

The SF scaffold with pore size 225-350 μm were further modified with SEP as bioactive material. As a chemical crosslinker, EDC reacts with the carboxylic acid groups of peptide chain which can then bind to the amino group in the reaction mixture of SEP, loaded in SF scaffold. The detailed mechanism of EDC/NHS crosslinking (Fig. 4.3.3) is reported in the published literature [Burdick et al., 2011]. The SEM image (Fig. 4.3.4) shows the porous structure of SEP-SF scaffold. It is observed that the pore size and porosity of the scaffold are not much affected by the conjugation with 2% (w/v) SEP. The pore size of the modified scaffold was obtained in the range 200-300 μm with porosity approximately 85-90%. The slight reduction in porosity and pore size may be due to blockage of pores after SEP conjugation. However, the scaffold has desired pore size and porosity to be used for tissue engineering applications.

Figure 4.3.3: Mechanism of SEP conjugated with SF scaffold

Figure 4.3.4: SEM of SEP conjugated SF scaffold

4.3.4. Elemental Analysis

The elemental analysis was done to measure the elements of SF, SEP and SEP-SF scaffolds. Each analysis was performed in triplicate and average value is shown in Table 2. The elemental composition of SF and SEP are very close to the experimental data published by wang et al. [Wang et al., 2011] and Yi et al. [Yi F. et al., 2004]. The elemental composition of SEP-SF which lies in between SF and SEP indicates the immobilization of soluble eggshell protein throughout the SF scaffold.

Table 4.3.2: Elemental composition of SEP, SF and SEP-SF scaffolds

Sample	wt.(mg.)	C (wt. %)	H (wt. %)	N (wt. %)	O (wt. %)	S (wt. %)
SF	2.001	43.30	6.04	14.78	27.9	0.35
SEP	1.989	46.53	6.7	15.93	11.76	2.89
SEP-SF	2.015	45.33	6.51	15.11	22.7	0.93

4.3.5. Structural Analysis

4.3.5.1. XRD Analysis

The conformational changes during the processing for scaffold fabrication were confirmed by analysing X-ray diffraction patterns of SEP and SF scaffolds as shown in Fig. 4.3.5. According to the research on the molecular conformation of silk fibroin protein [Tao et al., 2007], the XRD patterns (Fig. 4.3.5a) is determined as 12.5° (2θ) for α -helix (Silk I) and 20.4° (2θ) for β -sheet structure (Silk II). The XRD curve of the conjugated SF scaffold (Fig. 4.3.5b) shows two peaks around 12.6° (2θ) and 20.5° (2θ) indicating the co-existence of α -helix and β -sheet with partially induction of α -helix to β -sheet due to SEP conjugation. The XRD pattern of SEP (Fig. 4.3.5c) holds a broad peak at 20.2° (2θ) indicating the amorphous nature of material and the absence of crystalline material (eg. CaCO_3).

Figure 4.3.5: XRD pattern of (a) SF scaffold; (b) SEP-SF scaffold and (c) SEP

4.3.5.2. FTIR Study

The chemical characteristics of functional groups exposed to the extracellular matrix (ECM) and cells were studied by FTIR spectra. As shown in Fig. 4.3.6, the amide I band ($1600\text{-}1700\text{ cm}^{-1}$) is associated with the stretching vibrations of carbonyl groups (C=O bond) along the polypeptide backbone [Payne and Veis, 1988] and has been found most important for infrared spectroscopic analysis of the proteins secondary structure [Surewicz and Mantsch, 1988]. The FTIR spectrum of SF scaffold shows strong absorption bands at amide I (1654 cm^{-1}), amide II (1519 cm^{-1}), amide III (1220 cm^{-1}) and amide V (555 cm^{-1}) which can be attributed to mainly random coil conformation and the helix. It is indicated that the formation of SF scaffolds from regenerated SF solutions induced a conformational transition from random coil to β -sheet. The FTIR spectrum of SEP shows the main absorption bands of amide A (3215 cm^{-1}), amide B (2126 cm^{-1}), amide I (1654 cm^{-1}), amide II (1545 cm^{-1}) and amide III (1253 cm^{-1}). Amide A and amide B bands are related to NH stretching coupled with hydrogen bond and CH_2 asymmetrical stretch respectively. Amide II is associated with NH bending and CN stretching. These results are very close to FTIR analysis curve

of collagen from yellow fin tuna dorsal skin as reported earlier [Wang et al., 2008]. The specific absorption peaks of SF scaffold and SEP are evident in the spectrum of SEP-SF scaffold, indicating conjugation. The amide B group (2126) of SEP is also found to be present in the conjugated silk fibroin. The characteristic amide groups of silk fibroin (amide I, 1654cm^{-1} and amide II, 1519cm^{-1}) [Gil et al., 2007] are also detected in the SEP-SF scaffold. These results confirm the proper conjugation of SEP to SF by covalent immobilization method. EDC/NHS as a zero-length crosslinking agent is used to link carboxyl groups of SEP and primary amines of SF. The results suggest that the SEP conjugated silk fibroin scaffold contains bioactive functional groups at the interface of surface and ECM/Cells.

Figure 4.3.6: FT-IR spectra of (a) SF scaffold, (b) SEP-SF scaffold and (c) SEP

4.3.6. Thermal properties

The thermal properties of SEP, SF and SEP conjugated SF scaffolds were investigated by standard DSC and TGA (Figs. 4.3.7-8) methods. The results indicate that the weight loss of SEP (Fig. 4.3.7a) starts at about 180°C whereas the weight loss is observed with SF scaffold at 200°C (Fig. 4.3.7a). A slight weight loss as observed below 100°C may be due to the evaporation of a small

quantity of water which is also reported by Kweon et al. [Kweon et al.,2001b]. The major weight loss with SEP is observed to occur in the temperature range of 230–400°C. However, a sharp and rapid weight loss is observed with SF scaffold at 330°C which may be due to the thermal degradation of SF protein. Thus the result indicates the high crystallinity and molecular configuration of SF proteins which is also supported by the result of structural analysis. The residues of both SEP and SF samples at 500°C is about 25%. Thus SEP is found to be thermally stable.

Figure 4.3.7: TGA curves (a) SF scaffold (b) SEP-SF scaffold and (c) SEP

Figure 4.3.8: DSC curves (a) SF scaffold (b) SEP-SF scaffold and (c) SEP

From DSC curve (Fig. 4.3.8), it is indicated that, the denaturation of SEP onset at 46.10°C and reaches maximum at 65.03°C. The thermal stability of ESM is associated with the temperature inside and outside of the body and directly linked with **amino acids** (proline and hydroxyproline) content [Wong et al., 1989]. The thermal analysis of SF scaffold showed a different thermal calorimetric curve as compared to SEP-SF scaffold. SF scaffold exhibited a weak endothermic peak around 100°C which is also indicated in the corresponding TGA curve. This phenomena may be due to the evaporation of low water content of SF scaffold [Kweon et al., 2001b]. The exothermic peaks at 220°C, attributes to the crystallization of thermally induced SF protein and due to β -sheet structure of samples [Chapter 4, Part III; Kweon et al., 2001b]. A slight upward shift of the decomposition peak for SEP conjugated SF sample (endotherms around 260°C) as compared to the SF sample indicate a little higher thermal stability of the conjugated samples. This higher thermal stability of conjugated scaffold may be due to higher crystallinity and higher molecular weight (because of the presence of stabilizing amino acids eg. proline and hydroxyproline) compared to SF scaffold. No denaturation of SF and SF-SEP scaffolds was observed in the temperature range of 30-40°C. Thus it has been demonstrated that the scaffolds are thermally stable at both room and body temperature.

4.3.7. Compressive Strength

Scaffold material must have required mechanical strength to withstand the cellular in situ growth and tissue organization. The mechanical strength was determined from stress–strain graphs of the prepared scaffolds as shown in (Fig. 4.3.9a and 4.3.9b). SF and SEP-SF scaffolds are shown to have different line patterns which are the typical characteristics of the elastic/plastic material. For both scaffolds investigated, the steepest portion of the stress-strain curve is occurred in the range of 0–2% strain. The uncoated fibroin scaffold breaks between 200 and 300 KPa with a strain of 1.8 to 2.2%. The mechanical resistance was increased after SEP coating, supporting breaking forces higher than 3 N and strain over 2.8%. However, the average compressive strength was found to be 279.8 ± 36.2 KPa for SF and 321.5 ± 42.2 KPa for SEP-SF scaffolds.

Figure 4.3.9: Stress-Strain Curve of (a) SF and (b) SEP-SF scaffolds

4.3.8. Swelling Behavior

Water molecules, the component of coordination bond act as swelling agent, are undoubtedly needed for the dissolution of silk fibroin. Fig. 4.3.10 shows the swelling behavior of scaffolds. As it is indicated from graph, swelling index of 60.3% is achieved after 30min of soaking and that has

been increased to 133.36% after 48 h. The similar trend was observed with SF scaffold modified with SEP as well with a slight increase in swelling index during the period of study. The increase in swelling index may be due to the enhanced hydrophilicity of scaffold surface after SEP conjugation.

Figure 4.3.10: Swelling behavior of SF & SEP-SF scaffolds

4.3.9. Biodegradability

From Fig. 4.3.11, the initial weight loss of 0.08% and 0.04% were observed with SF and SEP-SF scaffolds respectively. However, the maximum weight loss achieved is 1.89% and 2.38% for SF and SF-SEP respectively after 192 hrs. The increase in biodegradation in conjugated scaffold as compared to control may be due to enhanced hydrophilicity and partial surface erosion from scaffolds in PBS [Jia et al., 2008].

Figure 4.3.11: Biodegradability of SF & SEP-SF scaffolds

4.3.10. Hydrophilicity

The hydrophilicity of the scaffolds was evaluated by contact angle measurement between the scaffold and pure water droplet. It is observed that the initial contact angle of the SF scaffold was $62.4 \pm 1.5^\circ$, indicating the higher wettability of SF scaffold surface. The contact angle decreases after SEP conjugation to $52.7 \pm 1.0^\circ$ may be due to enhanced hydrophilicity of SEP material. It is evident that conjugation of SEP makes SF scaffold more hydrophilic suitable for cellular response in aqueous medium.

4.3.11. Characterization of MSCs

The morphology of UCB derived hMSCs passaged upto 4th cycle is depicted in Fig. 4.3.12. The fibroblast-like cells with protrusions as obtained were further characterized by FACS analysis. The immunophenotypic profiling of cell surface markers CD34, CD45, CD90 and CD105 on isolated hMSCs was done using flowcytometry analysis. Fig. 4.3.13 shows that the isolated and cultured cells from fourth passage were positive for CD90 and CD105 and the expression level were 98.3% and 98.7% respectively but negative expression for CD34 (1.39%) and CD45 (1.30%) confirming the characteristics of mesenchymal stem cells. The cultured MSCs were further used for *in vitro* cytocompatibility evaluation.

Figure 4.3.12: Morphology of cultured UCB derived hMSCs after passage 1(a, 200X; b, 400X), passage 2 (c, 400X; d, 400X), passage 3 (e, 200X; f, 400X) and passage 4 (g, 200X; h, 400X)

Figure 4.3.13: Surface marker expression of CD34, CD45, CD90 and CD105 for cultured hMSCs analysed via FACS (fluorescence-activated cell sorting) incubated with relevant cell surface antibody.

4.3.12. Cell Morphology in Scaffolds

The SEM images of cell-scaffold constructs are shown in Fig. 4.3.14. After one day of cell seeding, cells were started to adhere and aggregate in the pores of both SF and SEP-SF scaffolds. Though initially cell adherence followed the similar trend for both the scaffolds, however cell adherence and spreading were found to be spread uniformly throughout the SEP-SF scaffolds during 7 to 14 days culture than that in the case of SF scaffold.

Figure 4.3.14: SEM of cell-scaffold construct on day 3(a, b), 7(c, d) and 14(e, f) days of culture. Figure shows the progressive adherence of MSCs in SEP conjugated scaffolds (b, d, e) and control (a, c). SEP conjugated scaffolds shows early adherence and morphological changes in cell shape than control. After 14 day of MSCs culture in modified scaffold (f1, f2, f3) was compared with SF scaffold (e1, e2, e3). The cells are found to spread all over the scaffold as depicted from the SEM images. Scale bar= 10 µm (a, b, d, e3, f3); 50µm (c, e1, e2, f1, f2)

4.3.13. Cell Adhesion and Proliferation

Attachment and the proliferation of cells on a given substrate are fundamentals for a functional tissue engineering scaffold. The viability of cells cultured on the scaffold was determined based on the linear correlation between cell count and OD570 value of MTT formazan [Zund et al., 1999]. The number of cells were observed to be increased with increase in culture period as observed with both SF and SEP-SF scaffolds though at varying proliferation rate as shown in Fig. 4.3.15. The viability of the proliferated cells on the SF scaffolds was found to gradually increase from 0.191 ± 0.018 to 0.493 ± 0.015 during 14 days culture (Fig. 4.3.15). The proliferation rate was observed to be higher with SF-SEP scaffold achieving 0.675 ± 0.031 OD on day 14 compared to the proliferation rate achieved with SF scaffold used as control. Cells entrapped inside the scaffold without adherence didn't show much spreading and proliferation at all. The cells did not survive during further cell culture as indicated by MTT assay done on 3rd day. Cells adhered over the surface and inside the scaffold were found to be grown, proliferate and differentiate. However, confluence of large number of cells was observed on 7th day of culture covering entirely the conjugated scaffold as compared to the SF scaffold. After 14 days of culture, cells were more prominently and uniformly spread on the pore surface with flat morphology (Fig.4.3.14f). Thus it is demonstrated in this study that the modified SF scaffold is more effective than SF scaffold which is evident from an improved cell proliferation and cell viability observed during cell culture. This enhanced expansion of cell culture could be attributed mainly to the SEP mediated improved surface hydrophilicity rather than the scaffold morphological change, as there is no significant morphological change was observed using 2% SEP solution for surface modification.

Figure 4.3.15: Comparison of optical density of MTT formazan on SF and SEP-SF Scaffolds during culture period ($p < 0.05$, $n=3$)

4.3.14. ALP Activity Assay

The osteogenic differentiation of hMSCs on the SF and SEP conjugated SF scaffolds was determined by endogenous alkaline phosphatase (ALP) activity measured on days 1, 7 and 14 of cell culture. Increased ALP production was observed with culture time. However, SEP conjugated SF scaffold showed significantly higher activity than the ALP production achieved with SF scaffold ($p < 0.01$) as indicated in Fig.4.3.16. This implies that the conjugated scaffolds prepared from SF conjugated with SEP are more favorable for cell differentiation.

Figure 4.3.16: ALP activity of hMSCs grown on SF and SEP-SF scaffolds for 1, 7 and 14 days. Each value represents the mean value \pm SD ($p < 0.05$, $n = 3$)

4.3.15. *In vivo* Biocompatibility Study

Transplantation of SEP-SF scaffolds was performed under surgically-created subcutaneous pouch in apparently healthy mice (Fig. 4.3.17a, both male & female for gender effect, if any). During the period of experiment, all mice remained in healthy condition and did not show any wound complications and no inflammatory and/or adverse tissue reactions were observed. Thus, transplanted scaffolds did not have any adverse effect on the physiology of animals (Fig. 4.3.17b). After one and four weeks of transplantation, mice were sacrificed and the host tissue reaction was analyzed by H&E staining. Macroscopically, all the scaffolds were encapsulated in thin fibrovascular tissues of recipient. After implanted for 7 days, more fibroblasts were grown into the scaffold and the inflammatory cells were in existence (Fig. 4.3.18a). However, when the test had processed for 4 weeks, a large number of fibroblasts were infiltrated into the scaffold and the morphology of scaffold was close to the surrounding dermal tissue (Fig. 4.3.18b). Thus, conclusion can be made as SEP-SF scaffold support the attachment, proliferation *in vivo* condition without causing infection, inflammation and/or tissue cell death.

Figure 4.3.17: *In vivo* biocompatibility study of SEP-SF scaffolds using ICR mice strain (a) Implantation of scaffold in male (b) Surgical recovery after one month in female

M: the implanted scaffold site. T: the subcutaneous connective tissue. M-T: the meso-dermal site as the interface of scaffold-tissue.

PART IV

Development of porous SF/PVA scaffolds with and without SEP conjugation

It is evident from published literature that the brittleness of pure SF scaffold limits their application in tissue engineering. The physical properties of SF scaffold can be enhanced by mixing it with other synthetic or natural polymers, such as poly-(vinyl alcohol) (PVA), collagen and chitosan [Gobin et al., 2005; Kweon et al., 2003; Du et al., 2006]. The cytocompatibility behaviour of such polymeric blend scaffolds has not been explored much. It has also been reported that polymer blended crosslinked system may show differential degradation behavior under physiological conditions [Ma et al., 2003]. In addition, a crosslinking process improves permeability and mechanical strength of polymers [Sabato et al., 2001]. Furthermore, the addition of glycerin (a commonly used plasticizer) improves silk film properties [Kawahara et al., 2006] and helps to reduce phase separation between silk and PVA in the blend [Dai et al., 1999]. Glycerin content in blend films is important for the control of silk secondary structural transitions and influencing the mechanical properties of the films [Lu et al., 2010]. PVA, a synthetic polymer has excellent hydrophilicity, biocompatibility, biodegradability and processability with ability to form high strength fibres suitable for medical applications [Mnasur et al., 2008; Mnasur et al., 2004]. In addition, the published literature has indicated that the amount of PVA accumulated in organs is too small to affect the biological fate, which suggested that PVA is excreted to the same extent supporting the cyto-compatibility of PVA [Yamaoka et al., 1995]. Incorporation of PVA solution in chitosan has shown improvement in biocompatibility of the blend system [Huang et al., 2005]. Silk fibroin and PVA have been separately investigated as candidate materials for tissue engineered constructs [Meinel et al., 2004a; Hofmann et al., 2007]. Though many research groups have studied the preparation method and properties of SF/PVA blends for improved stiffness of SF [Li et al., 2002; Dai et al., 2002; Li et al., 2001; Tanaka et al., 1998; Tanaka et al., 1997; Tsukada et al., 1994], it has not yet been explored much for its cytocompatibility and potential tissue engineering application. So efforts has been given in this phase of research work to prepare SF/PVA scaffold and its further improvement in surface properties by conjugation with SEP which has been found to enhance cell adhesion and proliferation property of SF scaffold in our previous research work [Chapter 4, Part III]. In the present study, green process has been employed for the fabrication of SF/PVA scaffolds of various pore sizes, modification with SEP and study of their biorelevant properties such as morphology, structure, mechanical properties, *in vitro* cell culture and *in vivo* biocompatibility.

4.4.1. Miscibility of SF/PVA Blend

Due to a noteworthy influence of the miscibility of polymer blend on their properties, the study of phase behavior during blending of polymers has been an important research area [Vucovic et al., 1999]. The effect of glycerin and ultra-sonication on the phase behavior and miscibility of SF and PVA were investigated by SEM. A series of SEM micrographs of SF/PVA (50:50) with different combination of blended system (with and without glycerine) and processing method (with and without ultrasonication) were studied, vizually (-Glycerine/-Ultrasonication), (-Glycerin/+Ultrasonication), (+Glycerine/-Ultrasonication) and (+Glycerine/+Ultrasonication) as shown in Fig. 4.4.1. As reported earlier, SF molecules are unstable and exist as colloidal state in aqueous system due to hydrophobic amino acids of SF and result in to molecular aggregation and gelation [Um et al., 2001]. On the other hand, PVA molecules are readily dissolved in water and are found as stable solution state in aqueous system. Due to the different solution stability in aqueous system between these two components, SF molecules tend to aggregate and form a separated domain in PVA matrix [Wang et al., 2010]. Ultrasonication induces the intra - and interchain crosslinking without any chemical additives [Jakobs, 2013]. In the present study, during sonication some of the silk fibroin chains in the SF/PVA blend were observed to form physical cross-links via β -sheet crystal networks rapidly by absorbing energy from the ultrasound process. The method is controllable and based on the energy input from ultrasonication to the system without involving any additional chemical processes. However, blending under ultrasonication without glycerine couldn't set homogeneity and still the distinct patches of SF and PVA exist (Fig. 4.4.1b).

The SF/PVA blend mixed under magnetic stirring using glycerine as plasticizer shows homogenous phase. SEM reveals patches of SF molecules at many places as shown in Fig. 4.4.1c. The silk fibroin film prepared by adding glycerin to SF solution is highly flexible as reported by Curvelo et al. [Curvelo et al., 2001]. The similar effect may act to reduce the heterogeneity between hydrophobic SF and hydrophilic PVA. The blend film of SF/PVA treated with glycerin, had shown the indistinct homogenous phenomenon, and presumably due to the glycerin induced intermolecular interactions between the polymers, such as hydrogen bonding of -OH groups of PVA, -OH groups of glycerin and -NH groups of SF [Dai et al., 2002]. In glycerin system, since SF molecules exist as a stable form, the possibility of heterogeneity due to solution instability may be excluded. SF molecules have polar groups including CO and NH. Therefore, there is some

possibility of molecular interaction between polar groups of SF and side groups of a second polymer. In addition, as mentioned above, OH group in PVA molecule is partially changed to ester group when PVA interacts with glycerin. It is well known that the miscibility of polymer blend is strongly connected to amorphous phase. Therefore, the increase in amorphous phase of PVA in SF/PVA blend system might enhance the miscibility with SF. Glycerol esterifies with SF and PVA greatly modify the compatibility and processing ability of SF/PVA blends as reported earlier [Dai et al., 2002]. A combination of ultrasonication and glycerine as plasticizer found to make a homogenous phase of SF/PVA blend as shown in Fig. 4.4.1d. This observation can be explained by two separate effects of ultrasonication and glycerine as mentioned above. The uniform blending of SF/PVA polymers influences the physical properties [Vucovic et al., 1999] of processed biomaterials.

Figure 4.4.1: SEM images of SF/PVA in aq. solution processed (a) without glycerine with magnetic stirring (b) without glycerine under ultrasonication (c) with glycerine with magnetic stirring (d) with glycerine under ultrasonication

4.4.2. Morphological Study

SEM images of salt leached porous SF/PVA (100:0) and SF/PVA (0:100) scaffolds are shown in Fig. 4.3.2 of (Chapter 4, Part III) and Fig. 4.4.2 respectively. Fig. 4.4.3 shows the scaffolds prepared from SF/PVA (75:25; 50:50; 25:75) by salt leaching using NaCl of various particles size as porogen. The pore size and porosity of the scaffolds corresponding to different particle size are presented in Table 4.4.1. The size of porogen is shown to have great influence on the pore size of the scaffold, while the polymer to porogen ratio is directly correlated to the amount of porosity of the final structure. From the SEM morphological study, it is revealed that the pore size is approximately 80% of particle size of NaCl particle. Methanol treatment during the processing for scaffold development is shown to enhance the crystallinity of the scaffold and results into water insoluble PVA component of scaffold. The scaffolds showed rough surface on the pores that are highly interconnected by a number of smaller pores (Fig. 4.4.3). The highly porous scaffolds with 91-94% porosity were developed from SF/PVA (50:50; 25:75) with pore size being in range of 230-360 μm (Table 4.4.1). The SF/PVA scaffolds with pore size range of 225-350 μm as recommended for cell based therapy [Karageorgiou et al., 2005; Murphy et al., 2010] were used for further modification with 2% SEP. The porosity of these modified SEP-(SF/PVA) scaffolds was measured around 84% with pore size range of 200-300 μm . The crystallites of SEP is found embedded with scaffold surface affecting the pore size of scaffold to some extent (Fig. 4.4.4).

Table 4.4.1: Pore size and porosity of SF/PVA scaffolds prepared from different blend ratio of SF (8 wt%) and PVA (10 wt%).* $(n=3)$

SF/PVA Ratio	NaCl particle size	Pore Size	Porosity*
75:25	100-200 μm	90-150 μm	80 %
	200-300 μm	140-230 μm	85 %
	300-500 μm	225-350 μm	75 %
50:50	100-200 μm	80-150 μm	85 %
	200-300 μm	150-250 μm	87 %
	300-500 μm	230-360 μm	91 %
25:75	100-200 μm	80-140 μm	81 %
	200-300 μm	150-260 μm	89 %
	300-500 μm	250-360 μm	94 %

Figure 4.4.2: SEM images of porous SF/PVA (0:100) scaffold prepared using NaCl particle size of range 300-500 μm

Figure 4.4.3: SEM images of SF/PVA scaffolds with blend ratio: 25/75 (a,d, g), 50/50 (b, e, h), 75/25 (c, f, i) prepared from 10 wt% PVA and 8 wt% SF aqueous solutions with NaCl particle size range of 100-200 (a, b, c), 200-300 (d, e, f) and 300-500 (g, h, i) μm .

Figure 4.4.4: SEM images of SEP-(SF/PVA) scaffold prepared from SF/PVA (75:25, 50:50 and 25:75, 300-500 µm) scaffolds conjugated with 2 wt% SEP solution. (a) The conjugated SEP macromolecule shows crystalline structure. Porous morphology of SEP-(SF/PVA) scaffolds with SF/PVA blend ratio of 75:25 (b), 50:50 (c) and 25:75 (d) are also accessible.

4.4.3. Structural Characterization

4.4.3.1. X-Ray Diffraction

X-ray diffraction curves of SF, PVA, and SF/PVA scaffolds with and without SEP conjugation are shown in Fig. 4.4.5. Pure SF scaffold showed characteristic major peak at $2\theta=19.7^\circ$ ($d=3.5 \text{ \AA}$) and minor peaks at $2\theta=8.8^\circ$ ($d=8.1 \text{ \AA}$) and $2\theta=23.2^\circ$ ($d=4.8 \text{ \AA}$) which are attributed to the silk II β -sheet crystalline structure [Um et al., 2001, Min et al., 2004]. PVA scaffold (Fig. 4.4.5f) cast from water as solvent is characterized by the presence of a minor broad peak at $2\theta=11.9^\circ$ ($d=9.7 \text{ \AA}$), in addition to a major broad diffraction peak at $2\theta=19^\circ$ ($d=4.4 \text{ \AA}$) [Nakane et al., 1999]. It is observed with SF/PVA scaffold that $2\theta = 19.7^\circ$ peak broadens and $2\theta = 8.8^\circ$ peak disappears with increase in PVA content indicating the increase in total crystallinity. In addition, a new peak not corresponding to SF or PVA lattice spacing appeared at around $2\theta=7.4^\circ$, which may be originated from crystalline fibroin–PVA complex. The β -sheet crystalline structure of SF in the polymer blend scaffold is partly induced by the addition of glycerine [Dia et al., 2002]. In SEP-(SF/PVA) scaffold, a new characteristic peak for SEP at $2\theta=22.6$ indicate the conjugation with SF/PVA scaffold [Guo et al., 2011].

4.4.3.2. FT-IR Spectroscopy

FTIR spectroscopy in transmittance mode was used to characterize the presence of specific chemical groups in SF, PVA, SF/PVA and SEP-(SF/PVA) scaffolds (Fig. 4.4.6). To minimize redundancy, the FTIR spectra were normalized and major vibration bands were analyzed for correlation with chemical groups. The FTIR spectrum of SF scaffold as illustrated in Fig. 4.4.6a shows strong absorption bands at amide I (1654 cm^{-1}), amide II (1519 cm^{-1}), amide III (1220 cm^{-1}) and amide V (555 cm^{-1}) which can be attributed to mainly random coil conformation and the α helix [Um et al., 2001]. The FTIR analyses indicate a conformational change from random coil to β -sheet with the formation of SF scaffolds from SF solutions. The PVA scaffold (Fig. 4.4.6f) shows absorption bands at 3425 (OH stretching), 2923 (CH stretching), 2850 (CH stretching), 1735 (C=O stretching), 1429 (CH₂ bending), 1250 (C-O stretching of acetate group) and 1091 (OH bending) cm^{-1} resonance which is in good agreement with the published literature [Finch et al., 1973; Finch et al., 1992]. The spectra for PVA also show a peak at 3398 cm^{-1} that indicates the presence of OH and N-H groups with polymeric association. Crystalline fraction of the polymeric chains affects the intensity of this peak for different SF/PVA blend ratio.

Figure 4.4.5: XRD pattern of SF/PVA scaffolds with different blend ratios (100:0, a; 75:25, b; 50:50, c; 25:75, e; 0:100, f) and SEP-(SF/PVA) (50:50, d) scaffolds

Figure 4.4.6: FTIR spectra of SF/PVA scaffolds with different blend ratios (100:0, a; 75:25, b; 50:50, c; 25:75, e; 0:100, f) and SEP-(SF/PVA) (50:50, d) scaffolds

The FTIR spectra of SF/PVA scaffold (Fig.4.4.6b-e) is characterized by the presence of typical absorption bands of SF and PVA scaffold whose intensity lies in between that of SF and PVA. However, the addition of glycerin causes the stretching of OH group in absorption band (3500-3200 cm^{-1}) [Speakman et al., 1975]. Such alteration in frequencies indicates the induction of intermolecular hydrogen bonding between two polymers namely SF and PVA. The polar OH group of glycerin plays vital role in strengthening OH group of PVA and NH group of SF [Lu et al., 1996]. The shifting of 1735 cm^{-1} of PVA to 1715 cm^{-1} in SF/PVA blend system is attributed to carbonyl groups which may be formed due to the esterification reaction of PVA and glycerol. The conjugation of SEP with SF/PVA (50:50) blend scaffold was confirmed by the presence of characteristics absorption peak of SEP at 2126 cm^{-1} (amide B group) (Fig.4.4.6d) as per reported literature [Wang et al., 2008].

4.4.4. Thermal Analysis

Even though microscopic observations depict no phase separation between SF and PVA, thermal analysis was carried out to make clear the interaction between SF and PVA during scaffold development and the effect of SEP conjugation on their thermal properties. Fig. 4.4.7 shows the DSC thermograms of various scaffolds prepared under study. The DSC curves of SF scaffold showed a weak endothermic peak around 100°C that is attributed to the evaporation of water content [Kweon et al., 2001b]. The typical endothermic peak near 240°C is due to the crystallization of thermally induced SF protein and β -sheet structure of samples while an endothermic peak at 283°C is attributed to thermal decomposition of scaffolds [Chapter 4, Part II; Kweon et al., 2001b]. The main endothermic peak for SF/PVA scaffolds at around 292°C is contributed by the thermal decomposition of both polymers. As the PVA content of SF/PVA scaffold increased, the thermal decomposition temperature increased which is depicted by the shifting of peaks to a higher temperature. The broad endothermic peak of PVA scaffold became sharper in SF/PVA scaffolds and shifted to a lower temperature indicating possible interactions between SF and PVA.

The glycerin content of hybrid scaffolds has been reported to shift melting peak towards the low temperature [Dai et al., 2002]. A weak but somewhat different endothermic peak for SF/PVA (50:50) scaffold is observed with SEP-(SF/PVA) scaffold at around 45°C indicating SEP conjugation. Both group of scaffolds, SF/PVA and SEP-(SF/PVA) scaffolds exhibit similar endothermic peaks at 292°C, that is probably assigned to the breakdown of peptide bonds within

chain and side chain groups of SF and SEP proteins. A slight upward shift in the decomposition peak for SEP conjugated SF/PVA scaffold as compared to SF/PVA (50:50) scaffold indicate higher thermal stability of conjugated samples. This behavior may be due to increased crystallinity and molecular weight particularly promoted by the presence of stabilizing amino acids eg. proline and hydroxyproline in SEP.

Figure 4.4.7: DSC thermograms of SF/PVA scaffold with different blend ratios (PVA:SF; 100:0, a; 75:25, b; 50:50, c; 25:75, e; 0:100, f) and SEP-(SF/PVA) (50:50, d) scaffolds

4.4.5. Mechanical Property

The optimal mechanical properties of scaffold to withstand the movement of surrounding tissues are required for tissue engineering applications. The mechanical properties of SF, SF/PVA, SEP-(SF/PVA) and PVA scaffolds were assessed based on stress-strain graphs (Fig. 4.4.8). The initial compressive modulus was measured as the maximum slope of the stress-strain curve over a 1.6% strain. It is observed that all scaffolds have the same line shapes which are the typical pattern of the plastic material demonstrating spongy behavior of scaffold materials with different stiffness. The addition of PVA to SF has shown to have a significant change in the mechanical properties. The

compressive strength of SF scaffolds (300 KPa) decreased when it was blended with PVA (235 ± 67.1 KPa) which maybe due to the closer packing of PVA polymer chains with SF. For most of the scaffolds investigated in this study, the steepest portion of the stress-strain curve is shown to

Figure 4.4.8: Stress–strain graph of SF/PVA scaffolds with different blend ratios (100:0, a; 75:25, b; 50:50, c; 25:75, e; 0:100, f) and SEP-(SF/PVA) (50:50, d) scaffolds measured at constant compression rate of 2 mm/min

occur in the range of 0-4% strain. The uncoated SF/PVA scaffolds break by external forces in between 200 and 300 KPa with 1.8 to 2.8% strain. The mechanical resistance is found to be increased with SEP modified scaffold as depicted from Fig. 4.4.8, supporting the breaking forces higher than 2.5 N and strain over 4%. The corresponding average compressive modulus is measured as 235 ± 67.1 KPa for the uncoated scaffolds and 247.5 ± 23.7 KPa for SEP coated scaffolds. The increase in amorphous PVA content has been reported to reduce the crystallinity of SF/PVA blend and act as lubricant for extensibility and flexibility [Lee et al., 2007] resulted into decrease in compressive strength of SF/PVA scaffold in comparison to SF scaffold. Overall, the scaffold

compressive modulus decreased with increased PVA reinforcement with same porosity. The research reports show that the increase in PVA content up to 50% decreases the tenacity while increases the elongation at break [Lee et al., 2007]. Hence, the SF/PVA blend with 40–50% PVA has a optimal mechanical properties (compressive strength and elongation at break) than filaments with lower/higher PVA [Lee et al., 2007]. According to Dai et al., although strength and elongation of the blend films are above that of the pure silk film, the value is relatively low as compare to the blends with the addition of glycerin [Dai et al., 2002]. Therefore SF, SF/PVA (50:50), SEP-(SF/PVA) scaffolds with pore size range of 230-360 μm were used for further study.

4.4.6. Swelling Behavior

From the experimental result shown in Fig. 4.4.9, the swelling pattern indicated an initial rapid water uptake at about 30 min, followed by mass stabilization over a period of 48hrs. Visual examination also showed appreciable increase in volume of the samples. Within a period of 30 min, SF scaffolds showed swelling of 60.3% and about 133.36% up to a period of 48 h. In comparison, the PVA scaffold showed much higher swelling index of 80.94%. As reported earlier, PVA scaffold without physical (cryogelation) or chemical (GA, 5%) crosslinking, doesn't withstand the water penetration and dissolves within a period of 48 hrs. [Dai et al., 2002], however, in our study the chemically crosslinked PVA, showed the swelling of 200% over a period of 48 hrs. Furthermore, SF/PVA (50:50) scaffold showed rapid swelling in comparison to SF scaffold with 227.06% swelling achieved at 48 hrs. The swelling behavior is markedly influenced by the presence of PVA in the blend, crosslinked by ultrasonication and glycerine. The observed swelling pattern is probably related to the crosslinking between –NH group of SF chains and -OH group of PVA chains by ultrasonication and glycerine, causing the formation of a rigid structure amongst the SF/PVA chains and reducing their solution uptake. SEP-(SF/PVA) scaffold shows higher rate of swelling which may be due to the presence of hydrophilic SEP and maximum swelling of 254.9% was observed at 48 h. The initial swelling behavior of SEP-(SF/PVA) scaffold is attributed to the combined effect of a more rigid net-work formed by the inter – intra polymer chain reactions as well incorporation of covalent bonds on scaffold surface, thus reducing the flexibility and number of hydrophilic groups of scaffold surface which is unfavorable to the swelling property. Similar trends in swelling behavior of PVA and SF supported these findings, where PVA has a swelling degree above 300% and SF of about 200%, depending on course of the solution conditions [Wang et al., 2004a; Wang et al., 2004b; Lin et al., 2008; Zhang et al., 2012].

Figure 4.4.9: Swelling Index of SF, PVA, SF/PVA (50:50) and SEP-(SF/PVA) scaffolds in SBF for different time period

4.4.7. *In vitro* Biodegradation

The degradation profile of scaffolds is shown in Fig. 4.4.10. It is observed that the rate of degradation of SF/PVA scaffold is more than SF scaffold. The faster degradation may be due to more hydrophilic PVA that shows strong intra and interchain H-bonding with polar solvent. The rate of degradation is further increased with SEP conjugation which may be due to the surface erosion caused by SEP conjugation. PVA scaffold (without physical or chemical crosslinking) showed low degradation initially and the rate became faster after 4 h and complete degradation achieved within 48 h. Polymer solubility in aqueous solution is reported to be controlled by intra and inter-molecular hydrogen bonding in which polymer–polymer hydrogen bonds are replaced by polymer–water hydrogen bonds [Tao et al., 2007]. At the end of 192 h, SF/PVA (50:50) scaffold is shown to have more degradation than SF scaffold which may be attributed to the presence of PVA (-OH group) but was found intact in SBF due to water resistance and penetration into the blend system. The presence of glycerine as plasticizer of thermoplastic blends, influences the degradation behavior of scaffold.

Figure 4.4.10: Weight loss of SF, SF/PVA (50:50) and SEP-(SF/PVA) scaffolds in SBF for different time period. The % weight loss of PVA scaffold (uncrosslinked) is not shown due to rapid dissolution in PBS within a period of 48 h.

4.4.8. Hydrophilicity

The wettability of the developed scaffolds was evaluated by contact angle measurement using sessile drop technique. The results for different scaffolds (SF, SF/PVA (50:50) and SEP-(SF/PVA)) are shown in Table 4.4.2. Results show that scaffold surface of each type is completely wettable. However, considerable decrease in water contact angles from $62.4 \pm 1.5^\circ$ to $41.0 \pm 1.3^\circ$ is observed due to much hydrophilicity of PVA that further decreases to $39.2 \pm 1.1^\circ$ because of the conjugation of SEP over the scaffold surface. It is evident that conjugation of SEP as hydrophilic components make the surface of SF based scaffold more hydrophilic that is suitable for cellular response in aqueous medium.

Table 4.4.2: Water contact angles measured on various SF scaffolds

Exp #	Sample	Water contact angle (X°)*
1.	SF	62.4 ± 1.5
2.	SEP-SF	52.7 ± 1.0
3.	SF/PVA (50:50)	41.0 ± 1.3
4.	SEP-(SF/PVA)	39.2 ± 1.1

*testing at three different sites for each scaffold

4.4.9. *In vitro* Cell Culture Study

4.4.9.1. *Cell morphology in seeded scaffolds*

Human mesenchymal stem cells (hMSCs) isolated from umbilical cord blood by differential density gradient centrifugation and plastic adherence technique are proliferated to achieve required viable cell density. The morphology of hMSCs in different culture time (Fig. 4.3.12), was observed and the cell culture upto 4th passage were seeded into scaffolds by static method for *in vitro* culture study. The morphology of cell-seeded scaffold (construct) as shown in Fig. 4.4.11, depicts the uniform distribution of cells on the scaffolds. hMSCs are observed to be attached and grown well on the SF/PVA and SE-(SF/PVA) scaffolds, as evident from SEM images (Fig. 4.4.11). On day 3, hMSCs are shown to be attached on the scaffold and formed small cell aggregates, which increased in size on day 7.

4.4.9.2. *Cell adhesion and proliferation*

The hMSCs proliferation on SF, PVA, SF/PVA and SEP-(SF/PVA) scaffolds was evaluated on day 1, 3, 7 and 14 using MTT assay. The results of MTT assay are presented in Fig. 4.4.12. As it is indicated in figure, SF, PVA, SF/PVA and SEP-(SF/PVA) scaffolds show supported cell viability and proliferation. After day 1, the cell count on scaffolds was higher in PVA as compared to SF scaffold. SF/PVA scaffold shows intermediate cell count between SF and PVA scaffold. This may be due to lowering in hydrophilicity and amorphous component of SF. SEP-(SF/PVA) scaffold has lowest value of cell count, may be because of coated SEP over scaffold restricting the cellular movement into the pores. On day 3, cell count is decreased due to washing out of non-adhered cells from the scaffold. While there is no significant difference in cell proliferation observed with PVA and SF/PVA scaffolds, however, the cell viability was found more for SEP-(SF/PVA) scaffold. This indicated the improved surface of composite scaffold due to introduction of SEP and proliferation of viable cells, capable of moving inside and adhered over scaffold. The SEM images (Fig. 4.4.11) show the cell spreading over the SF/PVA and SEP-(SF/PVA) scaffold. hMSCs are observed to be well acclimatized with the blended and conjugated scaffold and showed an increase in cell count with time. On day 7, while the cell count for SF/PVA were found a little more than SF scaffold, the SEP-(SF/PVA) scaffold has shown exponential increase in cell count. The hydrophilicity of PVA sample support the cell adherence but with progress in culture, the viability of cells is not supported much. Introduction of PVA in SF forming SF/PVA scaffold greatly enhances the cell viability and

proliferation. However, SF/PVA scaffold modified with SEP shows the highest cell proliferation, representing biocompatibility and surface property enhancement of SEP. The absorbance value being much higher in hybrid scaffolds as compared to that of control, confirms that hybrid scaffolds (SF/PVA and SEP-(SF/PVA)) are having enough pores and desired pore size allowed hMSCs to acclimatize and proliferate inside the scaffolds.

Figure 4.4.11: MTT Assay of hMSCs in SF (control), PVA, SF/PVA (50:50) and SEP-(SF/PVA) scaffolds for different culture period (1, 3, 7 and 14 days)

Figure 4.4.12: SEM of cell-scaffold constructs developed from SF/PVA (a, c, e, g) and SEP-(SF/PVA) (b, d, f, h) scaffolds for day 1 (a, b), day 3 (c,d), day 7(e, f) and day 14 (g, h) with umbilical cord blood derived hMSCs

Figure 4.4.13: H&E stained cross-section of the constructs developed from SF/PVA (a&b) and SEP-(SF/PVA) (c&d) cultured for 7(a, c) and 14 (b, d) days (Scale Bar: 500μm)

Thus, UCB derived hMSCs on blended scaffolds showed relatively better cell viability and proliferation compared to the control. The histology of cell seeded scaffolds was examined after 7 and 14 days with H&E staining (Fig. 4.4.13). Stained sections of scaffolds were observed using an inverted light microscope. Both SF/PVA and SEP-(SF/PVA) scaffolds have shown good proliferation of MSCs. These cell viability results based on *in vitro* MTT assay and H&E staining have offer further investigation on scaffold for *in vivo* testing in biomimic environment involving scaffolds direct contact with cells leading to human tissue regeneration.

4.4.10. ALP Activity of Scaffolds

To determine the early osteogenic differentiation of hMSCs on the scaffolds, the alkaline phosphatase (ALP) activity of the prepared scaffolds was measured. SF, PVA, SF/PVA (50:50) and SEP-(SF/PVA) scaffolds showed an enhanced ALP activity over the culture period of 14 days (Fig. 4.4.14). In comparison, PVA scaffolds showed slightly lower activity than SF and SF/PVA scaffold

($p < 0.01$). SF and SF/PVA scaffolds has shown very close ALP activity ($p < 0.01$), while SEP conjugated SF/PVA scaffolds has the highest level of activity ($p < 0.05$). Elevated level of ALP, a marker for osteoblastic phenotype thus confirm enhanced differentiation of hMSCs on SEP conjugated scaffolds compared to the SF scaffold [Park et al., 2010].

Figure 4.4.14: ALP activity of hMSCs grown on developed scaffolds for 1, 7 and 14 days. Each value represents the mean value \pm SD ($P < 0.05$, $n=3$)

4.4.11. *In vivo* Evaluation of Scaffolds

In vivo biocompatibility evaluation of SF/PVA (50:50) and SEP conjugated SF/PVA scaffolds were performed using ICR mice model (Fig. 4.4.15). Test animals for both groups of scaffolds were recovered after 1 month and showed no inflammatory reactions to host tissue as depicted by H&E stained micrographs (Figs. 4.4.16 & 17). The scaffolds were completely degraded without causing any necrosis. All mice were remained healthy and the scaffolds were found encapsulated in thin fibrovascular tissues of recipient. Observation made after 7 days showed fibroblasts grown into the scaffold with minor inflammation around implantation site (4.4.16a & 17a). However, after 4 weeks,

a large number of fibroblasts were infiltrated into the scaffold and the morphology of scaffold was similar to the adjacent dermal tissues (Fig. 4.4.16b &17b). Thus the scaffolds are shown to be 134iocompatible with recipient tissue.

Figure 4.4.15: Implantation of (a) SF/PVA (50:50) and (b) SEP-SF/PVA scaffold into ICR mice strain for *in vivo* biocompatibility study

Figure 4.4.16: Histological section of subcutaneous skin of ICR mice at the site of implanted SF/PVA (50:50) scaffolds after (a) 7 days & (b) 4 weeks. Bar indicates 200 μ m. Figure 4.4.17: Histological section of subcutaneous skin of ICR mice at the site of implanted SF/PVA (50:50) scaffolds after (a) 7 days & (b) 4 weeks. Bar indicates 200µm. M: the implanted scaffold site. T: the subcutaneous connective tissue. M-T: the meso-dermal site as the interface of scaffold and tissue

Comparison of the results

A comparison in terms of physico-chemical, thermal and biological properties of the various scaffolds developed under study were made as given in Table 4.4.3. It is observed that all the prepared scaffolds are shown to have integrated structure with interconnected pore network with a slight variation in porosity. The compressive strength of SF scaffold (279.8 ± 36.2 KPa) is increased with conjugation with SEP (321.5 ± 42.2 KPa), while a decrease in compression strength is observed with SF-PVA blend (235 ± 67.1 KPa). A further increase in compressive strength of SF/PVA (247.5 ± 23.7 KPa) is achieved with SEP conjugation which is, however, less than SEP-SF scaffold. The wettability of SF scaffolds ($62.4 \pm 1.5^\circ$) are found to be increased with SEP conjugation (SEP-SF; $52.7 \pm 1.0^\circ$) and blending with PVA polymer (SF/PVA; $41.0 \pm 1.3^\circ$). However, the highest wettability surface is obtained with SEP-(SF/PVA) scaffolds ($39.2 \pm 1.1^\circ$) representing better cell support. *In vitro* and *in vivo* study of all matrices showed cell-supportive behaviour with a varying degree. The improved cell adhesion and proliferation were achieved with SF and SF/PVA scaffolds conjugated with SEP. However, SEP-SF/PVA scaffold has shown the superior cell adhesion and proliferation with hMSCs culture. Comparable cell viability is also achieved with SF-SEP scaffold. Though comparatively low compressive stress is shown by SEP-SF/PVA scaffolds, comparing all the properties as shown in table and the added advantage of overcoming the problem of brittleness of SF scaffold using PVA, it is established that SEP-SF/PVA is the best scaffold among all the prepared SF scaffolds.

Table 4.4.3: Comparison of different SF based matrices based on some of the key properties

Sl. No.	Porous Matrices	Compressive Strength	Swelling Index (%)	Wt. Loss (%)**	Wettability (Degree) [±]	Cell Count (OD) ^{±±}	Porosity (%)	Morphology

CHAPTER 5

Summary & Conclusion

SUMMARY & CONCLUSION

In recent years tissue engineering has been considered as a promising alternative to the conventional clinical method for the treatment of patients suffering from tissue related diseases. The development of tissue engineered scaffold from a variety of biopolymers with a set of desired properties that can mimic the extracellular matrix is the key aspect of this new technique. In this context, silk fibroin is considered as a promising biopolymer to use as a scaffold material. Keeping this in view, the present work has been undertaken to develop silk fibroin (SF) based scaffolds with improved surface, mechanical and biological properties by blending with other polymers and modified with additive as surface enhancer. The outcome achieved through this research work is summarized as follows:

Part I: In the first phase of the dissertation work, silk fibroin solution was prepared from *B. mori* silk cocoon. Silk fibroin was extracted from raw silk cocoon by degumming method. The effect of key parameters on the extraction process was investigated to find the most favorable degumming condition. The optimum condition thus established as 0.02 M aq. Na₂CO₃, 70°C and 60 min degumming time achieving maximum amount of SF with maximum removal of sericin.

SF solution was prepared by the dissolution of SF in LiBr solution. The maximum solubility of silk fibroin was achieved at 9.3M LiBr concentration, 70°C and 3 hrs of treatment time. The SF solution was characterized by SDS-PAGE and particle size analysis. The extraction process was further optimized by Response Surface Methodology using Box-Behnken Design. The solution thus prepared was used as biopolymer for the development of scaffolds.

Part II: In this phase of study, an effort has been given for the preparation, characterization and *in vitro* biocompatibility study of silk fibroin hydrogel for its possible use in tissue engineering. A structurally and thermally stable fibroin hydrogel with well interconnected and open pores was prepared with β -oriented close network of fibroin molecules. Morphologically, the hydrogels show a sponge-like cross-linked structure formed by physical entanglement as well as chemical bonding involving hydrogen and covalent bonds. The rheological and swelling behaviors of fibroin hydrogel were appreciable at 37°C representing to mimic the body tissue. Thermal analysis supported the

prepared hydrogel as biomaterial with degradation characteristics suitable for human *in vivo* application. The cytocompatibility study by hMNCs culture has shown that the three-dimensional network of SF hydrogel facilitated cell adherence, cell proliferation and distribution throughout the scaffold. Thus it is concluded that the SF hydrogel is suitable as injectable biomaterial for soft tissue engineering.

Part III: In this part of the thesis work, an attempt has been made for the improvement of the surface properties of the SF scaffold. SF scaffolds were fabricated by salt leaching technique using NaCl as porogen. The effect of particle size of porogen was investigated and found to have a great influence on the pore size and porosity of the prepared scaffolds. The pore size and porosity of SF scaffold were measured as 70-350 μm and 85-93%. SF scaffolds were further modified with soluble egg cell protein (SEP) with the intention to improve its surface properties for better cell attachment and proliferation. The elemental analysis, XRD, FTIR, DSC and TGA study confirm successful conjugation of SEP over SF scaffold and structural and thermal stability of the modified scaffold. The pore size of the modified scaffold (SEP/SF) is found to be in the range 200-300 μm with porosity 85-90%. An increased compressive strength of SEP/SF scaffold is achieved (321.5 ± 42.2 KPa) in comparison to SF scaffolds (279.8 ± 36.2 KPa). The modified scaffold has further shown to have enhanced hydrophilicity (52.7 ± 1.0 contact angle with water droplet) representing more favorable to *in vivo* application as compared to SF scaffold as control.

The *in vitro* cell culture study has shown a significantly higher cell adhesion and proliferation on the conjugated scaffold in comparison to SF scaffold. The *in vivo* animal model evaluation depicted the biocompatibility of SEP-SF scaffolds. Therefore, this study has demonstrated that the porous SF scaffolds modified with SEP offers enhanced cell adhesion and proliferation and hence improved biocompatibility to facilitate its application in practical tissue engineering. Furthermore, the non-inflammatory response towards host ICR mice model indicated *in vivo* biocompatibility of the scaffold.

Part IV: It is evident from literature that the brittleness of SF scaffolds limits their use in tissue engineering. Poly vinyl alcohol (PVA), a synthetic polymer has excellent hydrophilicity, biocompatibility and biodegradability property. It is reported that the blending of SF with PVA can

reduce the crystallinity and improves the surface property as well. Therefore, in this phase of dissertation work, efforts have been given to develop SF/PVA scaffold by blending these two polymers followed by salt leaching. The SF/PVA blend was also modified with SEP to investigate its effect on the further improvement of the properties of SF/PVA scaffold. As in *part III*, three dimensional porous SF/PVA and SEP modified SF/PVA (SEP-SF/PVA) scaffolds were prepared by salt leaching method using NaCl as porogen. These scaffolds exhibited a hierarchical structure with interconnected macropores of different pore size range depending on particle size of porogen. The results have shown that the proportion of PVA to SF has a great impact in controlling porosity and interconnectivity of scaffold. FTIR spectroscopy associated with XRD has proven to very powerful tools for investigating the formation of conjugated and unconjugated SF/PVA blend scaffolds. Among the various SF/PVA scaffolds prepared with different blend ratio, SF/PVA (50:50; 230-360 μm) and SF/PVA (75:25; 250-360 μm) have shown most favorable pore size range, but since the later has more fragile nature causing mechanical stiffness, SF/PVA (50:50; 230-360 μm) is most preferred for tissue engineering application. The SF/PVA and SEP-SF/PVA have the desired compressive strength though the compressive strength is lower than that of SEP/SF scaffold. The corresponding compressive strength of SF/PVA and SEP-SF/PVA are 235 ± 67.1 KPa and 247.5 ± 23.7 KPa respectively. Further, the swelling and degradation of SEP-SF/PVA scaffolds were higher due to enhanced hydrophilicity (39.2 ± 1.1 contact angle) compared to SF/PVA (50:50) scaffolds (41.0 ± 1.3) and other SF scaffolds developed in this study.

The cytocompatibility of the scaffolds were confirmed by cell viability (MTT) assays. The SF/PVA scaffold was observed to support cell attachment and proliferation during culture of hMSCs in SF/PVA scaffolds. The cell proliferation result was similar to the result observed with SF scaffolds. However, significantly increase in cell proliferation and cell spreading were observed with SF/PVA scaffold conjugated with SEP. Furthermore, the *in vivo* biocompatibility of the scaffolds was confirmed by animal testing using ICR mice model.

Furthermore, though comparatively low compressive stress is shown by SEP-SF/PVA scaffolds, comparing all the other properties and the added advantage of overcoming the problem of brittleness of SF scaffold using PVA, it is established that SEP-SF/PVA is the best scaffold among all the developed SF scaffolds under study.

Overall, the research provides a potential SEP conjugated SF/PVA scaffold (SEP-SF/PVA that has the superior surface property (hydrophilicity), biological property (cell adhesion and proliferation) and compressive strength desired for its use in tissue engineering. It has been further demonstrated that SEP is an excellent additive that can be used as surface modifier for the scaffold biomaterials. Thus it is concluded that the SEP-SF/PVA can be a potential artificial extra cellular matrix particularly for soft and other non-load bearing tissue engineering applications. SEP conjugated SF/PVA scaffolds could be further designed utilizing more advanced fabrication technology according to patient prerequisite. Furthermore, developed scaffold material may be mechanically improved to make it suitable for hard tissue engineering.

Appendix A

Amino acid	one letter code	Three letters code
Alanine	A	Ala
Cysteine	C	Cys
Aspartic acid	D	Asp
Glutamic acid	E	Glu
Phenylalanine	F	Phe
Glycine	G	Gly
Histidine	H	His
Isoleucine	I	Ile
Lysine	K	Lys
Leucine	L	Leu
Methionine	M	Met
Asparagine	N	Asn
Proline	P	Pro
Glutamine	Q	Gln
Arginine	R	Arg
Serine	S	Ser
Threonine	T	Thr
Valine	V	Val
Tryptophan	W	Trp
Tyrosine	Y	Tyr

(Abstract)

BIOGRAPHY

Mahesh K. Sah is a PhD candidate in the Department of Biotechnology and Medical Engineering at National Institute of Technology Rourkela, India. He received his B.Tech. (Biotechnology) in 2007 from IET, Bundelkhand University, Jhansi (India) and joined NIT Rourkela. His interests include biomaterials processing and application for bone and cartilage tissue engineering, nanotechnology and stem cell research for efficient and improved tissue regeneration. He has won a number of prizes/ awards and more than twenty publications (journals and conferences) goes to his credit. He is member of Society for Biomaterials and Artificial Organs (India).

Personal Details:

Father's Name	Mr. Janardan Pd. Sah
Mother's Name	Mrs. Sushila Devi
Date of Birth	28th February, 1982
Gender	Male
Nationality	Indian
Language Known	Hindi, English, Bengali, Oriya
Permanent Address	c/o Shri Janardan Pd. Sah (Vikas Dresses) At+PO-Palajori Dist.: Deoghar, Jharkhand India-814146
