Abstract

The broad differential diagnosis of neonatal erythroderma often poses a diagnostic challenge. Mortality of neonatal erythroderma is high due to complications of the erythroderma itself and the occasionally severe and life-threatening underlying disease. Early correct recognition of the underlying cause leads to better treatment and prognosis. Currently, neonatal erythroderma is approached on a case-by-case basis. The purpose of this scoping review was to develop a diagnostic approach in neonatal erythroderma. After a systematic literature search in Embase (January 1990 – May 2020), 74 cases of neonatal erythroderma were identified, and 50+ diagnoses could be extracted. Main causes were the ichthyoses (40%) and primary immunodeficiencies (35%). Congenital erythroderma was present in 64% (47/74) of the cases, predominantly with congenital ichthyosis (11/11; 100%), Netherton syndrome (12/14, 86%) and Omenn syndrome (11/23, 48%). Time until diagnosis ranged from 102 days to 116 days for cases of non-congenital erythroderma and congenital erythroderma respectively. Among the 74 identified cases a total of 17 patients (23%) died within a mean of 158 days and were related to Omenn syndrome (35%), graft-versus-host disease (67%) and Netherton syndrome (18%). Disease history and physical examination are summarized in this paper. Age of onset and a collodion membrane can help to narrow the differential

[†]Member of the ERN-SKIN-subthematic group Ichthyosis

diagnoses. Investigations of blood, histology, hair analysis, genetic analysis and clinical imaging are summarized and discussed. A standard blood investigation is proposed, and the need for skin biopsies with lympho-epithelial Kazal-type related Inhibitor staining is highlighted. Overall, this review shows that diagnostic procedures narrow the differential diagnosis in neonatal erythroderma. A 6-step flowchart for the diagnostic approach for neonatal erythroderma during the first month of life is proposed. The approach was made with the support of expert leaders from international multidisciplinary collaborations in the European Reference Network Skin-subthematic group Ichthyosis.

Background

Neonatal erythroderma (NE) is erythema or generalized dermatitis covering at least 90% of the body surface, present at birth or appearing during the first 4 weeks after delivery.¹ Incidence rate of NE patients in the Netherlands is estimated among dermatologists to be 10 patients per 100 000 newborns.² Erythroderma itself is not a diagnosis, but a phenotype. Proper diagnosis is a challenge due to low incidence, phenotypical heterogeneity and a wide range of possible underlying diagnoses (Fig. 1). Etiologically, six main categories are known: congenital ichthyoses (including Netherton Syndrome (NS)), primary immunodeficiencies (PIDs), metabolic disorders, drug use, cutaneous infections and 'other'.^{3–5} The 'other' group contains common dermatoses, such as atopic dermatitis, psoriasis and seborrheic dermatitis, which mainly occur after 3 months of age.^{1,3,4,6} Congenital ichthyosis (including NS) (46%) and PIDs (30%) were the main causes in two studies, although erythrodermic cases from both neonates and infants were included.^{3,4} Previously reported mortality rate is high (16% after a mean of 17 months) due to complications of the erythroderma such as dehydration, electrolyte imbalance and infections, or due to severe and life-threatening underlying diseases such as PID and metabolic disorders.^{4,7} An optimal diagnostic approach and awareness of underlying causes is mandatory to prevent diagnostic delay, thereby decreasing the rate of complications and death. Since a differential diagnosis is often made on a case-by-case basis, an algorithmic approach would be recommended. Several authors proposed a multidisciplinary/diagnostic approach, which is mainly based on a differential diagnosis perspective and not on the clinical presentation.^{1,6,8–11} The present systematic literature search provides a scoping overview of diagnostic characteristics in cases of neonatal erythroderma during the neonatal period specifically that can lead to a timely diagnosis. Based on these results and the opinion of experts, a protocol for NE using an algorithmic approach is proposed.

Methods

A scoping review was performed based on a systematic literature search.

Search criteria and strategies

All publications which described diagnostic procedures in NE within the first year were included. A search strategy was developed by an experienced information specialist. First search (April 2020) was followed by a more extensive search (May 2020). The search was carried out in EMBASE, using specific search terms (Appendix S1). Publications were selected based on title and/or abstract. When abstracts were unavailable, full text was consulted. Reference lists of eligible articles were checked for other relevant publications. Finally, the included articles were analysed for study parameters, focused on diagnostic procedures, clinical symptoms, numbers of patients, age range and diagnosis.

Inclusion and exclusion criteria

Scientific publications (January 1990 – May 2020) were screened. English publications with clinical information (clinical and neonatal characteristics, extracutaneous and systemic symptoms) and/or diagnostic procedures (e.g. laboratory blood analysis, bacterial culture swabs, hair analysis, histopathology or genetics) on NE before the age of 1 year were included. Publications on NE that contained information about family (consanguinity and family history) and pregnancy (premature birth and complications) were also included. Review articles, expert opinions, case reports and case series were eligible. Additionally, textbooks on (paediatric) dermatology were screened. Publications with erythroderma, starting after the 1st month of age, were excluded. Publications were excluded when diagnostics or specific details of the clinical onset of NE were absent. Poster presentations, conference abstracts and publications with unavailable full text were excluded. As underlying diagnoses, congenital

(a) Self-healing collodion baby, (b) Omenn syndrome (courtesy by Iria Neri), (c) Ichthyosis variegata (courtesy by Anette Bygum), (d) Netherton syndrome (courtesy by Iria Neri), (e) diffuse cutaneous mastocytosis (courtesy by Iria Neri), (f) Harlequin ichthyosis (courtesy by Cristina Has), (g) Ichthyosis NOS, (h) Epidermolytic ichthyosis (courtesy by Cristina Has), (i) Omenn syndrome.

hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD) syndrome has been excluded due to an unilateral erythroderma, and Leiner disease has been excluded because in former cases the disease seemed to be related to NS and Omenn syndrome (OS).^{11–13}

Group experts

Members of the European Reference Network (ERN)-SKIN sub-thematic group Ichthyosis provided their expert opinion on the review and algorithmic diagnostic approach.

Results

The literature search identified 2127 publications. Finally, 183 publications were screened for further analysis leaving 98 publications for qualitative analysis (Appendix S2) in which eventually 74 cases were identified. The level of evidence was low (level 4) (59 case reports and 13 case series).¹⁴

Underlying diagnoses in neonatal erythroderma

Diagnoses of the 74 case reports, including age of onset of the erythroderma and the mean delay until the final diagnosis, are summarized in Appendix S3. Main causes were subtypes of ichthyoses (30/74; 40%) and PIDs (26/74; 35%). Syndromic ichthyoses subtypes were more prevalent (23/30; 77%). Ectodermal dysplasia (AEC) was described in 4 cases (6%). Other causes were infections (4/74; 5%, all SSSS), metabolic disorders (2/74; 3%) and drug-induced erythroderma (DIHS) (1/74; 1%). A complete overview of reported underlying diagnoses of congenital erythroderma and NE are summarized in Table 1. Underlying diagnoses described in reviews or textbooks are marked with an asterisk. Diagnoses that can be accompanied by a collodion membrane are indicated. Relatively new diagnoses such as severe dermatitis, multiple Allergies and metabolic wasting (SAM) syndrome (*DSGI* gene), which can resemble NS, or SAM-like phenotypes (*DSP* gene)⁶³ and autosomal recessive keratitis

AD, autosomal dominant; AR, autosomal recessive; ARCI, Autosomal recessive congenital ichthyosis; COFS, Cerebro-oculo-facio-skeletal syndrome; CVID, combined variable immunodeficiency; EB, epidermolysis bullosa; IFAP, Ichthyosis Follicularis Atrichia and Photophobia; SCID, severe combined immunodeficiency.

Diagnoses are marked when found in textbooks or reviews (*) or when associated with a collodion membrane ©

ichthyosis deafness (KIDAR) syndrome (*AP1B1* gene) must be considered.^{36,62}

Congenital erythroderma was described in a total of 47/74 cases (64%), predominantly in congenital ichthyoses (11/11; 100%), NS (12/14; 86%) and OS (11/23; 48%). In a study on PIDs, congenital erythroderma was frequently seen in cases of autosomal dominant hyper IgE syndrome (AD-HIES) (65–80%), autosomal recessive hyper IgE syndrome (AR-HIES) (24%) and Wiskott-Aldrich syndrome (WAS) (rare).^{67,79} NS often shows erythroderma within 1–2 days after birth.⁷⁹ Metabolic disorders and Sjögren-Larsson syndrome (SLS) should be considered as differential diagnoses when erythroderma develops in the first month

of life.^{6,80} Although one case of immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome was described in the first month, erythroderma in IPEX usually occurs after the first month.⁶⁷ Although congenital psoriasis was observed in two cases, it is rare in the neonatal phase.^{1,6,80} Erythroderma due to infections and drug reactions can occur at any age.

Time until final diagnosis differs with age of onset (Appendix S3). Mean age of diagnosis after the onset of the erythroderma in cases of congenital erythroderma vs non-congenital NE is 116 days (range 1 day–5 years, median 20 days) and 102 days (range 1 day–5 years, median 15 days) ($P < 0.4303$) respectively. Overall, the longest delay was observed in NS, IPEX,

OS and non-syndromic forms of ichthyoses such as ichthyosis with confetti (IWC), lamellar ichthyosis (LI) and congenital ichthyosiform erythroderma (CIE).

History features

Pregnancy, family history, consanguinity and gender

No details are known about complications during pregnancy as a possible underlying cause of NE, and less is known about the correlation between birth weight or pregnancy period and diagnostic outcome. From the 74 cases, details were extracted about pregnancy, drug use postpartum, family history, consanguinity and neonatal characteristics for example, e.g. gender. Details of the pregnancy period were described in 39/74 of cases. Prematurity would be more likely in cases of ichthyosis prematurity syndrome (IPS) and collodion babies.^{21,81} Preterm birth was described in 15/74 cases (median 35 weeks; range 26–36 weeks), mainly in neonates with NS (n = 5) (Appendix S3), and one collodion baby (out of 2) was born prematurely (33 weeks). Family history was positive in 13/74 cases and negative in 28/74 cases. In the present case series, a positive family history for atopy, PID, ichthyosis, psoriasis and NS increased the risk of the same diagnosis in the newborn. Besides NS and OS, family history of atopy was also reported in cases of seborrheic dermatitis, atopic dermatitis and selective IgA deficiency.⁴ Familial erythroderma was reported in cases of OS and NS.⁴ Spontaneous abortion was reported in a case of Harlequin ichthyosis (HI), while unexplained death of siblings was reported in families with PID and NS.⁴ Consanguinity was reported as a risk factor for NE in cases of ichthyosis ((25%), NS (88%), PID (33%) and in metabolic disorders.^{4,47} Variations exist due to cultural and regional backgrounds, for example in Egypt consanguinity was reported in the majority of congenital ichthyoses (79%), of which LI constituted 32%.⁸⁰ Chananin-Dorfman syndrome (CDS) was found in patients with consanguine parents from the Mediterranean, Middle-east, Saudi Arabia, India and Japan.⁸² Consanguinity was reported in 9/74 cases of which seven had lethal complications (Appendix S4). The majority of 14 NS cases were male (57%), whereas in 23 cases of OS the majority (57%) were female. One study reported a female predominance in NS,⁸³ however, not confirmed by others.⁸⁴ Male predominance (ratio 2,5:1) was suggested in diffuse cutaneous mastocytosis (DCM).⁷³

Medication and nutrition

Ceftriaxone, vancomycin and phenytoin can induce NE.^{6,10,69} Although treatment with penicillin, aminoglycosides and cephalosporin can cause an erythematous rash, it rarely results in erythroderma.¹⁰ Zinc deficiency is a significant finding in acrodermatitis enteropathica, although herein the erythroderma rarely occurs in the neonatal period.

Specifically related to NE, holocarboxylase synthetase deficiency manifests with alopecia, dehydration, secondary

cutaneous candidiasis and ketoacidosis. Patchy alopecia and acrodermatitis enteropathica-like skin lesions are suggestive for biotinidase deficiency. Psoriasis-like scaling appears periorificial before it generalizes. As human milk contains biotins, clinical manifestations in biotinidase deficient neonates occur earlier in breastfed than in formula-fed babies.¹⁰

Physical examination

Collodion membrane and scaling

A collodion membrane is a descriptive term for a transient condition in newborns, without implicating a specific diagnosis or disorder.⁸⁵ It can occur with erythroderma or the erythroderma appears when the collodion membrane disappears.^{1,4,6} The collodion membrane usually sheds within 3–4 weeks after birth.⁸⁵ In 10% of cases a collodion membrane sheds, without leaving any sign of ichthyosis and is known as self-healing collodion baby (SHCB, also known as self-improving congenital ichthyosis or lamellar ichthyosis of the newborn).⁸⁶ The most common related disorders associated with the collodion membrane are inherited ichthyoses (Table 1).^{85–88} Inherited ichthyosis has been divided in non-syndromic ichthyoses, syndromic ichthyoses and unspecified.^{86,89,90} From other studies, in 90% of cases of collodion babies, non-bullous ichthyoses were the underlying diagnosis.^{1,80} From the case series, 4/74 cases reported a collodion membrane: IWC, LI, Gaucher disease and holocarboxylase deficiency.

Rubio-Gomez et al. described a severity score for collodion baby in order to predict the underlying diagnosis, based on clinical characteristics, such as an ectropion and eclabium.²¹ A generalized collodion membrane was more common in autosomal recessive congenital ichthyosis (ARCI), while partial involvement was more frequent in unspecified congenital ichthyosis and syndromic ichthyosis.²¹ A 15-year retrospective study on collodion babies in the Netherlands could not confirm this severity score.⁹¹

The presence and type of scaling in patients with NE can help in the differential diagnosis.⁶ Neonatal scaling and exfoliative erythroderma are suggestive for ichthyoses and NS.⁶ In ichthyosis, rough, dry, scaly skin is commonly seen; brown, dark scaling (frequently with collodion membrane) is typical for LI, while brown and fine white scaling with erythroderma is suggestive for CIE.^{3,6} Annular scaling is suggestive for NS, but the typical ichthyosis linearis circumscripta is not always present.⁷⁹ Psoriasis can resemble ARCI, but usually more areas of unaffected skin can be seen.⁶ Recalcitrant diaper dermatitis with generalization and pustules, sometimes with fever, could suggest erythrodermic psoriasis, while greasy scales on scalp (cradle cap) and skin folds (axilla, neck, retro auricular and diaper areas) suggests seborrheic dermatitis.¹⁰ Perioral scale crusts in combination with desquamation, peeling and a characteristic tenderness of the skin suggest SSSS. Periorificial psoriasiform scaling should also suggest metabolic diseases such as holocarboxylase deficiency, biotinidase deficiency or acrodermatitis enteropathica. Due to

maternal zinc supplementation, signs of acrodermatitis enteropathica in the neonatal period are rare, especially an erythrodermic phenotype. Collaret scales are typical for congenital cutaneous candidiasis (CCC). Skin induration and pruritus is suggestive for a PID,⁴ although pruritus can also manifest in NS, scabies or desmosomal disorders, such as SAM syndrome.⁶²

Alopecia, bullae and pustules

Alopecia is common (45–46% of cases) and is considered as a complication of any severe type of NE.^{3,4} It frequently occurs in PIDs, particularly in OS,⁶ but also presents in metabolic disorders.^{4,10} Alopecia was mentioned in 12/74 cases: trichothiodystrophy (TTD) (1/1; 100%), NS (4/13; 31%), OS (6/23; 26%) and AEC syndrome (1/4; 25%). Alopecia totalis or alopecia of eyebrows and eyelashes is suggestive for a PID.^{4,6} Bullae can be seen in epidermolytic ichthyosis (EI) (formerly known as bullous ichthyosis, keratinopathic ichthyosis or epidermolytic hyperkeratosis), staphylococcal scalded skin syndrome (SSSS) and DCM. In EI, the bullae will diminish over time and are replaced by diffuse hyperkeratosis.⁸⁶ In SSSS, the skin is usually painful, and the child can present with fever, general malaise and irritability.^{6,92} The erythroderma starts abruptly with bullae developing within the erythematous area within 24–48 h.⁹² There can be desquamation with scalded appearance, mainly in friction zones, periorificial cracking and a positive Nikolsky sign.⁹² Mucosae are usually not affected and the erythema often starts in the umbilical area (omphalitis) and diaper area (e.g. pustules, impetigo and cellulitis).⁹² In neonatal DCM, a red skin and blistering was reported in 17/22 cases (79%).⁷³ Diffuse erythroderma is unusual in DCM that may show an indurated, thickening of the skin (peau d'orange).⁶ Extensive blistering with positive Darier sign is a more frequent presentation.⁶ In CCC, papules and pustules may evolve into NE and will usually spare the oral cavity and diaper area but may include palms and soles.⁶ Widely scattered spots on placenta and umbilical cord are a clue to the diagnosis.^{6,9} In CCC, as being a possible opportunistic infection, one must be aware of an underlying PID such as severe combined immunodeficiency (SCID).⁹³ Systemic infections are seen especially in premature infants.⁶

Extracutaneous involvement and systemic symptoms

Extracutaneous symptoms can occur in other organ systems and are often present in syndromic ichthyoses, PIDs and metabolic disorders.^{12,94} Common systemic symptoms in NS are failure to thrive (FTT) and hypernatremic dehydration.⁹⁵ FTT is absent in atopic dermatitis, minimal in ichthyosis but was described in 69% of erythrodermas, predominantly in NS and all PIDs.^{4,10,55} However, due to a protective effect of maternal antibodies, PIDs rarely give systemic symptoms at birth.¹⁰ NS is highly suspected when FTT is combined with a mild to severe erythroderma, sepsis and hypernatremic dehydration.⁶ A PID (OS or severe combined immunodeficiency (SCID)) should be suspected with

lymphadenopathy and hepatosplenomegaly in combination with diarrhoea and/or FTT.^{3,4,6} Opportunistic infections and candidiasis are mainly seen in PIDs.⁴

Specific combinations of cutaneous, extracutaneous and systemic symptoms can be found in NS, CDS, KID and DCM as showed in Appendix S5.^{79,93,95,96} Metabolic diseases are suspected when desquamative erythroderma is accompanied with neurological manifestations such as coma.⁶

Systemic symptoms and presence of syndromic symptoms of the 74 cases are summarized in Appendix S4. From these 74 cases, 17 died (23%) (range 3 days – 19 months; mean 158 days; median 60 days), with high individual mortality rates for OS (2/8; 35%), graft-versus-host disease (GvHD) (2/3; 67%), metabolic disorders (1/3; 33%), AEC syndrome (1/4; 25%) and NS (2/14; 18%). Complications described are septic shock, renal or hepatic failure, multi-organ failure, secondary hemophagocytic syndrome, failure of the central nervous system, respiratory failure, malnutrition, anaemia, thrombocytopenia and extensive diarrhoea.

Additional testing

Skin smears and culturing

If CCC or another fungal infection is suspected, a potassium hydroxide smear is recommended. A fungal culture and eventually polymerase chain reaction (PCR) can support the diagnosis.⁹⁷ If a local *S. aureus* or another infection such as SSSS is suspected, skin swabs from infected sites or from eyes, nose, umbilicus and the vagina of the mother should be sent for bacterial culture.^{7,92,97}

Blood tests

Sarkar stated that laboratory analysis in NE would contribute minimally and advice to start laboratory analysis after exclusion of atopic dermatitis, seborrheic dermatitis, ichthyosis and drug use.⁹⁷ We summarized the individual elements of laboratory tests as recommended by other authors (Table 2). These can be categorized in NE in general or specifically when certain diagnoses are suspected and are stratified as 'standard test' or as 'on indication'. Hypernatremic dehydration and hypoalbuminemia can occur in any case of NE but hypernatremia was more frequently reported in NS.^{4,6} Eosinophilia is common in NS^{4,83,97} although no relation between eosinophilia and severity of NE or underlying diagnosis in NE could be found.^{3,4} In DCM, elevated levels of serum tryptase in adults are correlated with systemic involvement in cutaneous mastocytosis, but this correlation has not been found in children.¹⁰¹ Laboratory results and other diagnostics in the 74 patients are summarized in Appendix S6.

Identifying SCID-PIDs, newborn screening can be facilitated by quantifying T-cell receptor excision circles (TRECs) and kappa deleting-recombination excision circles (KRECs).^{99,100} A quantitative assay of immunoglobulin subsets with flow

cytometry is recommended.^{97,102} However, immunoglobulins in neonates are not fully produced yet. Why immunoglobulin-E (IgE) is increased in neonates is unknown. IgE in newborns is well researched in relation to the risk of developing asthma and allergies.^{103,104} Atopy in the mother seems to be the highest risk factor,^{103,104} and this can contribute to a higher IgE level in the newborn.¹⁰⁵ However, no relation between family atopy and level of IgE level has been reported.¹⁰³ Chang et al. revealed that several genes are related to an increase of IgE production for diseases such as IPEX, OS and WAS syndrome.¹⁰⁶ This could be an explanation of increased IgE in newborns in cases besides atopy. Levels of IgE vary in cases of CDS (>1000 IU/mL),⁷⁹ NS (982–15302 IU/mL),^{83,95} WAS,¹⁰⁶ atopic dermatitis (0–1000 IU/mL),^{83,95} OS (0–45 000 IU/mL)^{83,95} and ichthyosis. IgA can be reduced in NS⁹⁸ or selective IgA deficiency.¹⁰² IgG levels can be reduced in cases of immunodeficiencies, or NS but can also be normal due to maternal IgG.⁹⁸ Although not considered as a routine investigation, elevation of activated IL17/IL-22 is mainly seen in ichthyosis.¹⁰⁷ Additional tests are also recommended in cases of ichthyosis combined with alopecia and neurological signs.

A blood smear is strongly advised when syndromic ichthyosis is suspected. Vacuolated leucocytes called lipid droplets (Jordan's anomaly) are mainly but not only found in CDS.^{6,82,108,109}

However, the severity of the disease is not related to the presence of lipid droplets.¹⁰⁸ When present, investigation of other organ systems, such as a liver ultrasound is recommended.⁸²

Skin biopsies

Histology of skin biopsies in NE is strongly recommended in several studies.^{6,67,97,110} A biopsy can confirm the diagnosis in ~40% of cases.^{3,4,7} Especially high specificity and sensitivity is reported in NS and PIDs, of which in NS due to the sensitive staining of lympho-epithelial Kazal-type related inhibitor (LEKTI) which is absent in NS.^{6,83,110} LEKTI staining is recommended particularly in psoriasiform epidermal hyperplasia to rule out NS,¹¹¹ but in rare cases can also differentiate from desmosomal disorders such as severe dermatitis, atopic diatheses and metabolic (SAM) syndrome, that can resemble NS.⁶² In NS, different histology patterns are seen, based on different phases within the spectrum.⁶⁷ In PID/OS, specific features are observed in the majority of cases.^{4,67} The diagnosis of PID is made based on a spongiotic reactions pattern with keratinocytic necrosis, satellite cell lymphocytes and infiltrates of lymphocytes with or without eosinophils.^{4,110} A biopsy is determinative in OS to differentiate with SCID and maternal GVHD¹; however, publications exist revealing no histological difference between OS and GVHD.¹¹⁰ In ichthyoses, a biopsy is helpful in ~50% of cases.⁴ Skin biopsies

were taken in cases of psoriasis (2/2), OS (9/24), NS (7/14), GvHD (2/3), DCM (1/1), AEC (3/4), non-syndromic ichthyosis (4/10), syndromic ichthyosis (1/2), metabolic disorder (1/3) and other (1/4). Besides classical H&E staining, electron microscopy examination may be helpful, for example, in NS.²⁸ Ultrastructural examination is not frequently performed nowadays. Skin histology is also helpful in SSSS⁶ and EI.^{1,6} In bullous skin diseases, EI can be differentiated from SSSS and hereditary epidermolysis bullosa (EB).¹ Also, in cases of skin detachment, to determine the level of detachment, immunofluorescence on skin biopsies is most valuable on narrowing the diagnosis. The recommended number of biopsies range from 2¹¹⁰ to 3⁹⁷ although original literature herein refers to obtain multiple biopsies in adult erythroderma, in which diagnosis confirmation could better be determined compared to a single biopsy.¹¹²

When a punch biopsy is not feasible or permitted, an alternative approach is described to differentiate between EI, toxic epidermal necrolysis (TEN) and SSSS: the 'jelly roll' frozen technique was described and proposed for cases of vesiculobullous diseases of the newborn, wherein sloughed skin is wrapped around a cotton tipped applicator and subjected to frozen section analysis.¹¹³

Hair analysis

Hair abnormalities are known in genetic disorders, such as NS, Menkes disease, TTD, uncombable hair syndrome and loose anagen hair syndrome. NS, Menkes disease and TTD are herein associated with NE. Hairs can be investigated through dermoscopy, reflectance confocal microscopy, optical microscopy and electron microscopy.¹¹⁴

In the published cases, hair analysis was limited to NS, Menkes disease and TTD, which showed characteristic features such as trichorrhexis invaginata, pili torti and trichorrhexis nodosa. In NS, also samples of pili torti and trichorrhexis nodosa were found. Hairs of scalp, eyebrows or eyelashes seems suitable for investigation.⁸³ One study advises to cut the hairs instead of plucking them.^{83,115} In TTD, hair shaft abnormalities will be profoundly seen in area of repeated trauma such as the occipital area.¹¹⁵ In NS, hair from eyelashes are easier to investigate than from the scalp.¹¹⁶ Trichorrhexis invaginata (bamboo hair) is specific for NS.^{11,117} Trichorrhexis nodosa seems non-specific, while seen in ectodermal dysplasia, TTD, NS and Menkes disease.^{83,115,118} In Menkes disease, due to mutations in the copper transporting ATPase, all the copper enzymes are defective and the cross-linking of collagen, elastin and keratin is impaired. Macroscopically, the hair is sparse, fine, slow growing, depigmented and lusterless with a peculiar steely consistency. On microscopic examination, pili torti or kinky hair is observed^{43,117,118} but this can also be found in NS.^{79,83} Trichoschisis, characterized by linear fracture of the hair shaft, given it the appearance of a 'tiger tail' is specific for TTD under polarized light microscopy.^{117,118} Although not seen in the

current literature case series, the majority of patients with keratosis ichthyosis deafness (KID) syndrome suffer from alopecia due to hair deformities.¹¹⁹ In a study on trichoscopy in erythroderma, hair deformities were found in 41% (mainly in NS), 31% in cases with neurological impairment and in 33% of cases with immunological defects.¹¹⁹ Hair abnormalities are not always present at the onset of NE, but many details are unknown. In cases of NS, trichorrhexis invaginata was found after an average of 10 months⁴ with a range from 7 months³ to several years.⁷⁹ Therefore, repeated hair samples may be required to confirm the diagnosis.

Molecular genetic analysis

Genetic mutation analysis is available for almost the complete differential spectrum of NE, but features prominently in diagnosing primary immunodeficiencies, metabolic disorders and all types of ichthyoses (syndromic and non-syndromic). In ichthyoses, 13 genes are currently associated with ARCI: *ABCA12*, *ALOX12B*, *ALOXE3*, *CASP14*, *CERS3*, *CYP4F22*, *LIPN*, *NIPAL4*, *PNPLA1*, *SDR9C7*, *SLC27A4* and *TGMI*.¹ However, in not all patients a known mutation is found.⁶ *TGMI* mutations was most frequently (30–75%) found in ARCI patients but varied due to geographical and cultural origin.^{80,120–122} A correlation between phenotype and genotype variations has been described in *SPINK5*, associated with NS.^{3,98}

Genetic analysis was performed in 39/74 cases and found positive in 30/74 (41%) cases; in OS (16/24; 67%), NS (4/14; 29%), AEC (3/4; 75%), HI (2/4; 50%), EI (2/2; 100%) and non-EI (3/4; 75%). In cases of OS, mutations were found in *RAG1* (14/16; 88%), *RAG2* and *Artemis*. Mutation analysis was also diagnostic in single cases of TTD, IPEX, Menkes disease, KID, holocarboxylase deficiency and kindler epidermolysis bullosa (EB). Remarkably, in a case of HI, DNA was extracted from hairs.¹⁴ No mutation was found in cases of SSSS, DCM and CDS.

Recently in a prospective study, in 70% of patients with NE, a mutation could be detected by next generation sequencing (NGS), with a selected gene panel of 60 genes¹²³ that will be adjusted according to this review (Appendix S7). Based on the diagnostic delay in cases of NS, OS, IPEX and non-syndromic ichthyosis in this review, one can assume that performing mutation analysis in an early phase is important to limit complications. Although in most cases in this review genetic analysis was performed on blood samples, collecting material via non-invasive methods are important to consider as a future alternative in patients with NE. Collecting saliva in neonates with buccal swabs for DNA and RNA sampling seem very promising, but different techniques herein determine optimal outcome.¹²⁴

Imaging investigations

Several imaging investigations are described as useful for the diagnosis in NE, especially in PIDs related to NE.¹⁰² In X-linked agammaglobulinemia, chest X-rays shows sparse lymphoid tissue

(tonsillar and adenoidal), while in common variable immunodeficiency (CVID), bronchiectasis, bronchial wall thickness and atelectasis are seen.^{125,126} In CVID, a magnetic resonance imaging (MRI) of the central nervous system can display diffuse leptomeningeal thickness and enlargement with cerebral atrophy and abscesses.¹²⁵ In SCID and DiGeorge syndrome (DGS), chest X-ray can show a narrow upper mediastinal contour and retrosternal lucency, due to the absence of thymus.^{125,127} In SCID, DGS and WAS recurrent pneumonias can be seen.¹²⁸ As is shown in Supplemental S5, skeletal deformities can be visualized with X-rays in SLS, Conradi-Hünermann-Happle syndrome (CHH) and DGS. Echocardiography can be performed when suspicion arises for DGS, SLS or KID. In our cases found, investigations such as X-rays (NS, Menkes disease and DCM), ultrasonography (AEC), EEG (Menkes disease) and MRI (DCM) were performed, though in the majority did not lead to the diagnosis. Considering that imaging can be useful in typical cases, imaging is predominantly performed after the neonatal period.

Assessment of diagnostic approach

A multidisciplinary approach is highly recommended by previous publications wherein an alternative approach in patients with NE was reported.^{1,6,9–11,90,94} According to this scoping review, many aspects of diagnostics contribute in finding a highly suggestive or definite diagnosis in patients with NE. A multidisciplinary 6-step diagnostic approach is proposed (Fig. 2).

Step 1. A combined approach of dermatologists and paediatricians is recommended with a complete medical history (pregnancy, complications and miscarriages, recent medication use, consanguinity, family history of PID, ichthyosis, atopy and psoriasis) and physical examination with special attention to the presence of collodion membrane, alopecia, blisters and pustules. The collodion membrane suggests a subtype of ichthyoses. When blisters are present, it is recommended to perform an additional skin biopsy (in addition to step 3) for immunofluorescence microscopy to detect the level of blister formation, and have the possibility to detect absence/reduction in desmosomal proteins. Exclude bacterial or fungal infections such as SSSS or CCC, by taking swabs.

Step 2. In all cases of NE a baseline laboratory blood test should be started for 'NE in general' (Table 2). Evaluate findings of step 1 and blood test results to specify a diagnosis.

Step 3. If no diagnosis is found, blood tests should be expanded (Table 2), and histology of skin performed (including LEKTI staining) eventually also trichoscopy. A single skin biopsy is sufficient for evaluation by a dermatopathologist. After genetic counselling and consent, whole blood samples (or DNA) can be sent for molecular genetic testing (e.g. Sanger sequencing, targeted NGS panel, WES and WGS)

(Appendix S7). Genetic testing in an early phase is recommended.

Step 4. Investigate for extracutaneous, syndromic and/or systemic symptoms. If present, consult a paediatric immunologist, neurologist, cardiologist, ENT specialist or ophthalmologist. The combination of neurological signs, hair abnormalities and specific extracutaneous symptoms can narrow down the possible diagnosis towards types of syndromic ichthyosis such as NS, PIDs and metabolic diseases should be excluded, especially in cases with failure to thrive, superimposed infections or lack of response to therapy. On indication, further research can be done.

Step 5. When step 4 shows no abnormalities, consider an inherited ichthyosis. Also consider benign inflammatory skin disorders, such as atopic dermatitis, psoriasis and seborrheic dermatitis, which are rare in the neonatal period and when erythrodermic, mainly manifest after three months of age.

Step 6. No recommendations on follow-up are known, but we recommend first check within 1-2 weeks after first clinical evaluation, if possible by a neonatologist or paediatrician and a dermatologist in an academic hospital. Then, a complete physical examination and re-evaluation of systemic or extracutaneous symptoms if indicated.

Discussion and conclusions

NE comprises a heterogeneous group of underlying potentially life-threatening diagnoses. This literature review on NE systematically describes the many characteristics based on the medical history, family history, physical characteristics and additional diagnostic tests that can aid the clinician in narrowing the differential diagnoses. The aid of the ERN-SKIN-subthematic group Ichthyosis have resulted in an expert opinioned diagnostic approach for practical use.

Additional testing is recommended and helpful in the majority of cases wherein molecular genetics is preferred to start in an early stage of the diagnostic process. However, they are less feasible in cases of (financial) restrictions or lack of (familial) consent and genetic testing is a time-consuming process in which the results are not always known on a short notice. In those cases, the multidisciplinary diagnostic proposed can be very helpful. Molecular genetics is an evolving area nowadays though, wherein establishing a diagnosis can be done more quickly in time to come. In specific cases, such as bullous characteristics, PIDs and NS, histology of skin biopsies (including LEKTI staining) is a critical element that can easily exclude other causes of NE. Blood tests are needed in NE in general, to reduce and monitor common complications as hypernatremia, dehydration and infections. Specific blood tests can be initiated on indication when metabolic disorders, syndromic ichthyoses or PIDs are suspected and infectious diseases are excluded. In collodion babies, the approach with diagnostic tests could be

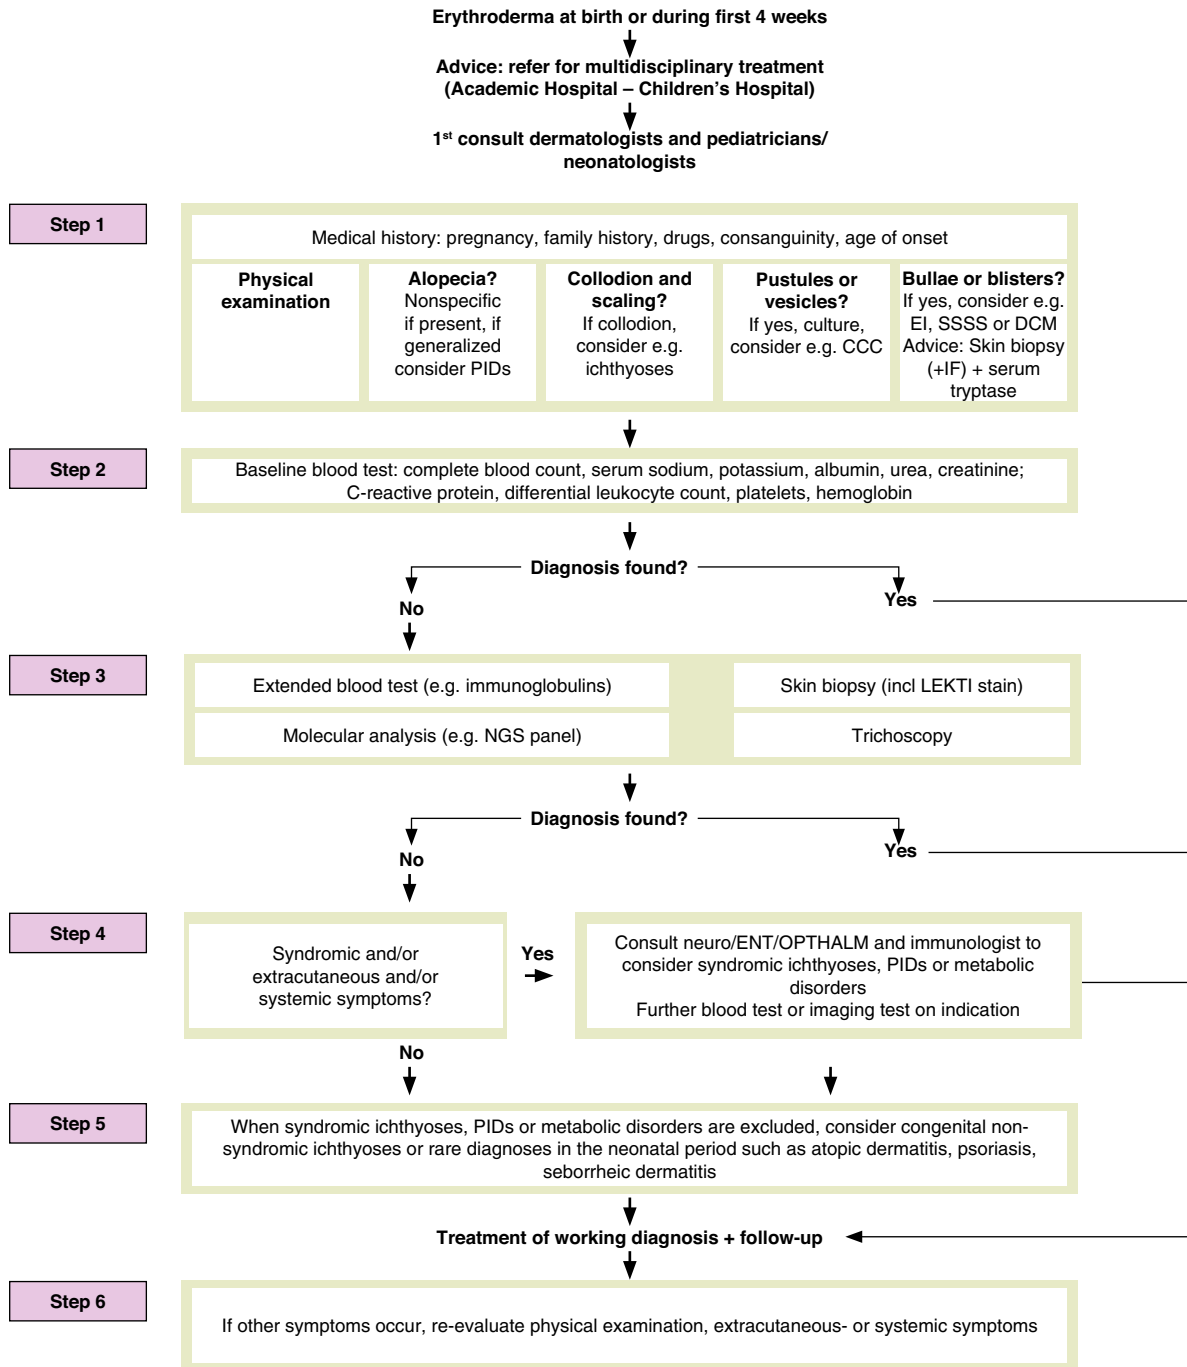

Figure 2 A 6-step approach of neonatal erythroderma.

limited because the etiological entities in congenital ichthyoses, wherein metabolic diseases and PIDs are not obvious. Imaging studies seems to have minimal added value in most cases of NE.

The strengths of this review are the systematic literature search, the assistance of a library expert and the expert opinion by the ERN-SKIN group. Limitations are the design of a scoping review, and included cases are prone to publication bias. Future

recommendations in the approach of NE include a high sensitivity of skin biopsies, short-time delay of molecular genetics, and an ongoing multidisciplinary approach in these rare cases. In the Netherlands based on the literature, a NGS NE panel has been developed that is available internationally.

In conclusion, this scoping review with a systematic literature search highlights the characteristics all around NE and proposes a systematic diagnostic approach for all patients with NE, with help from expert opinion of the ERN-SKIN group-subthematic Ichthyosis.

Acknowledgements

No conflicts of interest. This study is part of the Academic Centers of Excellence of Congenital Anatomical Abnormalities and Primary Immunodeficiency Center of the Erasmus MC University Medical Center-Sophia Children's Hospital and of the European Reference Network-SKIN-Ichthyosis. The (parents of the) patients in this manuscript have given written informed consent to the publication of their case details. We thank Wichor Braamer, PhD, information technologist of the Erasmus MC University Medical Center Rotterdam, The Netherlands, for his contribution to the systematic literature search.
