Abstract

Resonant structure in the dipion mass spectrum produced via $B^+ \rightarrow \chi_{c1}(3872)K^+$, $\chi_{c1}(3872) \rightarrow J/\psi\pi^+\pi^-$, with $J/\psi \rightarrow \mu^+\mu^-$ is analyzed using Run 1 and Run 2 data samples from the LHCb experiment. The spectrum is dominated by $\rho^0 \rightarrow \pi^+\pi^-$, but cannot be described by this contribution alone. A significant $\omega \rightarrow \pi^+\pi^-$ contribution, interfering with ρ^0 , is observed for the first time. This is a more significant observation ($> 7.1\sigma$) of $\chi_{c1}(3872) \rightarrow \omega J/\psi$ decays, than previously achieved with $\omega \rightarrow \pi^+\pi^-\pi^0$ decays. The relative contribution of ω to the total $\chi_{c1}(3872) \rightarrow \pi^+\pi^- J/\psi$ rate is at the level expected from the measured $\chi_{c1}(3872) \rightarrow (\omega \rightarrow \pi^+\pi^-\pi^0)J/\psi$ rate, if the interference between the ρ^0 and ω amplitudes is neglected, $(1.9 \pm 0.4 \pm 0.3)\%$. The interference enhances the importance of ω contribution by an order of magnitude to $(21.4 \pm 2.3 \pm 2.0)\%$. The results support interpretations of the $\chi_{c1}(3872)$ state as an exotic hadron, since its isospin violating $\rho^0 J/\psi$ decay rate, relative to isospin conserving $\omega J/\psi$ decay, is an order of magnitude larger than expected for an ordinary charmonium state.

Observation of ω contribution in the

$\chi_{c1}(3872) \rightarrow \pi^+ \pi^- J/\psi$ decays

Acknowledgements

There are a number of people who contributed to this thesis. Foremost, I would like to express my sincere gratitude to professor Tomasz Skwarnicki, my advisor. Since I became his student, he showed me his unwavering support and guided me with great patience when I had difficulties during the physics analysis work. His immense high energy physics knowledge, experience and genuine, caring personality set a standard that I strive to reach.

I also like to thank professor Sheldon Stone. His vast physics analysis and detector construction knowledge make him a great leader of Syracuse University's LHCb group. I also want to extend my thanks to professor Marina Artuso and professor Raymond Mountain. It was great fun to work with them. Professor Marina Artuso was immensely helpful during the silicon sensor study. She was always willing to help when I had questions, and it was easy to communicate with her. Working with professor Raymond Mountain was a delightful experience. His knowledge in detector physics and managing skills made our lab work pleasant, and he was accommodating and open to discussions. Also, thanks to professor Matt Rudolph and professor Steve Blusk for always being approachable.

Many thanks to Mikhail Mikhasenko for providing us with a theoretical model for our dipion mass spectrum analysis. Also, many thanks to Alessandro Pilloni, César Fernández-Ramírez and Adam Szczepaniak for fruitful discussions on the X(3872) study.

I want to say thank you to my mentor, PhD Orlokh Dorjkhaidav, who sadly passed away. Special thanks to Ivan Polyakov and Xuhao Yuan. They were helpful during the laboratory work. I am also grateful to my friends Arvind, Scott, Michael, Hangyi, Xixin and Andy. Special thanks to my good friend Sagnik who I had great conversations about many different topics.

Finally, I want to mention that I am forever grateful to my mother and grandparents for their love and support. They always stay with me during my difficult times. If my father were still alive, he would be incredibly proud of my achievement.

Dedicated to my mother, father and my grandparents.

35	<i>The distribution of $p_T(B^+)$ for the data (points with error bars) and for the MC (histogram). The distributions were corrected for the varying bin width. The data points were obtained by fitting the $X(3872)$ peak in the $J/\psi\pi^+\pi^-$ mass distributions for various bins. The MC events were weighted by the run-dependent and dipion-mass dependent weights. The MC distribution was normalized to the same number of entries as the data.</i>	47
36	<i>The ratio of the data and MC distributions of $p_T(B^+)$ (Fig. 35), fit with a smooth function used as a correction weight for simulated events.</i>	48
37	<i>The distributions of p_T of various reconstructed particles, and of $X(3872)$ helicity angle, for the data (points with error bars) and for the MC (histogram). The distributions were corrected for the varying bin width. The data points were obtained by fitting the $X(3872)$ peak in the $J/\psi\pi^+\pi^-$ mass distributions for various bins. The MC events were weighted by the run-dependent, dipion-mass-dependent and $p_T(B^+)$-dependent weights. The MC distributions were normalized to the same number of entries as the data. .</i>	49
38	<i>Fits of Gaussian function to $m_{\pi\pi}^{reco} - m_{\pi\pi}^{true}$ distributions in different slices of $m_{\pi\pi}^{true}$.</i>	51
39	<i>Dipion mass resolution extracted from the simulations. The red curve is a fit of a smooth function described in the text.</i>	52
40	<i>Dipion mass resolution comparison between 8 TeV (labeled as Run 1) and 13 TeV (Run 2) simulations.</i>	52
41	<i>Fit to the B^+ mass peak (double sided Crystal Ball function) plus a flat background in the simulated $X(3872)$ sample.</i>	53
42	<i>Fit to the $J/\psi\pi^+\pi^-$ distribution in the signal simulations, after the 2σ B^+ mass cut, and with the PV, J/ψ and B^+ mass constraints. We used DSCB for the signal peak and flat background. The blue line represents the total fit. The fitted background level is only 2.8 ± 0.5 events per bin. The signal shape parameters are: $48,805 \pm 216$ signal events, $m = 3,871.91 \pm 0.01$ MeV, $\sigma = 2.47 \pm 0.02$ MeV, $n_1 = n_2 = 10$ (fixed), $\alpha_1 = 1.40 \pm 0.02$, and $\alpha_2 = 1.78 \pm 0.03$.</i>	54

43	<i>Variation of the reconstruction efficiency with dipion mass. Units of efficiency are arbitrarily chosen to be close to 1 near 700 MeV, as only the relative variation matters in this analysis. Quadratic fit function is superimposed: $\epsilon(m_{\pi\pi}) = 0.966 + 1.345 \cdot 10^{-3} (m_{\pi\pi} - 700 \text{ MeV}) + 1.607 \cdot 10^{-6} (m_{\pi\pi} - 700 \text{ MeV})^2$, where $m_{\pi\pi}$ is in MeV.</i>	55
44	<i>Variation of the reconstruction efficiency with dipion mass fit to a cubic polynomial.</i>	56
45	<i>Fit of ρ^0 Breit-Wigner amplitude to the data. The pulls shown below are the data points minus the fit function value, divided by the error on the data. The fit qualities are $\chi^2/\text{NDoF} = 366.6/34$ and $pV = 2 \times 10^{-57}$. . .</i>	58
46	<i>Fit of a sum of Breit-Wigner amplitude for ρ^0 and ω. The total fit is shown by the red line. Individual contributions are shown by the blue and green lines respectively. In this model they interfere destructively except for the highest mass bins. The fit qualities are $\chi^2/\text{NDoF} = 102.9/33$ and $pV = 4 \times 10^{-9}$.</i>	59
47	<i>Two different models of 3π P-wave phase space.</i>	64
48	<i>The isovector $\pi^+\pi^-$ P-wave and F-wave scattering phases extracted from the scattering data by the phenomenological analysis of Ref. [1] (GKPY), compared to the single-pole Breit-Wigner model (BW) with the two different values of R, and Gounaris-Sakurai parameterization [2] from Eq. (43). Note that the blue line is right on top of the black line with a little deviation at the limit of the phase space studied in this analysis. Note also, that the red line is close to zero everywhere. The deviations of the BW and GS models from the GKPY P-wave are shown in the bottom part.</i>	66
49	<i>Fit of the coupled-channel model with ρ^0 alone (i.e. $\alpha_{3\pi} = 0$) and constant $\alpha_{2\pi}(s)$. $\chi^2/\text{NDoF} = 367.8/34$, $pV = 1 \times 10^{-57}$. This fit is almost identical to the fit with ρ^0 Breit-Wigner amplitude (Fig. 45).</i>	69
50	<i>Fit of the coupled-channel model with the ρ^0 and ω contributions and constant $\alpha_{2\pi}$. $\chi^2/\text{NDoF} = 55.1/33$, $pV = 0.0093$.</i>	70
51	<i>Fit of the coupled-channel model with ρ^0 alone with linear $\alpha_{2\pi}$. $\chi^2/\text{NDoF} = 90.5/33$, $pV = 2 \times 10^{-7}$, and $P_1 = 0.50 \pm 0.04$.</i>	71

52	<i>Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. This is our default fit to the data. $\chi^2/\text{NDoF} = 24.7/32$, $pV = 0.82$, and $P_1 = 0.226 \pm 0.045$.</i>	72
53	<i>Fit of the coupled-channel model with ρ^0 alone and quadratic $\alpha_{2\pi}$. $\chi^2/\text{NDoF} = 54.9/32$, $pV = 0.0071$, $P_1 = 0.16 \pm 0.05$, and $P_2 = 0.17 \pm 0.02$.</i>	73
54	<i>Fit of the coupled-channel model with ρ^0 and ω and quadratic $\alpha_{2\pi}$. $\chi^2/\text{NDoF} = 24.6/31$, $pV = 0.78$, $P_1 = 0.21 \pm 0.07$, and $P_2 = 0.02 \pm 0.05$.</i>	74
55	<i>The amplitude model obtained by the fit to the LHCb data, with the phase-space limit extended by setting $X(3872)$ mass to 4000 MeV. The actual phase-space limit imposed by the true $X(3872)$ mass is indicated by the vertical dashed line. No mass resolution, nor detector efficiency were included here.</i>	75
56	<i>Fits of the coupled-channel model with ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. In this fit, m_ρ mass is a free parameter. $\chi^2/\text{NDoF} = 24.7/31$, $pV = 0.78$, $m_\rho = 777.1 \pm 10.8$ MeV and $P_1 = 0.23 \pm 0.06$.</i>	77
57	<i>Fits of the coupled-channel model with ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. In this fit, Γ_ρ mass is a free parameter. $\chi^2/\text{NDoF} = 24.7/31$, $pV = 0.78$, $\Gamma_\rho = 144.2 \pm 12.4$ MeV and $P_1 = 0.21 \pm 0.08$.</i>	78
58	<i>Fits of the coupled-channel model with ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. In these fits, $R = 1.3$ (1.6) GeV^{-1} at the top (bottom) displays. The P_1 coefficients are 0.21 ± 0.05 (0.24 ± 0.05), respectively.</i>	79
59	<i>Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. The top (bottom) figures are obtained with $R_{\text{prod}} = 0$ (30) GeV^{-1} (see the text). The P_1 coefficients are 0.17 ± 0.04 (0.56 ± 0.05), respectively.</i>	80
60	<i>Fit of the coupled-channel model with ρ^0 and ω contributions and constant dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. Non-resonant $\pi^+\pi^-$ terms is added to the production vector. $\chi^2/\text{NDoF} = 24.5/32$ and $pV = 0.82$.</i>	81

61	<i>Fit of the coupled-channel model with ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. An excited ρ^0 is included in the K-matrix. $\chi^2/\text{NDoF} = 25.1/32$, $pV = 0.80$ and $P_1 = 0.32 \pm 0.05$.</i>	82
62	<i>Fits of the coupled-channel model with ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. Fit result when $g_{\omega \rightarrow 2\pi}^2$. $\chi^2/\text{NDoF} = 24.7/32$, $pV = 0.82$ and $P_1 = 0.23 \pm 0.05$.</i>	83
63	<i>Likelihood-weighted distribution of the D-wave fraction as extracted from the analysis of angular correlations in $X(3872)$ decays to J/ψ and $\pi^+\pi^-$ (Fig. 2 from Ref. [3]).</i>	83
64	<i>Fit of the coupled-channel model with the ρ^0 and ω contributions, linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$ and $A_D = 0.176$, which gives the D-wave fraction of 4%. $\chi^2/\text{NDoF} = 24.5/32$, $pV = 0.82$, and $P_1 = 0.313 \pm 0.046$.</i>	84
65	<i>Dipion mass efficiency for $\cos\theta_X > 0$ and $\cos\theta_X < 0$ samples.</i>	86
66	<i>Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. The top: fit sample is in the $\cos\theta_X > 0$ region, $\chi^2/\text{NDoF} = 42.2/32$, $pV = 0.11$. The bottom: fit sample is in the $\cos\theta_X < 0$ region, $\chi^2/\text{NDoF} = 26.9/32$ and $pV = 0.72$. θ_X is the helicity angle of $X(3872)$. The P_1 coefficients are 0.16 ± 0.05 and 0.31 ± 0.08, respectively.</i>	87
67	<i>A fit to the $\psi(2S)$ peak in the $J/\psi\pi^+\pi^-$ mass distribution after the $\pm 2\sigma$ cut on the B^+ mass.</i>	89
68	<i>A fit to the B^+ mass peak after the $\pm 2\sigma$ cut on the $\psi(2S)$ mass.</i>	90

72	<i>Fits to B^+ mass peak after the default selection (blue) and after the additional cut on the BDT discriminant (red).</i>	93
73	<i>BDT cut on the data sample. Cut value is -0.1091.</i>	93
74	<i>BDT cut on the MC sample. Cut value is -0.1091.</i>	94

75	<i>Variation of the reconstruction efficiency with dipion mass after the BDT cut (blue points), compared to the efficiency with the default cuts (red points). The differences are small.</i>	94
76	<i>Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. The BDT cut is applied to this sample. $\chi^2/\text{NDoF} = 24.6/32$, $pV = 0.82$ and $P_1 = 0.24 \pm 0.04$.</i>	95
77	<i>The distribution of $p_T(K)$ for the data (points with error bars) and for the MC (histogram). The distributions were corrected for the varying bin width. The data points were obtained by fitting the $X(3872)$ peak in the $J/\psi\pi^+\pi^-$ mass distributions for various bins. The MC events were weighted by the run-dependent, dipion-mass dependent, and $p_T(B^+)$ weights. The MC distribution was normalized to the same number of entries as the data.</i>	97
78	<i>The ratio of the data and MC distributions of $p_T(K)$ when using PIDcalib package in MC. Fit of a smooth function, used as a correction weight for simulated events, is shown.</i>	98
79	<i>The distributions of p_T of various reconstructed particles, and of $X(3872)$ helicity angle, for the data (points with error bars) and for the MC (histogram) with use of PIDcalib package. The distributions were corrected for the varying bin width. The data points were obtained by fitting the $X(3872)$ peak in the $J/\psi\pi^+\pi^-$ mass distributions for various bins. The MC events were weighted by the run-dependent, dipion-mass-dependent and $p_T(B^+)$-dependent weights. The MC distributions were normalized to the same number of entries as the data.</i>	99
80	<i>Variation of the reconstruction efficiency with dipion mass obtained using PIDcalib in the simulations (blue points), compared to the efficiency with the default simulations (red points).</i>	100
81	<i>Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. The BDT cut is applied to this sample. $\chi^2/\text{NDoF} = 24.6/32$, $pV = 0.82$ and $P_1 = 0.22 \pm 0.04$.</i>	101

82	<i>Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. This fit was performed with the dipion mass resolution taken from simulations without any correction factor. $\chi^2/\text{NDoF} = 26.6/32$, $pV = 0.74$, $P_1 = 0.23 \pm 0.05$.</i>	102
83	<i>Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. This fit was performed with the dipion mass resolution scaled up by 14%. $\chi^2/\text{NDoF} = 22.6/32$, $pV = 0.89$, $P_1 = 0.23 \pm 0.05$.</i>	103
84	<i>Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. This fit was performed in reduced mass range from 380MeV to 775MeV. $\chi^2/\text{NDoF} = 18.0/31$, $pV = 0.97$, $P_1 = 0.24 \pm 0.05$.</i>	104
85	<i>Fit to the $J/\psi\pi^+\pi^-$ distribution in the signal simulations, after the 2σ B^+ mass cut, and with the PV, J/ψ and B^+ mass constraints. We used Gaussian function for the signal peak and flat background. The blue line represents the total fit. Compare to fit with the double-sided Crystal Ball lineshape shown in Fig. 42.</i>	105
86	<i>The distribution of $m_{J/\psi\pi^+\pi^-}$ with the 2σ B^+ mass signal cut, with the PV, J/ψ and B^+ mass constraints, fit with a Gaussian for the signal, and quadratic polynomial for the background. The blue line represents the total fit, red is the signal component, and the dashed-green is the background. Compare to the fit with the double-sided Crystal Ball lineshape in Fig. 30.</i>	106
87	<i>Projections of unbinned fits to $m_{J/\psi\pi\pi}$ vs. $m_{\pi\pi}$, with Gaussian X(3872) shape, in different $m_{\pi\pi}$ bins, onto the $m_{J/\psi\pi\pi}$ axis. The total fit, the X(3872) signal and the background components are shown by the green, red and blue lines, respectively. Compare to the fits shown done with double-sided Crystal Ball lineshape in Fig. 33.</i>	107
88	<i>Variation of the reconstruction efficiency with dipion mass obtained using Gaussian lineshape for X(3872). Units of efficiency are arbitrarily chosen to be close to 1 near 700 MeV, as only the relative variation matters in this analysis. Compare to the efficiency obtained with the double-sided Crystal Ball lineshape in Fig. 43.</i>	108

89	<i>Fit of the coupled-channel model to the mass spectrum obtained using Gaussian $X(3872)$ shape, with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. $\chi^2/\text{NDoF} = 20.0/32$, $pV = 0.95$, and $P_1 = 0.242 \pm 0.045$.</i>	109
90	<i>Fit of the coupled-channel model to the mass spectrum obtained using Gaussian $X(3872)$ shape, with the ρ^0 contribution alone and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. $\chi^2/\text{NDoF} = 72.8/33$, $pV = 8 \times 10^{-5}$, and $P_1 = 0.48 \pm 0.04$.</i>	110
91	<i>Fit of ρ^0 Gounaris-Sakurai model to the data. The fit qualities are $\chi^2/\text{NDoF} = 290.0/34$ and $pV = 2 \times 10^{-42}$.</i>	112
92	<i>Fit of Gounaris-Sakurai model of ρ^0 plus a simple Breit-Wigner formula for ω (Eq. 51) to the data. The relative phase was set to 95° (the fit is insensitive to it as discussed in Sec. 10). The fit qualities are $\chi^2/\text{NDoF} = 90.0/33$ and $pV = 3 \times 10^{-7}$.</i>	113
93	<i>Fit of Gounaris-Sakurai model of ρ^0 coupled with ω via Eq. 50. The relative phase was set to zero. The fit qualities are $\chi^2/\text{NDoF} = 34.4/33$ and $pV = 0.40$.</i>	114
94	<i>Fit of Gounaris-Sakurai (GS) model of ρ^0 coupled with ω via Eq. 50, and ρ^0, in the GS representation added to the fit. The relative phase of ω was set to zero. The relative phase of ρ^0 was set to 3.76 rad [4]. The fit qualities are $\chi^2/\text{NDoF} = 24.8/32$ and $pV = 0.81$.</i>	115

1 Standard Model particles

The Standard Model of particle physics describes the interaction between the fundamental particles in nature and how they behave. The universe is governed by four fundamental forces: gravity, electromagnetic, strong and weak forces. Bosons have integer spins and they are governed by Bose-Einstein statistics. Fermions, or matter particles, are described by Fermi-Dirac statistics and they have non-integer spins. The Standard Model concerns about electromagnetic, strong and weak forces but not gravity. Gravity is too weak to play an important role in particle physics so we can simply ignore it. Quantum field theory tells us that all forces in nature have a force carrier particle which mediates force between fermions when they interact with each other. For example, when two fermions interact electromagnetically, they exchange photons. Photons are the quanta of the electromagnetic force. Likewise, strong and weak forces have their own force carriers and they are gluon and W, Z bosons.

So far, the Standard Model (see Figure1) of particle physics is the most successful theory that we currently have. All particles in the Standard Model have been experimentally proven. An important recent discovery was the famous Higgs boson¹ measured by the ATLAS and CMS collaborations in July 2012 [5,6]. However, there are still unanswered questions about the masses of neutrinos, the generation problem,² dark matter etc.

All twelve fermions are grouped into three generations. They only differ by their masses from their corresponding particles from other generations. Heavier the mass, the more unstable the particle will become, so our current matter-dominated universe is only made up of the first generation. High energy accelerators can produce muons, taus, and hadrons made up of charm, bottom, and strange quarks, but these particles are not completely stable.

¹Higgs bosons give mass to other particles.

²The Standard Model has three fermion generations. We don't know why there are three.

Figure 1: *Standard Model of particle physics.*

25 Quarks are unique particles, and they possess electric, weak and colour charge, which
 26 is an intrinsic property. One can imagine colour as a degree of freedom of a quark, and
 27 each quark carries one of three colour charges: red, blue, and green. Anti-quarks have an
 28 anti-colour charge. Due to the quark confinement, see Figure.2, no single quark can be
 29 observed, and all hadrons, meson and baryon, are colourless. Plus, they form structures
 30 like meson and baryon. Quark and anti-quark bounded by gluon forms meson, and three
 31 quarks with distinct colours make up baryon. Quarks are subject to all four fundamental
 32 forces. Leptons on the other hand, do not participate in strong interaction. They are
 33 elementary particles and have integer electric charge. The standard model assumed
 34 neutrinos were massless, but experiments showed these particles must have specific masses
 35 due to the neutrino oscillation. They only interact via electroweak and gravitational
 36 forces, so neutrino detection is enormously difficult. See Table.1 for more details about
 37 the properties of the Standard Model particles.

Figure 2: *Illustration of quark confinement. Top: Meson, Middle: Baryon, Bottom: anti-Baryon.*

	Symbol	Name	Mass	Charge
Quarks	u	Up	2.2 MeV	$\frac{2}{3}$
	d	Down	4.7 MeV	$-\frac{1}{3}$
	c	Charm	1.28 GeV	$\frac{2}{3}$
	s	Strange	96 MeV	$-\frac{1}{3}$
	t	Top	173 GeV	$\frac{2}{3}$
	b	Bottom	4.18 GeV	$-\frac{1}{3}$
Leptons	e	Electron	0.511 MeV	-1
	ν_e	Electron neutrino	< 1.0 eV	0
	μ	Muon	105.66 MeV	-1
	ν_μ	Muon neutrino	< 0.17 MeV	0
	τ	Tau	1.7768 GeV	-1
	ν_τ	Tau neutrino	< 18.2 MeV	0

Table 1: *Standard Model fermions and their properties.*

38 In 1940s, the quantum theory of electrodynamics was formulated by Richard Feynman,
 39 Shinichiro Tomonaga, and Julian Schwinger. Quantum Electrodynamics, or QED, is an
 40 abelian gauge theory with symmetry group U(1). Quanta (photons) of an abelian gauge
 41 field must be massless, uncharged and have integer spin. The first quantum theory of
 42 weak interaction was presented by Enrico Fermi and put into its present form by Sheldon
 43 Glashow, Steven Weinberg, and Abdus Salam in the 1960s. The weak interactions,
 44 which account for example for beta decay, are mediated by W^\pm and Z bosons. These
 45 particles are accurately described by an SU(2) gauge theory. In 1983, W^\pm , Z bosons were
 46 discovered in CERN by the UA1 and UA2 collaborations. There was no quantum theory
 47 of strong interactions until the development of Quantum Chromodynamics in 1970s. QCD
 48 is non-abelian gauge theory with symmetry group SU(3) and gluons are the quanta. The
 49 existence of gluons was initially theorized by Gell-Mann and experimentally proven at
 50 DESY in 1978. Currently, we have no successful quantum theory for gravity. See Table.2
 51 for more information about the relative strengths of four fundamental forces.

Interaction	Relative Strength (Relative to Gravity)	Force Carrier	Mass(GeV)
Strong	10^{38}	Gluon	0
Electromagnetism	10^{36}	Photon	0
Weak	10^{25}	W^\pm and Z bosons	80.4 and 91.2
Gravitation	1	Graviton(hypothetical)	0

Table 2: *Standard Model forces and their relative strengths.*

2 Exotic Hadrons and X(3872) state

The quarks (q) can't exist individually in nature. Instead, they form structures like mesons ($q\bar{q}$) and baryons (qqq). When Gell-Mann proposed quarks, all known hadrons (i.e. particles which can have strong interactions) could be explained as either $q\bar{q}$ or qqq bound states. Theoretically, there is no limit in number of quarks to form a hadron. Hadrons with more than the minimal quark content are often called exotic. Physicists couldn't confirm the existence of exotic hadrons made out of light quark (u , d or s) like tetra- ($qq\bar{q}\bar{q}$) or penta-quarks ($qqqq\bar{q}$) for many years. Fortunately, B-factory experiments have collected huge statistics from e^+e^- collision. An abundant bottom (b) and charm (c) productions brought an ideal playground for the exotic hadrons involving quarks. Top quark (t) is too short-lived to form hadrons.

In 2003, Belle found a very narrow resonance in the $\pi^+\pi^-J/\psi$ invariant mass distribution at 3,872 MeV in $B^\pm \rightarrow \pi^+\pi^-J/\psi K^\pm$ decays [7]. Due to its narrow width, and mass being close to the $D^0\bar{D}^{*0}$ threshold, it was suggested that the X(3872) was not a conventional charmonium state ($c\bar{c}$), but might be a loosely bound $D^0\bar{D}^{*0}$ molecular state (in molecular state two hadrons are bound together by nuclear-type force) or tightly bound tetraquark (direct colour interactions of four quarks). A lot of discussions emerged seeking to give a proper interpretation to this state. Determining its quantum number was crucial. A five-dimensional amplitude analysis was performed by the LHCb collaboration of angular correlations in $B^+ \rightarrow X(3872)K^+$, $X(3872) \rightarrow \pi^+\pi^-J/\psi$, $J/\psi \rightarrow \mu^+\mu^-$ decays and $J^{PC} = 1^{++}$ was determined [8]. Such quantum numbers can be accommodated in both tetraquark and molecular models, as well as in X(3872) interpretation as a charmonium state, $\chi_{c1}(2P)$.

Figure 3: The distribution of mass difference between $\pi^+\pi^- J/\psi$ and J/ψ in $B^\pm \rightarrow \pi^+\pi^- J/\psi K^\pm$ decays. The peak at 0.59GeV is due to the $\psi(2S)$ charmonium state. The peak corresponding to the $X(3872)$ discovery is indicated with an arrow.

75 In a tetraquark model, mass splitting due to the mixing between $u\bar{u}c\bar{c}$ and $d\bar{d}c\bar{c}$ was
 76 predicted [9], $M(h) - M(l) = (7 \pm 2)/\cos\theta \text{ MeV}$, where $M(X_{h,l})$ are the masses of the
 77 higher and lower states after the mixing of the two states. The difference is expected to
 78 appear as the difference in the $X(3872)$ masses separately measured in $B^\pm \rightarrow X(3872)K^\pm$
 79 and $B^0 \rightarrow X(3872)K^0$. The Belle result for this difference in the $\pi^+\pi^- J/\psi$ mode is found
 80 to be $(-0.71 \pm 0.96(\text{stat}) \pm 0.19(\text{syst}))\text{MeV}$ [10], which disfavors this particular tetraquark
 81 model.

82 A $D^0\bar{D}^{*0}$ molecular interpretation of $X(3872)$ is very plausible, because of its narrow
 83 width, ($\Gamma < 1.2\text{MeV}$), and the mass being very close to ($M = 3,871.69 \pm 0.17\text{MeV}$).
 84 Both features are expected for loosely bound D^0 and \bar{D}^{*0} . Inspired by this argument,
 85 $B \rightarrow D^0\bar{D}^{*0}K$ decays were reconstructed to examine the $D^0\bar{D}^{*0}$ mass spectrum and a
 86 clear overabundance was observed near the threshold. The observed $X(3872)$ mass peak
 87 was consistent with that determined by the $\pi^+\pi^- J/\psi$ mode [11, 12]. The $\mathcal{BR}(X(3872 \rightarrow$
 88 $D^0\bar{D}^{*0}))$ was found to be ten times as large as $\mathcal{BR}(X(3872 \rightarrow \pi^+\pi^- J/\psi))$. This was again
 89 expected in the molecular model.

90 The conventional charmonium state, $\chi_{c1}(2P)$, is expected near or above the $D^0\bar{D}^{*0}$

91 threshold. If its mass coincided with the threshold, such state would also be narrow
 92 (decays to $D\bar{D}$ are forbidden), and like to decay to $D^0\bar{D}^{*0}$ above the threshold. Such state
 93 would also be expected to have photon and light-hadron transitions to lower charmonium
 94 excitations: $\gamma\psi(2S)$, $\gamma J/\psi$, $\pi\pi\chi_{c1}(1P)$ and $\omega J/\psi$. A small fraction of ω decays to $\pi^+\pi^-$,
 95 which would give rise to $\pi^+\pi^- J/\psi$ decays, with the dipion mass peaking sharply near its
 96 upper kinematic bound reaching the tail of the relatively narrow ω particle. However, the
 97 observed dipion mass distribution in $X(3872)$ decays is broadly peaking towards its upper
 98 end suggestive of $\rho^0 \rightarrow \pi^+\pi^-$ resonance. Large isospin violating $X(3872) \rightarrow \rho^0 J/\psi$ decays
 99 are not expected for a normal charmonium state. However, the large isospin violation finds
 100 natural explanation in the molecular model, because of about 8 MeV difference between
 101 the $D^0\bar{D}^{*0}$ and D^+D^{*-} thresholds. This thesis is concerned with the analysis of the dipion
 102 mass spectrum in $X(3872) \rightarrow \pi^+\pi^- J/\psi$ decays in order to determine relative strength of
 103 isospin violating $\rho^0 J/\psi$ and isospin conserving $\omega J/\psi$ decays. This in turn should help us
 104 understand the nature of this mysterious resonance.

105 Recently, the $X(3872)$ state was renamed to $\chi_{c1}(3872)$ by the Particle Data Group. In
 106 this thesis, we refer to this particle by its traditional label.

107 The data were collected with the LHCb detector operating at the Large Hadron
 108 Collider (LHC) in 2011-2012 (Run 1) and 2015-2018 (Run 2) periods.

109 3 Detector Description

110 3.1 The LHC Machine

111 The LHC, Large Hadron Collider, is the world’s largest hadron colliding machine located
112 on the border between Swiss and France, close to Geneva. The circumference is 27 km,
113 and it sits between 50 to 175 meters beneath the ground (see Figure 4). It is designed
114 to accelerate beams of protons up to an energy of 7 TeV and has two counter-rotating
115 proton beams. These beams must travel in a vacuum environment to avoid collision with
116 gas molecules. The vacuum is cooled to cryogenic temperature — which is at -271.3°C —
117 using the liquid helium. To bend the proton beams, LHC uses 1232 dipole magnets and
118 400 quadrupole magnets to focus the beam in the traverse plane. Each proton beam will
119 have 2808 bunches, and each bunch contains 1.15×10^{11} protons. The LHC accelerates
120 protons to 99.9991% of the speed of light and collides them at four interaction points.
121 There are four detectors in each of these points: ATLAS, CMS, ALICE, and LHCb.
122 ATLAS and CMS are designed to study massive particles like Higgs boson. ALICE is
123 to study heavy-ion collisions and quark-gluon plasma, which is the fifth state of matter
124 in which quarks and gluons are freed. The LHCb detector focuses on the CP violation
125 measurements in b and c meson decays, probing a physics beyond standard model and
126 exploring the exotic hadronic states, which later will be discussed in length.

Figure 4: *LHC underground complex.*

127 In order to accelerate protons to the energy of 7 TeV, several stages of acceleration are
128 applied. The process begins with the extraction of protons by ionizing the hydrogen gas
129 and accelerates them up to 50 MeV in LINAC 2 using radio frequency cavities. After the

130 initial acceleration, protons will be injected into the Proton Synchrotron Booster. With
 131 synchrotron rings, the energy of protons will reach 1.4 GeV and start feeding into the
 132 Proton Synchrotron(PS)(see Figure 5). The energy will reach 25 GeV in this step. From
 133 here, beam will enter Super Proton Synchrotron(SPS) and accelerated to an energy of
 134 450 GeV. Finally, the accelerated protons are injected in the LHC. Proton beams are
 135 separated from one another by a time-space of 25 ns corresponding to a bunch crossing
 136 rate of 40 MHz. The LHC's luminosity can get to $\mathcal{L} = 10^{34} \text{cm}^{-2} \text{s}^{-1}$ at the CM(center of
 137 mass) energy of $E_{cm} = 14 \text{TeV}$.

Table 3: *Two main LHC parameters of proton-proton collision.*

Year	2011	2012	2015	2016	2017	2018
\sqrt{s} TeV	7	8	13	13	13	13
Lumi fb^{-1}	1.0	2.0	0.3	1.6	1.7	2.1

Figure 5: *The LHC accelerator complex.*

138 3.2 LHCb Detector

139 The LHCb is a single-arm forward spectrometer with an angular coverage roughly from
 140 10 mrad to 300 mrad. The layout of the detector is show in Figure.6. This corresponds to
 141 a pseudorapidity range of $1.8 < \eta < 4.9$. The unique design of the LHCb detector is due to
 142 the production of b and \bar{b} quarks at the LHC collision such that their production likely to
 143 be along the beam direction and this allows the LHCb to cover optimal amount of the b
 144 and \bar{b} quark scattering thus, have a huge quantity of B meson data(see Figure. 7).

Figure 6: *LHCb Detector.*

145 The LHCb consists of multiple subdetectors, and each has its specific role in the
 146 experiment:

- 147 • The Vertex Locator, or VELO, is the silicon vertex tracker built around the beam
 148 pipe. Its role is to resolve Primary Vertex with high precision.
- 149 • The Ring Imaging Cherenkov (RICH1) is one of the two Cherenkov detectors used
 150 for particle identification.
- 151 • The Tracker Turicensis (TT), is the first tracking station. It is located before the
 152 LHCb's dipole magnet.
- 153 • The Outer Tracker (OT) and Inner Tracker (IT) are subsequent detectors right after

154 the magnet. OT covers the entire magnet. IT covers the high occupancy region
 155 close to the beam pipe.

- 156 • The RICH2 is the second Cherenkov detector.
- 157 • Calorimetry has two subsystems, the Electromagnetic calorimeter(ECAL) and the
 158 Hadronic calorimeter(HCAL). These two detectors' purpose is to measure the energy
 159 deposited by electromagnetic and hadronic showers, respectively.
- 160 • Muon stations are the final part of the LHCb detector. Five of them are located
 161 after the ECAL and HCAL.

162 All of these subdetectors will be discussed briefly in the following sections. A more
 163 detailed explanations can be found in [13].

Figure 7: *PYTHIA8* simulation of $b\bar{b}$ production in LHCb. Red region shows the LHCb acceptance.

164 3.3 Tracking system

165 The purpose of the tracking system is the momentum measurement of the charged particle.
 166 When charged particles travel through the magnetic field, the particle's trajectory will
 167 bend due to the Lorentz force. By measuring the radius of the curvature, one can know
 168 the momentum of the particle. The LHCb's tracking system consists of VELO, dipole
 169 magnet, and tracking stations(TT, OT, and IT). The TT is placed directly upstream
 170 from the magnet, while the rest are down-stream(see Figure. 8). The magnetic field is
 171 designed to have a strong y component; therefore, the particles traveling along the z-axis
 172 will be bent mostly in the x-z plane.

Figure 8: Schematic of the tracking components with different types of track definitions. The main magnetic component (B_y) as a function of the z coordinate is plotted above.

173 3.3.1 Vertex Locator(VELO)

174 The VELO is located around the pp interaction point. It closely wraps the beam pipe
 175 to measure the primary interaction and secondary displacement vertices. The VELO
 176 operates in intense radiation environment which requires the detector to have high
 177 radiation tolerance. The VELO has the full angular acceptance of the pseudorapidity
 178 range $1.6 < \eta < 4.9$. At least three VELO station hits are required to reconstruct the

179 tracks. The signal to noise ratio is larger than 14. This certify efficient trigger performance.
 180 The spatial resolution of the VELO is $4\ \mu\text{m}$ for 100mrad tracks in the smallest strip pitch
 181 region. Pitch is the space between the strips of the sensor. The R sensor of VELO has
 182 the pitch range from $40\ \mu\text{m}$ to $102\ \mu\text{m}$. For the Φ sensor, the range is $38\ \mu\text{m}$ to $96\ \mu\text{m}$.
 183 The VELO consists of 21 stations, with each containing two half-disk-shaped silicon-strip
 184 detector modules. They consist of two different types of $300\ \mu\text{m}$ thick sensors mounted
 185 back to back. The R sensors measure the radial distance of a particle track to the beam
 186 axis and are made of circular strips around the beam. The Φ sensors are made of straight
 187 radial strips and measure the polar angle of the tracks(see Figure. 10).

Figure 9: *Top left: The LHCb VELO vacuum tank. The cut-away view allows the VELO sensors, hybrids and module support on the left-hand side to be seen. Top right: A photograph of one side of the VELO during assembly showing the silicon sensors and readout hybrids. Bottom: Cross-section in the x-z plane at $y=0$ of the sensors and a view of the sensors in the x-y plane.*

188 Additional two pile-up stations are located upstream of the VELO consisting of two
 189 r-sensor modules. They are used in the hardware trigger, Level-0 Trigger will be discussed
 190 in section, to detect beam-gas interactions. The precision of the reconstructed vertices

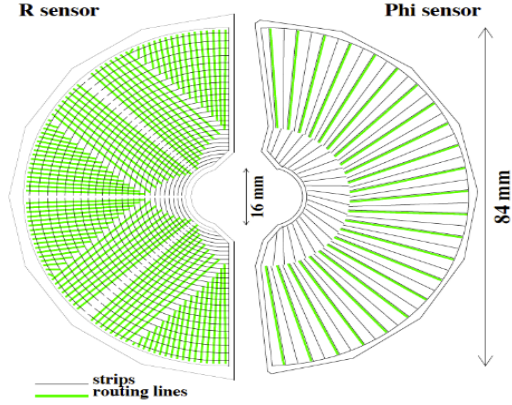

Figure 10: Representation of an R and ϕ sensor.

191 depends on the extrapolation of the measured track positions. Therefore, the VELO
 192 modules are placed close to the interaction point. The sensitive regions of the modules
 193 starts in 8mm distance from the beam line. To protect the sensors from excessive radiation
 194 damage during unstable beam conditions, the half modules can be moved away from the
 195 beam line.

196 3.3.2 Dipole Magnet

197 A dipole magnet consists of two separate aluminum coils, shaped like a saddle and
 198 mounted symmetrically in a window-frame magnetic yoke(see Figure. 11). The magnetic
 199 field is vertically oriented (in the y -direction), and covers $\pm 250\text{mrad}$ vertically and
 200 $\pm 300\text{mrad}$ horizontally. The integrated magnetic field for tracks of 10m in length is 4Tm .
 201 In order to obtain the desired momentum resolution, the integrated magnetic field must
 202 be with a precision on the order of 10^{-4} .

Figure 11: *The LHCb magnet.*

203 3.3.3 Tracker Turicensis

204 The Tracker Turicensis (TT) is a silicon strip tracking station. It is located upstream of
 205 the dipole magnet (closer to the pp region and the VELO detector). It has two 150cm wide
 206 and 130cm high stations with an area of 8.4 m². Each station consists of two detection
 207 layers with the $x - u$ and $v - x$ arrangement. All four layers are separated from each other
 208 by 27cm along the beam axis. The middle two-layer can rotate with a stereo angle of
 209 $\pm 5^\circ$. This orientation provides high precision tracking for the track reconstruction. The
 210 TT contains 143,360 readout strips. The strips are 500 μm thick with a pitch of 183 μm .
 211 The single hit resolution of the TT is around 50 μm . Each half-module consists of a row
 212 of seven silicon sensors positioned as shown in Figure.12. The seven silicon sensors are
 213 grouped into two (4-3) or three (4-2-1) readout sectors. 4-3 type and 4-2-1 type half
 214 modules have L sector formed by the four sensors closest to the readout. These four
 215 sensors are bounded together and directly connected to the lower-most readout hybrid.
 216 For 4-3 type half module, the remaining sector is M sector which is composed of three
 217 sensors. These three sensors are connected to a second readout hybrid mounted on top of
 218 a hybrid by a kapton flex cable with a length of 39 cm. The TT sensors are read out with
 219 Beetle front-end chips. For the TT sensors, they have 512 readout strips. The sensors are
 kept below 5°C by aluminium and copper blocks and cooled with C₆F₁₄.

Figure 12: *Schematics of the TT. Each color corresponds to different readout sections.*

Figure 13: *The TT half module.*

221 3.3.4 Inner Tracker

222 The Inner Tracker is a silicon strip detector with four sections: ASide, CSide, Top, and
 223 Bottom, located in the center of the three tracking stations after the TT. It covers the
 224 region around the beam pipe 120cm wide and 40cm high with an area of around 4 m².
 225 Similar to the TT, it has four layers with $x - u - v - x$ arrangement, and the middle
 226 two-layer are rotated with an angle of $\pm 5^\circ$. The strip geometry was chosen to limit the
 227 maximum hit occupancy per sensor to a few percents. The pitch between the sensors
 228 is about 200 μm leading to a single hit resolution about 50 μm , similar to the TT. The
 229 IT modules consists of either one or two silicon sensors that are connected via a pitch
 230 adapter to a kapton front-end readout hybrid. The IT sensors are read out with Beetle
 231 front-end chips. The IT sensors are 7.6cm wide and 11cm long, and carry 384 readout
 232 strips. Like the TT, IT sensors are kept below 5°C.

233 The Beetle chip is connected to 128 readout strips. The Beetle chip sample the detector
 234 signals at the 40MHz and store the sampled data in an analog pipeline. Then the signals
 235 from one front-end readout hybrid are transmitted from the detector boxesto the service
 236 boxes via a shielded 68-wire twisted-pair cable. The procedure is illustrated in Figure.15.

Figure 14: *Left: IT is wrapped around the beam pipe. Right: IT layout.*

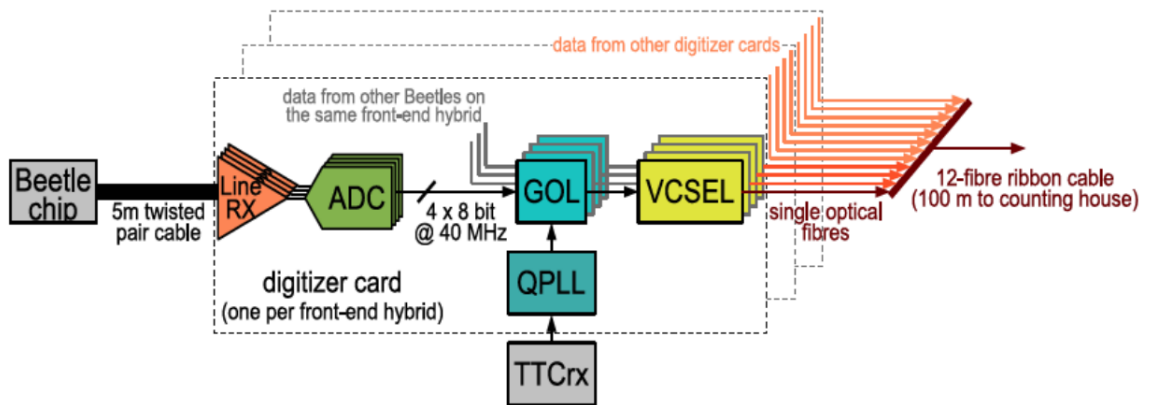

Figure 15: *Signal processing from Beetle chip.*

237 **3.3.5 Outer Tracker**

238 The Outer Tracker(OT) is drift-time detector that include three stations. The design of
239 the OT was based on the need to achieve momentum resolutions δ_p/P of close to 0.4%
240 to resolve the mass of reconstructed B-hadrons to within 10 MeV. The OT cover the
241 IT entirely and it covers 30 m^2 active area. With this coverage, OT is able to measure
charged particle with huge acceptance. The OT uses gas-tight straw-tube modules. Each

Figure 16: *The Outer Tracker detector.*

242

243 module has two stacked layers of drift tubes. The drift tubes are 12 m long with 4.9 mm
244 inner diameters. To keep the fast drift time below 50 ns , The tubes are filled with a gas
245 mixture of Argon (70%), CO_2 (28.5%) and Oxygen (1.5%). Along the center of the drift
246 tube, there is an anode wire which is made of gold plated tungsten of $25\ \mu\text{m}$ diameter and
247 set to +1550 Volts. The outside of the cylinder is made out of cathode and it is grounded.
248 When charged particle traverse through the drift tube, it will ionize the gas inside the
249 chamber. The electrons will drift to the anode wire. Thickness of the cathode material is
250 $40\ \mu\text{m}$ and its is made out of carbon-doped polyamide foil wound simultaneously with a
251 $20\ \mu\text{m}$ thick kapton aminated with aluminum of $12.5\ \mu\text{m}$ thickness. The cross section of

the OT module is shown in Figure.17.

Figure 17: *The Outer Tracker cross section.*

252

253 **3.4 Particle Identification System**

254 Particle Identification(PID) is crucial for the LHCb analysis. The LHCb's PID system
 255 consists of two Ring Imaging Cherenkov Detector(RICH1 and RICH2), Electromagnetic
 256 Calorimeter(ECAL), Hadronic Calorimeter(HCAL), and Muon stations. The two RICH
 257 detectors will identify charged mesons and baryons in different momentum ranges. The
 258 ECAL and HCAL will measure electrons and neutral particles by their energy deposited
 259 in the detector. The Muon stations are for identifying the muons.

260 **3.4.1 The Ring Imaging Cherenkov Detectors**

261 The two Ring Imaging Cherenkov (RICH1 and RICH2) detectors distinguish kaons from
 262 pions and protons. The first (RICH1) is located between the VELO and the magnet and
 263 occupies the region $990 < z < 2165mm$. The second(RICH2) is placed downstream of the
 264 T-stations with its front face positioned at $9500mm$ from the interaction point and with
 265 a depth of $2332mm$. The RICH detectors rely on Cherenkov radiation emitted at angle
 266 θ_C to the direction of motion of a particle travelling at velocity $v > c/n$ in a medium
 267 with refractive index $n > 1$. The Cherenkov angle is given by $\cos\theta_C = c/nv$. The ring
 268 resolution is proportional to σ_θ/\sqrt{N} where σ_θ is the uncertainty on the Cherenkov's angle

269 and N is the number of photoelectrons in the ring [14]. Figure.19 shows the relation
 270 between Cherenkov's angle and particle momentum in different radiators.

271 The RICH1 detector give particle identification in the momentum range $1 < p < 60 \text{ GeV}$
 272 while RICH2 operates in a reduced acceptance of ± 15 to $\pm 120 \text{ mrad}$ in the horizontal
 273 plane and $\pm 100 \text{ mrad}$ in the vertical plane, and identifies particles with momenta in the
 274 range $15 < p < 100 \text{ GeV}$ (see Figure.18). The detector instrumentation is kept out of the
 275 detector acceptance region by reflecting the light out of the chamber to hybrid photon
 276 detectors(HPDs) with spherical and flat mirrors. HPDs have great spatial resolution
 277 and response time. The RICH1 contains aerogel and C_4F_{10} while RICH2 contains CF_4 .
 278 Aerogel is made up of grains of amorphous silicon dioxide with size ranging from 1 to 10
 nm linked together in a three dimensional structure filled by air. These gases are chosen for

Figure 18: *Left: RICH1, Right: RICH2.*

279 their refractive indices, n , which are appropriate for the momentum spectrum of the decay
 280 products of b and c mesons. A track passing through 5 cm of aerogel with refractive index
 281 $n = 1.03$ for light of wavelength 400 nm is expected to yield around 6.5 photoelectrons in
 282 a ring from a charged particle. The corresponding yields for 95 cm of C_4F_{10} ($n = 1.0014$
 283 at 400 nm), and 180 cm of CF_4 ($n = 1.0005$ at 400 nm) are 30 and 22 photoelectrons
 284

285 respectively. To determine whether the ring best matches the expectation from a kaon,
 pion, or proton hypothesis, a likelihood fit is used. The photons are emitted in the shape

Figure 19: Cherenkov angles as a function of momentum.

286

287 of a cone along each track in the radiators, and spherical mirrors are used for focusing
 288 the light. The spherical mirrors and flat mirrors work together and bring the image to
 289 the photon detectors which are mounted out of the acceptance to avoid degrading the
 290 tracking. The detection of photons is measured by Hybrid Photon Detectors (HPD) which
 291 use silicon detector anode inside the vacuum tube(see Figure.20). Each tube comprises
 292 1024 pixels arranged as a 32×32 matrix, while each pixel has size of $500 \times 500 \mu\text{m}^2$. The
 293 HPDs are arranged in a hexagonal pattern outside the RICH detectors. They are shielded
 294 from the magnetic field by large iron boxes. The photoelectrons are released in the HPDs
 295 during the interaction of incident photons with the photocathode(see Figure.21). The
 296 photoelectrons are accelerated by an applied voltage of 10 to 20 kVolts onto a reverse
 297 biased silicon anode and this gives the creation of an average of one electron-hole pair for
 298 every 3.6 eV of deposited energy. The HPDs are read out by integrated pixel chips. The
 299 silicon anodes of the HPD are bump bonded to the LHCbPIX1 binary read out ASIC and
 300 thence to the RICH electronics implemented on FPGAs. Specifically designed algorithms
 301 converts the rings seen in the RICH detectors to a likelihood for a kaon, pion, or proton

mass hypothesis. Combining the information of velocity with the momentum measured

Figure 20: *Left: Hybrid Photon Detector schematics. Right: HPD array of the RICH1 detector.*

302

303 from tracking system, the probability likelihood distribution is determined for each type of
 304 particle and compared to a probability likelihood of pions in the RICH detectors. The
 305 difference in log-likelihood function is $DLL_{X\pi} = \log(P_X/P_\pi)$. Here P is the momentum
 306 and X is the particle to be defined. A plot of difference in log-likelihood is shown in
 307 Figure.22 for tracks that have been matched to true kaons and pions [15]. In Figure.22,
 308 DLL value for kaons tends to be positive but pions tends to be negative. A data-driven
 309 approach is used to check the PID performance of RICH detector. This requires large pure

Figure 22: *Difference in log-likelihood between kaon and pion hypotheses for kaons (top) and pions (bottom).*

310 samples. Each sample covers the full momentum range of 2 to 100 GeV. Furthermore,
 311 the selection of such control samples has to be independent of PID information. Kaon and
 312 pion samples are reconstructed from $K_S^0 \rightarrow \pi^+\pi^-$, $\Lambda \rightarrow p\pi^-$, and $D^{*+} \rightarrow D(K^-\pi^+)\pi^+$.
 313 The Figure.23, the kaon efficiency, pion misidentification rate as a function of momentum.
 314

315 3.4.2 The Calorimeters

316 The calorimeters have dual role of identifying and reconstructing neutral particles like
 317 photons, π^0 , and electrons, and measuring the transverse energy of electron, photon and
 318 charged hadron showers for the hardware trigger. They operate by collecting scintil-
 319 lation light from particle interactions with dense material through optical fibres. The
 320 LHCb's calorimeter system consists of three parts: the preshower/scintillator pad de-
 321 tector(PS/SPD), the electromagnetic calorimeter(ECAL) and the hadronic calorime-
 322 ter(HCAL). The PS/SPD is to distinguish electrons from charged hadrons and neutral

Figure 23: The kaon identification efficiency and the rate of muon misidentification as a function of momentum.

323 pions. It consists of a 15 mm thick lead plate sandwiched between two layers of scintillator
 324 pads, before ECAL(see Figure.24). Charged particles like electrons deposit energy in
 325 the first scintillator and can be differentiate from neutral particles, such as photons.
 326 The SPD/PS detectors use scintillator pad readout by wavelength-shifting (WLS) fibers
 327 coupled to multi-anode photo-multiplier tubes (MAPMT)via clear plastic fibers, and
 328 cover $7.6 \times 6.2 \text{ m}^2$ active area [16]. The SPD/PS detectors consist of two almost identical
 329 rectangular scintillator planes with 12032 channels(cells) of scintillator pads, while a lead
 330 converter of 15mm thickness is between the two planes. Each plane is made of two halves
 331 which can slide independently on horizontal rails. Furthermore, each plane is divided into
 332 three sections:inner(3072 cells), middle(3584 cells) and outer (5376 cells). Hadrons have a
 333 longer interaction length and therefore they pass through without depositing not much
 334 energy. Around 99.6% of pions don't deposit sufficient energy to meet the threshold to be
 335 identified as an electron, while at least 90% of electrons with momenta above 10 GeV pass
 336 the threshold and can be detected.

337 The ECAL is a lead sampling scintillator. It is subdivided into inner, middle, and outer
 338 sections of increasing cell size, a scheme also adopted in the PS/SPD. The dimensions of
 339 the ECAL are $7.76 \times 6.30 \text{ m}^2$ with angular coverage of $\pm 25 \text{ mrad}$ to $\pm 300 \text{ mrad}$ horizontally

Figure 24: *View of the SPD/PS detectors.*

340 and ± 250 mrad vertically. The purpose of the ECAL is to identify neutral particles like
 341 photons and π^0 for trigger and offline analysis. The total thickness of the ECAL layers is
 342 42 cm and it is enough for all energy in an electromagnetic shower to be captured. This
 343 required for good energy resolution. Each module is constructed from alternating layers of
 344 2 mm thick lead, 120 μm thick reflecting paper and 4 mm thick scintillator tiles. When
 345 excited by the passage of a charged particle, the polystyrene scintillator molecules release
 346 a small fraction of the excitation energy as photons. The Molière radius (transverse shower
 347 size) of the stack of modules is 3.5 cm. The energy resolution $\sigma(E)/E$ was determined
 348 using a test beam and improves from 3% to 1% as the momentum increase from 15 to 100
 349 GeV [17].

350 The HCAL has similar structure but the absorber is iron rather than lead. It is divided
 351 into square cells of length 131.3 mm in the inner section and 262.2 mm in the outer section.
 352 Hadronic triggering does not require such good energy resolution, so to save space for
 353 the muon stations the thickness of the HCAL is 5.6 interaction lengths. The resolution
 354 is much worse than the resolution of the ECAL. The $\sigma(E)/E$ varying as a function of
 momentum from 23% at 15 GeV to 12% at 100 GeV.

Figure 25: Segmentations of the SPD/PS and ECAL(left) and HCAL(right).

Figure 26: Overview of the ECAL and HCAL. Left: ECAL and Right: HCAL.

356 The cells in ECAL and HCAL(see Figure.25) are read out to photomultiplier tubes by
357 plastic wavelength-shifting fibers. The PS/SPD photomultipliers have multiple anodes,
358 each of which covers several cells. The photomultiplier tubes are encased in iron to shield
359 them from stray magnetic fields. A pulse shaper takes the output of photomultiplier
360 tubes and removes the tail of pulses that are extending beyond 25 ns, so that every LHC
361 bunch crossing can be measured and potentially activate the trigger. The front end board
362 receives the resulting pulses and digitises them.

363 3.4.3 The Muon System

364 Muons are important for LHCb analysis because they are present in many b meson
365 decays. Plus, the easiest way to trigger the detector is on muons with high transverse
366 momentum p_T . There are five muon stations in LHCb. First muon station(M1) is located
367 between RICH2 and ECAL. The remaining four stations (M2-M5) are placed downstream
368 of the HCAL. The muon stations covers an angular acceptance of ± 20 mrad to ± 306
369 mrad horizontally and ± 16 mrad to ± 258 mrad vertically(see Figure.27). Muons play
370 crucial role for determining the ω contribution in $B^+ \rightarrow X(3872)K^+$, $X(3872) \rightarrow J/\psi\rho^0$,
371 $J/\psi \rightarrow \mu^+\mu^-$, and $\rho^0 \rightarrow \pi^+\pi^-$ decays, which will be discussed in later chapter. The
372 whole muon system consists of 1368 multi-wire proportional chambers and 12 sets of three
373 gas electron multiplier foils in the region closet to the beam pipe in the most upstream
374 station where the particle flux is highest. Each station of the muon system is divided into
375 four regions, R1 to R4 with different logical pad dimensions. Their pad segmentations
376 scale in the ratio 1:2:4:8 (see Figure.28). The stations are divided into cells. Each cell
377 gives a binary decision to trigger, which requires aligned hits above the discriminator
378 threshold in all five stations to fire. The efficiency of each station must be above 95%.
379 The spatial resolution is determined by the cell size. The timing resolution is adequate
380 to distinguish LHC bunch crossing at $40MHz$. The multi-wire proportional chamber is
381 a kind of proportional counter constructed with changing planes of high voltage wires
382 and sense wires grounded or connected to a negative voltage. The chamber is filled with
383 fast, non-flammable gas mixtures of Ar,CO₂, and CF₄. The studies show that a time
384 resolution of around 5 ns can be achieved in a gas gap with 2 mm wire spacing and 5 mm
385 gas gap.

4 Introduction

Nearly twenty years have passed since the Belle experiment discovered the narrow $X(3872)$ peak in the $\pi^+\pi^-J/\psi$ mass distribution, from $B^{\pm,0} \rightarrow K^{\pm,0}\pi^+\pi^-J/\psi$ decays, right at the $D^0\bar{D}^{*0}$ mass threshold [7]. Its narrow width and the coincidence with this threshold have fueled speculations that the $X(3872)$ is not a normal charmonium state but a $D^0\bar{D}^{*0}$ molecule. The $X(3872)$ was later confirmed by the other experiments, produced either in B decays or in prompt production in hadron collisions [18–20]. Its spin and parities were determined to be $J^{PC} = 1^{++}$ [3, 21]. Since no isospin partners are observed, the state is believed to be iso-singlet. As it necessarily contains $c\bar{c}$ among its valence quarks, a state with such quantum numbers is labeled $\chi_{c1}(3872)$, according to the recent PDG naming convention. In this note, we use $\chi_{c1}(3872)$ and $X(3872)$ interchangeably. The first radial excitation of axial vector spin-triplet $c\bar{c}$ state, $\chi_{c1}(2^3P_1)$, is expected with these quantum numbers in this mass range. However, such interpretation is challenged not only by the coincidence with the $D^0\bar{D}^{*0}$ threshold, but also by non-observation of $\pi^0\pi^0J/\psi$ decays, indicating that the $\pi^+\pi^-$ system in the discovery mode is in isovector state. In fact, from early on, peaking of the $\pi^+\pi^-$ mass distribution towards its upper kinematic limit near 776 MeV, has been suggestive of being dominated by the $\rho^0(770)$ resonance. While it is rare to discover a new state in an isospin violating strong decay, such decays have been observed among charmonium states, with appropriately small rates. For example, the $\psi(2S)$ state decays via isospin conserving $\pi^+\pi^-$ and $\pi^0\pi^0$ transitions to $J/\psi(1S)$ with a total rate of $(54.9 \pm 0.4)\%$, while its rate for the isospin violating decays $\pi^0J/\psi(1S)$ is more than two-orders of magnitude smaller, $(0.13 \pm 0.03)\%$ [22]. Therefore, it is of key importance to relate $X(3872) \rightarrow \pi^+\pi^-J/\psi$ rate to an isospin conserving decay, such as $X(3872) \rightarrow \omega J/\psi$. In fact, a well established $\chi_{b1}(2^3P_1)$ state in the bottomonium system is observed to decay to $\omega\Upsilon(1^3S_1)$ with a total rate of $(1.6^{+0.4}_{-0.3})\%$, but its isospin violating decays have not been observed yet. Its isospin conserving $\pi\pi$ transition rate to $\chi_{b1}(1^3P_1)$ is only $(0.9 \pm 0.1)\%$ [22]. The $\omega(782)$ resonance decays $(89.3 \pm 0.6)\%$ of the time to isospin conserving $\pi^+\pi^-\pi^0$ channel, and $(1.53 \pm 0.06)\%$ of the time to isospin violating $\pi^+\pi^-$. Only the low-mass tail of the relatively narrow ω ($\Gamma = 8.49 \pm 0.08$ MeV) can contribute to the $X(3872)$ decays in the phase-space suppressed region. Nevertheless, the evidence for $X(3872) \rightarrow \omega J/\psi$, $\omega \rightarrow \pi^+\pi^-\pi^0$ decays was observed a while ago by Belle [23], with a rate

417 of $\mathcal{R}_{\omega/\pi\pi} \equiv \mathcal{BR}(X(3872) \rightarrow \omega J/\psi) / \mathcal{BR}(X(3872) \rightarrow \pi^+\pi^- J/\psi) = 1.12 \pm 0.45 \pm 0.34$, and
418 by BaBar [24], $\mathcal{R}_{\omega/\pi\pi} = 0.8 \pm 0.3$. More recently BESIII has established $X(3872) \rightarrow \omega J/\psi$
419 decays with $> 5\sigma$ significance at the rate of $\mathcal{R}_{\omega/\pi\pi} = 1.6_{-0.3}^{+0.4} \pm 0.2$ [25]. Averaging the three
420 determinations we obtain $\mathcal{R}_{\omega/\pi\pi} = 1.35 \pm 0.26$. The phase-space suppresses ω relative to
421 ρ^0 , assumed to dominate the $\pi^+\pi^- J/\psi$ decays, by about an order of magnitude [26], Thus,
422 leaving the isospin violation in $X(3872) \rightarrow \pi^+\pi^- J/\psi$ rate still an order of magnitude
423 too large for X to be an ordinary charmonium state. As pointed out by many authors,
424 such large isospin violation finds a natural explanation in stronger coupling of $X(3872)$
425 to the $D^0\bar{D}^{*0}$ pairs, than to the D^+D^{*-} pairs which are heavier by 8 MeV, for example
426 via molecular model, making the $\mathcal{R}_{\omega/\pi\pi}$ ratio very important for $X(3872)$ interpretations
427 [27–36].

428 Naively, from the $X(3872) \rightarrow \omega J/\psi$, $\omega \rightarrow \pi^+\pi^-\pi^0$ measurements, we can expect
429 ω to be present in $X(3872) \rightarrow \pi^+\pi^- J/\psi$ decays at $R_\omega \equiv \mathcal{R}_{\omega/\pi\pi} \cdot \mathcal{BR}(\omega \rightarrow \pi^+\pi^-) =$
430 0.021 ± 0.004 level. However, the interference with ρ^0 can enhance its overall importance,
431 thus complicating translation of R_ω value to the ratio of isospin violating ($\rho^0 J/\psi$) to
432 isospin conserving ($\omega J/\psi$) rates.

433 The CDF collaboration analyzed dipion mass spectrum with 1260 ± 130 $X(3872)$
434 candidates from prompt production at the Tevatron [37]. They used Breit-Wigner sum to
435 model the ρ^0 - ω interference and found that the ω fit fraction was insignificant, $< 10\%$, but
436 $\rho^0 - \omega$ interference was producing $R_\omega \sim 23\%$ (no errors given). The Belle collaboration
437 also performed the same type of analysis, with 159 ± 15 $X(3872) \rightarrow \pi^+\pi^- J/\psi$ candidates
438 reconstructed in the $B^\pm \rightarrow X(3872)K^\pm$ decay mode [38]. Since the backgrounds under the
439 $X(3872)$ peak in such exclusive reconstruction are small, sensitivity of Belle’s analysis was
440 competitive to the CDF analysis in spite of the smaller $X(3872)$ yield. The ω contribution
441 was insignificant³ (1.3σ). Including the interference effects⁴, $R_\omega \sim (12 \pm 8)\%$.

442 The LHCb experiment is well suited to look for ω contribution to $X(3872) \rightarrow \pi^+\pi^- J/\psi$
443 decays, because it has the largest sample of exclusively reconstructed $B^\pm \rightarrow X(3872)K^\pm$,
444 $X(3872) \rightarrow \pi^+\pi^- J/\psi$ decays. Such exclusive reconstruction keeps the backgrounds in
445 check. It also has an excellent mass resolution which becomes important when probing

³Estimated by us from the χ^2 difference between the S -wave fits without and with the ω term.

⁴Estimated by us from the event yields given in Table VI in Ref. [38] for the S -wave fit, as $(0.6 + 17.8)/159 \pm \sqrt{0.5^2 + (17.8 \Delta r_\omega / r_\omega)^2} / 159$. The statistical error only.

446 for the ω tail in the sharply falling $\pi^+\pi^-$ mass spectrum when approaching the upper
447 kinematic bound.

5 Data Selection

The B2XMuMu stripping line⁵ is used as a starting point for selection of $B^+ \rightarrow J/\psi K^+ \pi^+ \pi^-$, $J/\psi \rightarrow \mu^+ \mu^-$ candidates from Run1 and Run2 running periods.⁶ The stripping line cuts for this final state, selected as $B^+ \rightarrow \mu^+ \mu^- K_1^+$, $K_1^+ \rightarrow \pi^+ \pi^- K^+$ candidates, are summarized in Table 4. We impose additional selection criteria as listed in Table 5. All charged tracks are required to be good quality ($\chi_{track}^2 < 4.0$), not clone candidates, and have a low ghost probability ($TRGHP < 0.45$). In addition to muons, also hadron candidates are required to miss the primary pp interaction vertex by three standard deviations ($\chi_{IP}^2 > 9.0$). The two oppositely charged muons must form a good secondary vertex ($\chi_{vtx}^2 / \text{ndf}(\mu^+ \mu^-) < 9.0$), and must be in the J/ψ mass window ($3040 \text{ MeV} < m_{\mu\mu} < 3140 \text{ MeV}$). Since the stripping lines does not impose hadron ID criteria, we require pion (kaon) candidates to satisfy loose hadron identification criteria, $PIDK < 5$ ($PIDK > -5$). We also require that the kaon candidate is more likely to be a kaon than the two pion candidates ($K_PIDK > \max(Pi1_PIDK, Pi2_PIDK)$). In addition to the vertex requirements on the B^+ candidate in the stripping line, we demand that its proper decay time (τ) is larger than 0.25 ps. DecayTreeFitter algorithm is applied to the B^+ candidate to implement the J/ψ mass, which improves the B^+ candidate mass resolution. After the candidate passes B^+ mass cut, we also implement B^+ mass and pointing to PV constraints, to improve sub-system mass resolutions.

Our initial analysis was performed without specific trigger requirements. In this version of the analysis, we have added TOS requirements on Hlt1 and Hlt2 trigger lines, listed in Tab. 6, which has reduced the $X(3872)$ signal yield in the data by only 0.7%.

When there is more than one B^+ candidate in the event, we choose the one with the highest sum of p_T over the two pions, the kaon and the J/ψ . This reduces the $X(3872)$ signal yield in the data by 2.4%. The background under the $X(3872)$ mass peak is reduced by 13%.

The $J/\psi \pi^+ \pi^- K^+$ mass distribution for the selected candidates is fitted with double-

⁵The following stripping versions were used v21, v21r1, v24r1, v28r1, v29r2, and v34 for 2011, 2012, 2015, 2016, 2017 and 2018 data, respectively.

⁶We have also investigated FullDSTDiMuonJpsi2MuMuDetached stripping line as a starting point for our data selection, but the gain in $X(3872)$ signal yield was only 14%, on expense of much larger background after simple preselection cuts.

475 sided Crystal Ball (DSCB) line shape for the signal and a second-order polynomial
 476 background. The power-law tail parameters of the DSCB shape, n_1 and n_2 are fixed at
 477 10 (the choice motivated by the simulations). The α_1 , α_2 , mean, σ and the polynomial
 478 coefficients are floating parameters. This leads to $878,186 \pm 1,279$ B^+ signal yield (see
 479 Figure.29). After 2σ cut around the B^+ mass, we fit the $J/\psi\pi^+\pi^-$ mass distribution for
 480 the $X(3872)$ signal using the same signal and background parameterization and obtain a
 481 yield of $6,788 \pm 115$ (see Fig. 30), which is 43 times larger than analyzed by the Belle
 482 collaboration in this B^+ decay channel [38]. The α_1 , α_2 , mean, and σ parameter values
 483 from this fit are later used when fitting $X(3872)$ signal in slices of the $\pi^+\pi^-$ mass.

484 The background under the $X(3872)$ peak (Fig. 30) is about 23% in the $\pm 2\sigma$ mass
 485 window. However, a large part of it is the irreducible background from B^+ decays to J/ψ
 486 and kaon excitations, with latter decaying to $K^+\pi^+\pi^-$. The background from false B^+
 487 candidates is only about 9.4% as estimated from the fit to B^+ mass distribution after the
 488 $X(3872)$ mass cut (see Fig. 31). Since further reduction of the latter background is hardly
 489 worth complicating the data selection, especially since the both types of background are
 490 subtracted by the fits to $J/\psi\pi^+\pi^-$ mass spectrum, this sample is used in our default
 491 analysis. We later pursue multivariate data selection among systematic variations (Sec. 17).

Figure 29: Fitted $M(J/\psi\pi^+\pi^-K^+)$ mass distribution for $B^+ \rightarrow J/\psi K^+\pi^+\pi^-$ decay with the PV and J/ψ mass constraints. We used DSCB for the signal peak and quadratic polynomial for the background. The blue line represents the total fit, red is the signal component, and the dashed-green is the background.

6 Extraction of the dipion mass spectrum

To extract $dN_X/dm_{\pi\pi}$ distribution (N_X is the $X(3872)$ signal yield), we perform a two-dimensional, unbinned fit to $[m_{J/\psi\pi\pi}, m_{\pi\pi}]$ masses in $m_{\pi\pi}$ slices. The $m_{\pi\pi}$ dependence within its slice is needed for an accurate description of the phase-space factor, which becomes important near the upper kinematic boundary.

The $X(3872)$ signal shape is described using Double Sided Crystal Ball function (DSCB). The DSCB the power-law tail parameters, n_1 and n_2 , are fixed to 10, as motivated by the fit to the simulated data (Fig. 42). The other parameters of the DSCB function are fixed by a fit to the total $m_{J/\psi\pi\pi}$ distribution with 2σ B^+ mass signal cut (see Figure 30). There is no evidence for variation of the $X(3872)$ mass resolution with the $m_{\pi\pi}$ as

Table 6: *Tigger requirements on B^+ candidates.*

Figure 32: *The $X(3872)$ mass resolution (σ) as obtained by fitting the $J/\psi\pi^+\pi^-$ mass in the signal simulations with the DSCB shape in various $m_{\pi\pi}$ bins.*

502

503 The background under the X peak is described with a quadratic function (free
504 parameters in each $m_{\pi\pi}$ bin). Both are multiplied by the phase-space factor, $P_{J/\psi}$, i.e. the

505 momentum of J/ψ in the $X(3872)$ rest frame.⁷ The total PDF has the following form:

$$PDF(m_{J/\psi\pi\pi}, m_{\pi\pi}) = P_{J/\psi}(m_{J/\psi\pi\pi}, m_{\pi\pi})[N_X DSCB(m_{J/\psi\pi\pi}) + b_0 + b_1(m_{J/\psi\pi\pi} - m_{X(3872)}) + b_2(m_{J/\psi\pi\pi} - m_{X(3872)})^2] \quad (1)$$

506 The signal shape, $P_{J/\psi}(m_{J/\psi\pi\pi}, m_{\pi\pi}) DSCB(m_{J/\psi\pi\pi})$, is normalized by numerical two-
 507 dimensional integration in the fitted phase-space region. We divide the data sample into
 508 thirty-five $m_{\pi\pi}$ slices in the interval of [380,780] MeV. To match the rising signal statistics,
 509 the $m_{\pi\pi}$ -slice width ($\Delta m_{\pi\pi}$) varies from 40 to 5 MeV. We display fit results in the units
 510 of signal yield per 5 MeV, thus rescale the fit results via:

$$dN_{X_i} = \frac{N_{X_i}}{\Delta m_{\pi\pi i}} \times 5MeV \quad (2)$$

511 Projections of the 2D fits onto $m_{J/\psi\pi\pi}$ distributions in a sample of various $m_{\pi\pi}$ slices
 512 are shown in Fig. 33 (all slices are shown in Appendix B, Figs. 100-102). The obtained
 513 $dN_X/dm_{\pi\pi}$ distribution is displayed in Fig. 34.

⁷The momentum of J/ψ in $X(3872)$ rest frame is a function of both $m_{J/\psi\pi\pi}$ and $m_{\pi\pi}$:

$$P_{J/\psi} = \frac{\sqrt{(m_{J/\psi\pi\pi} - m_{J/\psi} - m_{\pi\pi})(m_{J/\psi\pi\pi} + m_{J/\psi} - m_{\pi\pi})(m_{J/\psi\pi\pi} - m_{J/\psi} + m_{\pi\pi})(m_{J/\psi\pi\pi} + m_{J/\psi} + m_{\pi\pi})}{2m_{J/\psi\pi\pi}},$$

where $m_{J/\psi}$ is fixed to its PDG value.

Figure 33: *Projections of unbinned fits to $m_{J/\psi\pi\pi}$ vs. $m_{\pi\pi}$, in different $m_{\pi\pi}$ bins, onto the $m_{J/\psi\pi\pi}$ axis. The total fit, the $X(3872)$ signal and the background components are shown by the green, red and blue lines, respectively.*

Figure 34: *Extracted dipion mass distribution in $X(3872) \rightarrow \pi^+\pi^- J/\psi$ decays.*

7 Monte Carlo simulations

To interpret dipion mass spectrum from the $X(3872)$ decays, it is necessary to understand the dipion mass resolution and relative efficiency variation with this mass. We use Monte Carlo (MC) simulations to study these effects.

In total, we used 0.346×10^6 MC events generated for Run 1 and 1.279×10^6 MC events generated for Run 2. The events were generated according to EventType 12145003, in which $B^+ \rightarrow K^+ X(3872)$, $X(3872) \rightarrow J/\psi \rho^0$, $\rho^0 \rightarrow \pi^+ \pi^-$, $J/\psi \rightarrow \mu^+ \mu^-$ decays are simulated using the helicity model in which $1^{++} X(3872)$ decays in S-wave, which describes the angular distributions in the data well [3]. The EvtGen generator handling this EventType does not implement right phase-space factor for broad ρ^0 reaching the kinematic boundaries, and as a consequence, overpopulates dipion mass entries close to the upper mass bound (see Appendix A for more details). This is actually advantageous for this analysis, since we gain more statistics in the dipion mass range, where ω contribution becomes important. As we use simulations only for variation of the resolution and efficiency with dipion mass, we do not depend on the generated dipion mass distribution, thus it does not matter that the MC model does not include ω contribution. When comparing the simulations and data on distributions integrated over the dipion masses, we reweight the MC to the dipion mass distribution as described in Appendix A.

To properly weight different running conditions, we determined the number of reconstructed $X(3872)$ events in the data and in the simulated samples for various running conditions as documented in Table 7. For overall simulation sample, we assign a relative weight to each run period given by the ratio of the reconstructed signal events in the data and in the Monte Carlo. We did not have a dedicated 2011 Monte Carlo sample, thus we assumed that the 2012 Monte Carlo sample adequately represents the combined data set of 2011-2012 data. This is a safe assumption since the difference in 2011 and 2012 pp collision energy (\sqrt{s}) is small (7 vs. 8 TeV), and the luminosity ratio is 1 : 2. It should be also stressed that we rely on the simulations only for a relative change of the efficiency with dipion mass and not on absolute efficiency values. The dipion mass resolution does not change between 8 and 13 TeV collision energies, as discussed in Sec. 8. The last, but not least, the 2011 data constitutes only 5.5% of the total data sample.

Even though it is not an aim of this analysis to determine any absolute cross-sections,

545 the information given in Table 7 can be used to perform a crude check on how well the
 546 simulations track the real data for changes in absolute efficiency with a run period. For
 547 that purpose, we calculate efficiency as a ratio of the reconstructed and generated events
 548 in the MC. This is not a true absolute reconstruction efficiency, since we do not fold
 549 in efficiency of generator level cuts, which may vary slightly with the collision energy.
 550 We then calculate visible cross-section (σ_{vis}) for $B^\pm \rightarrow K^\pm X(3872)$, $X(3872) \rightarrow J/\psi\rho^0$,
 551 $\rho^0 \rightarrow \pi^+\pi^-$, $J/\psi \rightarrow \mu^+\mu^-$ decays, by dividing the signal yield in the data, by the integral
 552 luminosity and such determined efficiency. Within the four 13 TeV data sets, the values
 553 are consistent with each other at a p-value of 18%, and average to 22.7 ± 0.4 pb. The
 554 ratio of b -quark cross-sections was determined by LHCb to be $R_\sigma = 2.14 \pm 0.13$ between
 555 13 TeV and 7 TeV collisions [39]. Assuming that the 2011 and 2012 efficiencies are the
 556 same, we calculate 7 TeV visible cross-section in our analysis, and determine this ratio
 557 to be 2.04 ± 0.17 , in excellent agreement with the proper LHCb measurement quoted
 558 above.⁸ Assuming that the b -quark cross-section scales linearly with the collision energy
 559 between 7 and 13 TeV, we can estimate from R_σ , that the expected ratio between visible
 560 cross-sections in 2012 (8 TeV) and 2011 (7 TeV) data should be 1.19 ± 0.02 , which is
 561 again in excellent agreement with 1.18 ± 0.11 determined in our analysis. To summarize
 562 this paragraph, the simulations reproduce within the statistical errors, the dependence
 563 of overall detection efficiency on running conditions, including the assumption that the
 564 efficiency does not change between 2011 and 2012 data.

565 The reconstructed p_T distribution of B^+ is somewhat harder in the Monte Carlo than
 566 in the data, as illustrated in Fig. 35. To extract such distribution in the data we fitted
 567 the $X(3872)$ peak in $J/\psi\pi^+\pi^-$ mass distributions for various p_T bins. We fit a smooth
 568 correction function to the ratio of the data and MC $p_T(B^+)$ distributions, and apply it
 569 as a weight for further use of the simulated events (see Fig. 36). After this correction,
 570 agreement between the data and the MC is fairly good for p_T distributions of all final
 571 state particles and for the $X(3872)$ helicity angle (Fig. 37).

⁸Our error is statistical only, while the error on R_σ is essentially all systematic.

Table 7: *Different LHCb run periods. Number of reconstructed $X(3872)$ signal events in the data and in the MC are given as determined by fits to the reconstructed $J/\psi\pi^+\pi^-$ mass distributions (see Fig. 30 for an example). Efficiency is calculate as a simple ratio between the reconstructed and generated $X(3872)$ events in the MC, and does not include efficiency of generator level cuts. The visible cross-section (σ_{vis}) is calculated by dividing the signal yield in the data, by the integral luminosity and such determined efficiency.*

Figure 35: *The distribution of $p_T(B^+)$ for the data (points with error bars) and for the MC (histogram). The distributions were corrected for the varying bin width. The data points were obtained by fitting the $X(3872)$ peak in the $J/\psi\pi^+\pi^-$ mass distributions for various bins. The MC events were weighted by the run-dependent and dipion-mass dependent weights. The MC distribution was normalized to the same number of entries as the data.*

Figure 36: *The ratio of the data and MC distributions of $p_T(B^+)$ (Fig. 35), fit with a smooth function used as a correction weight for simulated events.*

Figure 37: The distributions of p_T of various reconstructed particles, and of $X(3872)$ helicity angle, for the data (points with error bars) and for the MC (histogram). The distributions were corrected for the varying bin width. The data points were obtained by fitting the $X(3872)$ peak in the $J/\psi\pi^+\pi^-$ mass distributions for various bins. The MC events were weighted by the run-dependent, dipion-mass-dependent and $p_T(B^+)$ -dependent weights. The MC distributions were normalized to the same number of entries as the data.

8 Dipion mass resolution

Using MC truth information, we get $m_{\pi\pi}^{true}$ for reconstructed signal events. For different slices of $m_{\pi\pi}^{true}$, we obtain $m_{\pi\pi}^{reco} - m_{\pi\pi}^{true}$ distribution and fit them with a Gaussian function as shown in Figure 38. Monte Carlo events for different run periods were weighted to properly represent the distribution of the signal yield in real data over these run periods. They were also weighted in $p_T(B^+)$ distribution, as discussed in Sec. 7. The mass slices have different widths to follow increase of the simulation statistics with the mass. The Gaussian σ from each fit is an entry to a distribution of mass resolution shown in Figure 39. The mass resolution increases as the $m_{\pi\pi}$ gets further away from the $2m_\pi$ threshold (279 MeV). It is about 2.2 MeV near the upper kinematic bound, where it plays an important role due to the steep drop in $PDF(m_{\pi\pi})$ imposed by the phase-space factor ($p_{J/\psi} \rightarrow 0$). This is also a crucial region for searching for effects due to the tail of the ω resonance, which peaks slightly above the kinematic limit.

To interpolate between bins we fit the obtained mass resolution with the following function,

$$\sigma_m(m) = a_1 (1 - e^{-\frac{m}{\lambda}}) + a_2 e^{-\frac{m}{\lambda}}, \quad (3)$$

and obtain $a_1 = 2.39 \pm 0.04$ MeV, $a_2 = -5.4 \pm 1.0$ MeV, and $\lambda = 220.3 \pm 17.2$ MeV. With $\chi^2 = 38.3$ per 39 degrees of the freedom, and a p -value of 50%, this function provides excellent description of the simulation results (Fig. 39) and is used in the fits to the dipion mass resolution by smearing theoretical fit functions.

We also show in Figure 40, a comparison between the mass resolution determined in 8 TeV (2012) and 13 TeV (2015-2018) simulation samples. There is essentially no difference.

Monte Carlo is known to underestimate mass resolution somewhat. The B^+ mass resolution in the data is 7.16 ± 0.13 MeV (see Fig. 31), while in MC simulations (Fig. 41) is 6.30 ± 0.04 MeV (14% smaller). The $X(3872) \rightarrow J/\psi\pi^+\pi^-$ mass resolution is a better proxy for how well dipion mass resolution is simulated, since the events are constrained to the known J/ψ mass. The fit to the data gives $\sigma_m^{data} = 2.66 \pm 0.09$ MeV (Fig. 30). The fit to the MC gives $\sigma_m^{MC} = 2.47 \pm 0.02$ MeV (Fig. 42). Both are dominated by the resolution, but the natural width can affect them at a couple of percent level. From the average over the two LHCb width determinations, $\Gamma_X^{data} = 1.19 \pm 0.21$ MeV [22]. From the MC truth information, we see that the simulations were performed with the width of $\Gamma_X^{MC} = 0.33$ MeV. Unfolding

Figure 38: Fits of Gaussian function to $m_{\pi\pi}^{reco} - m_{\pi\pi}^{true}$ distributions in different slices of $m_{\pi\pi}^{true}$.

Figure 39: *Dipion mass resolution extracted from the simulations. The red curve is a fit of a smooth function described in the text.*

Figure 40: *Dipion mass resolution comparison between 8 TeV (labeled as Run 1) and 13 TeV (Run 2) simulations.*

602 the natural width effects from the data and MC we obtain the ratio: $\sigma_m^{data\ corr.}/\sigma_m^{MC\ corr.} =$
603 $\sqrt{\sigma_m^{data^2} - (\Gamma_X^{data}/2.35)^2}/\sqrt{\sigma_m^{MC^2} - (\Gamma_X^{MC}/2.35)^2} = (2.61\pm 0.10)/(2.47\pm 0.02) = 1.06\pm 0.04.$
604 We scale the $\pi^+\pi^-$ mass resolution obtained from the simulations up by 1.06. We explore
605 uncertainty in this factor among systematics, by varying it between 1.00 and 1.14.

Figure 41: *Fit to the B^+ mass peak (double sided Crystal Ball function) plus a flat background in the simulated $X(3872)$ sample.*

Figure 42: *Fit to the $J/\psi\pi^+\pi^-$ distribution in the signal simulations, after the 2σ B^+ mass cut, and with the PV , J/ψ and B^+ mass constraints. We used DSCB for the signal peak and flat background. The blue line represents the total fit. The fitted background level is only 2.8 ± 0.5 events per bin. The signal shape parameters are: $48,805 \pm 216$ signal events, $m = 3,871.91 \pm 0.01$ MeV, $\sigma = 2.47 \pm 0.02$ MeV, $n_1 = n_2 = 10$ (fixed), $\alpha_1 = 1.40 \pm 0.02$, and $\alpha_2 = 1.78 \pm 0.03$.*

606 9 Efficiency variation with the dipion mass

607 For relative variation of reconstruction efficiency with the dipion mass, we divided the
 608 distribution of reconstructed mass in simulations, by the generated one, after we had
 609 smeared the generated mass with the mass resolution determined as described in the
 610 previous section. The result is shown in Fig. 43. We parameterize this variation with
 611 a quadratic function (also shown), which multiplies any theoretical function fit to the
 612 dipion mass distribution in the data. In evaluation of systematic uncertainties, we use
 613 cubic polynomial instead (Fig. 44).

Figure 43: Variation of the reconstruction efficiency with dipion mass. Units of efficiency are arbitrarily chosen to be close to 1 near 700 MeV, as only the relative variation matters in this analysis. Quadratic fit function is superimposed: $\epsilon(m_{\pi\pi}) = 0.966 + 1.345 \cdot 10^{-3} (m_{\pi\pi} - 700 \text{ MeV}) + 1.607 \cdot 10^{-6} (m_{\pi\pi} - 700 \text{ MeV})^2$, where $m_{\pi\pi}$ is in MeV.

Figure 44: Variation of the reconstruction efficiency with dipion mass fit to a cubic polynomial.

614 10 Fits of Breit-Wigner amplitudes to the $\pi^+\pi^-$ mass 615 distribution

616 Any theoretical probability density function to be fit to the data, $PDF(m_{\pi\pi})$, is multiplied
617 by the relative efficiency variation with the mass (Sec. 9) and smeared with the mass
618 resolution (Sec. 8).

619 A relation of a theoretical matrix element, M , to the PDF fit to the data is,

$$PDF(m_{\pi\pi}) = S p_{J/\psi} p |M|^2, \quad (4)$$

620 where $p_{J/\psi}$ is the J/ψ momentum in the $X(3872)$ rest frame, p is the pion momentum in
621 the ρ^0 rest frame, and S is a scale factor between the unnormalized PDF and the data.
622 The scaling factor is always a free parameter in fits to the data, and its value is not of
623 physics interest.

624 All fits to the data are minimal χ^2 fits. While some mass bins have very low signal
625 yield, the errors on these yields are Gaussian, since they come from the fits subtracting
626 the backgrounds under the $X(3872)$ peak in the $\pi^+\pi^-J/\psi$ distributions (Sec. 6).

627 We first attempt to fit ρ^0 resonance alone, represented by a following Breit-Wigner
628 amplitude,

$$M = BW_\rho(m_{\pi\pi}|m_\rho, \Gamma_\rho) = \frac{m_\rho \Gamma_\rho F_1(p, p_\rho)}{m_\rho^2 - m_{\pi\pi}^2 - i m_\rho \Gamma_\rho(m_{\pi\pi})}, \quad (5)$$

$$\Gamma_\rho(m_{\pi\pi}) = \Gamma_\rho \frac{p}{p_\rho} \frac{m_\rho}{m_{\pi\pi}} F_1(p, p_\rho)^2, \quad (6)$$

$$F_1(p, p_\rho) = \sqrt{\frac{B_1(p)}{B_1(p_\rho)}}, \quad (7)$$

$$B_1(p) = p^2 \frac{1}{1 + (Rp)^2}, \quad (8)$$

$$p_\rho = p(m_\rho), \quad (9)$$

629 where m_ρ and Γ_ρ , are ρ^0 mass and width, which are fixed to the PDG values: 775.26
630 (± 0.23) MeV and 147.4 (± 0.8) MeV, respectively [22]). This form assumes the S -wave
631 $\chi_{c1}(3872) \rightarrow \rho^0 J/\psi$ decay, as well motivated by the previous analysis of the angular
632 correlations [3]. The $B_1(p)$ is the Blatt-Weisskopf barrier factor for P -wave decay of a
633 vector particle (here ρ^0) to $\pi^+\pi^-$, and contains an effective hadron-size parameter R ,
634 which we fix to a value motivated by the $\pi\pi$ scattering data, 1.45 GeV⁻¹ (see Sec. 12).

635 The scaling factor S (Eq. 4) is the only free parameter in the fit. The fit fails miserably,
 636 with a χ^2 per number of degrees of freedom (χ^2/NDoF) equal to $366.6/34$, which has
 637 p -value (pV) of 2×10^{-57} . The fit is displayed in Fig. 45.

638 Fitting the mass and width of the ρ^0 resonance, improves the fit ($\chi^2/\text{NDoF} = 48.9/32$,
 639 $pV = 0.028$), however gives the mass and width values which are way outside what can
 640 be considered reasonable: $m_\rho = 782.9 \pm 3.5$ MeV, $\Gamma_\rho = 96.4 \pm 2.5$ MeV.

Figure 45: *Fit of ρ^0 Breit-Wigner amplitude to the data. The pulls shown below are the data points minus the fit function value, divided by the error on the data. The fit qualities are $\chi^2/\text{NDoF} = 366.6/34$ and $pV = 2 \times 10^{-57}$.*

641 In the next step, we try the matrix element model previously employed by the CDF [37]
 642 and Belle [38] to fit $m_{\pi\pi}$ distribution from $X(3872) \rightarrow J/\psi\pi\pi$ decays, which takes a sum
 643 over ρ^0 and ω Breit-Wigners,

$$M = BW_\rho(m_{\pi\pi}|m_\rho, \Gamma_\rho) + A_\omega e^{i\phi} BW_\omega(m_{\pi\pi}|m_\omega, \Gamma_\omega), \quad (10)$$

644 where A_ω and ϕ are relative magnitude and phase of the ω contribution with respect to

645 the dominant ρ^0 term. The mass and width of ω are fixed to the central values of the
646 PDG averages, $m_\omega = 782.66 (\pm 0.13)$ MeV, $\Gamma_\omega = 8.68 (\pm 0.13)$ MeV [22]. The fits to the
647 data are insensitive to the phase value, as long as it is in 90-170 degree range. We fix
648 it to 95° , the value previously used by the CDF and Belle and motivated by the other
649 measurements [37,38]. The fit quality is improved substantially relative to ρ^0 contribution
650 alone, $\chi^2/\text{NDoF} = 102.9/33$, but it is still unacceptably low $pV = 4 \times 10^{-9}$ (see Fig. 46).

Figure 46: *Fit of a sum of Breit-Wigner amplitude for ρ^0 and ω . The total fit is shown by the red line. Individual contributions are shown by the blue and green lines respectively. In this model they interfere destructively except for the highest mass bins. The fit qualities are $\chi^2/\text{NDoF} = 102.9/33$ and $pV = 4 \times 10^{-9}$.*

651 It is well known that summing Breit-Wigner amplitudes has theoretical drawbacks,
652 especially for strongly overlapping resonances with the same quantum numbers, since
653 it leads to a matrix element which is not unitary, violating first principles of scattering
654 theory. In the next section, we develop a more sophisticated theoretical approach.

11 Coupled-channel model

While looking for models that can describe the data well, we had first tried single-channel K-matrix approach, with ρ^0 and ω poles coupling to the $\pi^+\pi^-$ channel. Such model is able to describe the data well, if we also allow for a small contribution which does not vary much within the fitted range, either a non-resonant term, or the tail of the ρ' resonance. However, we have settled on a K-matrix model, which is theoretically more appealing, with a proper two-channel K-matrix coupling the $\pi^+\pi^-$ and $\pi^+\pi^-\pi^0$ channels. While ρ^0 pole couples only to the $\pi^+\pi^-$ channel, ω pole couples mostly to the $\pi^+\pi^-\pi^0$ channel, but also has a rare isospin violating decay to $\pi^+\pi^-$ channel. This generates, a small off-diagonal couplings between these two channels of opposite G -parity. The K-matrix is given by,

$$K = \frac{1}{m_\rho^2 - s} \begin{pmatrix} g_{\rho \rightarrow 2\pi}^2 & 0 \\ 0 & 0 \end{pmatrix} + \frac{1}{m_\omega^2 - s} \begin{pmatrix} g_{\omega \rightarrow 2\pi}^2 & g_{\omega \rightarrow 2\pi} g_{\omega \rightarrow 3\pi} \\ g_{\omega \rightarrow 2\pi} g_{\omega \rightarrow 3\pi} & g_{\omega \rightarrow 3\pi}^2 \end{pmatrix}, \quad (11)$$

where $s = m_{\pi\pi}^2$, and g are the coupling constants discussed later. The T-matrix is obtained from,

$$\hat{T} = [1 - i K \rho]^{-1} K, \quad (12)$$

where the phase-space matrix ρ is diagonal,

$$\rho = \begin{pmatrix} \rho_{2\pi}(s) & 0 \\ 0 & \rho_{3\pi}(s) \end{pmatrix}. \quad (13)$$

We choose a notation in which the Blatt-Weisskopf barrier factors are integrated with the phase-space matrix⁹, thus

$$\rho_{2\pi}(s) = \frac{2p}{\sqrt{s}} B_1(p), \quad (14)$$

$$p(s) = \frac{1}{2} \sqrt{s - (2m_\pi)^2}. \quad (15)$$

A naive implementation of $\rho_{3\pi}(s)$ element, assumes symmetric decay to three pions,

$$\rho_{3\pi}(s) = \frac{2p_3}{\sqrt{s}} B_1(p_3),$$

$$p_3(s) = \frac{1}{3} \sqrt{s - (3m_\pi)^2}. \quad (16)$$

⁹Alternatively, they can be attached to the K-matrix elements. Both approaches lead to the same fits.

672 A better implementation, models the decay to three pions via P -wave decay to $\rho\pi$, as in
 673 fact observed for the ω decay,

$$\rho_{3\pi}(s) = \int_{(2m_\pi)^2}^{(\sqrt{s}-m_\pi)^2} d\sigma \frac{2p(\sigma)}{\sqrt{\sigma}} \frac{B_1(p(\sigma))}{(m_\rho^2 - \sigma)^2 + (m_\rho \Gamma_\rho)^2} \frac{2p'_3(s, \sigma)}{\sqrt{s}} B_1(p'_3(s, \sigma)) \quad (17)$$

$$p'_3(s, \sigma) = \frac{[(s - (\sqrt{\sigma} + m_\pi)^2)(s - (\sqrt{\sigma} - m_\pi)^2)]^{1/2}}{2\sqrt{s}} \quad (18)$$

674 We use the latter formula, though the naive formula gives almost identical results, as
 675 $\rho_{3\pi}(s)$ affects only the tail of the ω resonances, which is relatively short due to its narrow
 676 width. For a comparison of the two $\rho_{3\pi}(s)$ shapes see Fig. 47.

677 We take Q-vector approach to the production of these two channels in $X(3872)$ decays.
 678 The decay amplitudes are given by,

$$\begin{pmatrix} \hat{A}_{2\pi} \\ \hat{A}_{3\pi} \end{pmatrix} = \hat{T} \begin{pmatrix} \alpha_{2\pi} \\ \alpha_{3\pi} \end{pmatrix}, \quad (19)$$

679 where the elements of the production vector $(\alpha_{2\pi}, \alpha_{3\pi})$ are real and subject of the fit to
 680 our data. Only the $\hat{A}_{2\pi} = \alpha_{2\pi} \hat{T}_{2\pi, 2\pi} + \alpha_{3\pi} \hat{T}_{2\pi, 3\pi}$ amplitude matters for this analysis,

$$M = \hat{A}_{2\pi} \sqrt{B_1(p)}. \quad (20)$$

681 The couplings constants are fully determined by the other experiments,

$$g_{\rho \rightarrow 2\pi}^2 = m_\rho \Gamma_\rho / \rho_{2\pi}(m_\rho^2), \quad (21)$$

$$g_{\omega \rightarrow 3\pi}^2 = m_\omega \Gamma_\omega \mathcal{B}(\omega \rightarrow 3\pi) / \rho_{3\pi}(m_\omega^2), \quad (22)$$

$$g_{\omega \rightarrow 2\pi}^2 = m_\omega \Gamma_\omega \mathcal{B}(\omega \rightarrow \pi^+ \pi^-) / \rho_{2\pi}(m_\omega^2), \quad (23)$$

682 where $\mathcal{B}(\omega \rightarrow 3\pi) = (89.2 \pm 0.7)\%$, and $\mathcal{B}(\omega \rightarrow \pi^+ \pi^-) = (1.53 \pm 0.12)\%$ [22].

683 Numerically, $g_{\omega \rightarrow 2\pi}^2 / g_{\rho \rightarrow 2\pi}^2 \sim 0.0009$, while $g_{\omega \rightarrow 2\pi} g_{\omega \rightarrow 3\pi} / g_{\rho \rightarrow 2\pi}^2 \sim 0.01$. Thus, the
 684 diagonal ω coupling to 2π can be neglected in comparison to the off-diagonal coupling. In
 685 this excellent approximation,

$$\hat{T}_{2\pi, 2\pi} \approx \frac{g_{\rho \rightarrow 2\pi}^2}{m_\rho^2 - s - i g_{\rho \rightarrow 2\pi}^2 \rho_{2\pi}(s)}, \quad (24)$$

686 is simply the ρ^0 Breit-Wigner amplitude, and $\alpha_{2\pi}$ is the ρ^0 production factor in the
 687 $X(3872)$ decay. In the simplest approach, $\alpha_{2\pi}$ can be taken as a constant. However, a

688 slight s -dependence of this factor is possible. Therefore, we allow polynomial dependence
 689 on s . It is convenient to use Chebyshev polynomials (C_n) as a basis,

$$\alpha_{2\pi}(s) = \sum_{n=0}^{n=N} P_n C_n(\hat{s}), \quad (25)$$

690 since they are orthogonal to each other, and properly normalized, where¹⁰

$$\hat{s} = 2 \frac{s - s_{min}}{s_{max} - s_{min}} - 1, \quad (26)$$

$$C_0(\hat{s}) = 1, \quad (27)$$

$$C_1(\hat{s}) = \hat{s}, \quad (28)$$

$$C_2(\hat{s}) = 2\hat{s}^2 - 1. \quad (29)$$

691 A numerical value of P_n from a fit to the data, reflects relative importance of the n^{th} order
 692 term. Since the scaling factor S already takes care of scaling the fit model to the data,
 693 $P_0 = 1$. For the results to have the expected physical behavior, we can check that the
 694 series is converging, $|P_{n+1}| < |P_n|$, and that the maximal order to obtain a good fit to the
 695 data, N , is small.

696 The ω contribution enters via,

$$\hat{T}_{2\pi,3\pi} \approx \frac{g_{\omega \rightarrow 2\pi} g_{\omega \rightarrow 3\pi} (m_\rho^2 - s)}{(m_\rho^2 - s - i g_{\rho \rightarrow 2\pi}^2 \rho_{2\pi}(s))(m_\omega^2 - s - i g_{\omega \rightarrow 3\pi}^2 \rho_{3\pi}(s))}. \quad (30)$$

697 This term becomes zero at the ρ^0 pole, which is an artifact of the K-matrix approach,
 698 which is particularly inconvenient since this is in the region of the interest for the ω
 699 contribution. Since the bare mass does not have physical meaning and can be shifted
 700 arbitrary, the zero does not need to be enforced there. To remove it and restore more
 701 physical behavior of the ω term, we set

$$\alpha_{3\pi} = A \frac{1}{m_\rho^2 - s}. \quad (31)$$

702 While in principle A can have polynomial dependence on s , in practice, the ω resonance
 703 is so narrow, that the data are completely insensitive to it. Therefore, A (denoted also as
 704 A_ω) is made constant in the fits to the data. Its value controls a relative importance of
 705 the ω term, with respect to the dominant ρ^0 contribution.

¹⁰We fix $s_{min} = 380^2 \text{ MeV}^2$ and $s_{max} = 775^2 \text{ MeV}^2$ in all fits.

706 Using Eqs. 24, 30 and 31, with $\alpha_{2\pi}$ constant ($N = 0$), is the popular way to describe
 707 $\rho^0 - \omega$ interference in various analyses of the $\pi^+\pi^-$ system (see Sec. 21). We perform our
 708 fits, using the exact K-matrix formulae, even though the results are almost identical when
 709 using the approximation given by Eqs. 24 and 30 (see Sec. 22).

710 The subject of our analysis is to establish if a model with ρ^0 and ω can describe the
 711 data well, determine significance of the ω contribution, and quantify the latter numerically.

712 In view of Eq. 24, we interpret $\alpha_{3\pi} = 0$ models as containing ρ^0 only. The χ^2 difference
 713 between fits with $\alpha_{3\pi}$ set to zero, or allowed to vary, serves determination of the ω
 714 significance.

715 To quantify a relative rate of the ω contribution, we calculate the following integrals¹¹,

$$I_{tot} = \int_{s=(2m_\pi)^2}^{s=(m_{X(3872)} - m_{J/\psi})^2} ds PDF(s) \quad (32)$$

$$I_\rho = \int_{s=(2m_\pi)^2}^{s=(m_{X(3872)} - m_{J/\psi})^2} ds PDF(s | \alpha_{3\pi} = 0) \quad (33)$$

$$I_\omega = \int_{s=(2m_\pi)^2}^{s=(m_{X(3872)} - m_{J/\psi})^2} ds PDF(s | \alpha_{2\pi} = 0). \quad (34)$$

716 A measure of ω contribution, which includes all $\rho^0 - \omega$ interference effects, is obtained
 717 from

$$R_\omega^{all} \equiv 1 - \frac{I_\rho}{I_{tot}}. \quad (35)$$

718 A stripped down version, which excludes interference between the $\hat{T}_{2\pi,2\pi}$ and $\hat{T}_{2\pi,3\pi}$ terms,
 719 is defined as

$$R_\omega^0 \equiv \frac{I_\omega}{I_{tot}}. \quad (36)$$

720 Finally, we also define the most convenient ratio for quantifying the ratio of isospin
 721 violating and conserving couplings,

$$R_{\omega/\rho}^0 \equiv \frac{I_\omega}{I_\rho}. \quad (37)$$

722 To propagate fit errors to these quantities, we perform statistical simulations, in which
 723 the fit parameters are fluctuated according to the multidimensional (in case of more than
 724 one theory parameter fit to the data) Gaussian distribution, which takes the fit values
 725 and the fit covariance matrix into account. For each set of the fit parameter values, the
 726 R_ω^{all} , R_ω^0 and $R_{\omega/\rho}^0$ are recalculated. Their RMS spreads over many iterations are taken as
 727 their statistical errors.

¹¹The $PDF(s)$ is not smeared with the mass resolution, nor multiplied by the efficiency function.

Figure 47: Two different models of 3π P -wave phase space.

12 Matching the amplitude model to known $\pi^+\pi^-$ phase shifts

The effective hadron size parameter, R , appearing in the Blatt-Weisskopf momentum barrier factor (Eq. 8), in the Breit-Wigner amplitude can be constrained from the data from scattering experiments. This parameter also appears in the coupled-channel model (Eqs. 14, 17 and 20). In fact, the coupled channel model reduces to the ρ^0 Breit-Wigner amplitude, when the ω contribution is eliminated.

The isovector P -wave $\pi^+\pi^-$ interactions are elastic below 1 GeV, therefore the scattering/production amplitudes are proportional to the sine of the scattering phase. This scattering phase has been extracted from the scattering data e.g. by García-Martín *et al.* [1] (Madrid group), and it is shown in the mass range relevant for this analysis by the black line in Fig. 48 (labelled "GKPY P -wave"). This behavior can be matched almost exactly by the ρ^0 Breit-Wigner amplitude with $R = 1.45 \text{ GeV}^{-1}$, shown by the blue line overlapping the black line. The value of this parameter in the range from 1.3 to 1.6 GeV^{-1} gives the phase shift barely distinguishable from the isovector P -wave $\pi^+\pi^-$

743 phase shift extracted by the Madrid group. A value often utilized in Breit-Wigner fits,
744 $R = 5 \text{ GeV}^{-1}$, does not work as well, as shown by the green curve.

745 Since single Breit-Wigner (BW) with $R = 1.45 \text{ GeV}^{-1}$ describes the isovector P -wave
746 $\pi^+\pi^-$ scattering phase well, it should not be necessary to include a tail of $\rho(1450)$ resonance
747 in our analysis.

748 The phase shift for an alternative parametrization, the Gounaris-Sakurai model (GS)
749 discussed in the Sec. 21 (see Eq. (43)), is also shown for ρ^0 in Fig. 48 by the orange line.
750 It matches the GPKY phase within 2 deg. We note that the BW and GS curves pass
751 through 90 deg near the nominal ρ^0 mass. The phase of the GPKY parameterization is
752 slightly larger at that point (see the lower part of Fig. 48). We explore a possibility of
753 small contributions other than the ρ^0 (and ω) in the fits to our data.

754 The F -wave $\pi^+\pi^-$ scattering phase extracted from the data by the same group is also
755 shown in the upper part of Fig. 48 (the red line labelled "GPKY F-wave" very close to
756 the horizontal axis). This phase barely reaches 0.25 degrees at $m_{\pi\pi} = 0.8 \text{ GeV}$, which is
757 extremely small in comparison to 108.7 degrees reached by the P -wave phase. Therefore,
758 contributions from spin 3 resonances can be safely neglected in our analysis.

Figure 48: The isovector $\pi^+\pi^-$ P-wave and F-wave scattering phases extracted from the scattering data by the phenomenological analysis of Ref. [1] (GKPY), compared to the single-pole Breit-Wigner model (BW) with the two different values of R , and Gounaris-Sakurai parameterization [2] from Eq. (43). Note that the blue line is right on top of the black line with a little deviation at the limit of the phase space studied in this analysis. Note also, that the red line is close to zero everywhere. The deviations of the BW and GS models from the GKPY P-wave are shown in the bottom part.

13 Fits of the coupled-channel model to the $\pi^+\pi^-$ mass distribution

The coupled-channel fit, with $\alpha_{3\pi}$ set to zero ($A = 0$ in Eq. 31) is nearly identical to the fit of ρ^0 Breit-Wigner amplitude described in Sec. 10, as already discussed in Sec. 11 (Eq. 24). They differ only via diagonal coupling of $\omega \rightarrow 2\pi$, which is very small $(g_{\omega \rightarrow 2\pi}/g_{\rho \rightarrow 2\pi})^2 \sim 0.0009$. In fact, such fit displayed in Fig. 49, has a χ^2/NDoF value of 367.8/34, as compared to 366.6/34 obtained with the ρ^0 Breit-Wigner amplitude (Fig. 45).

Allowing for the 3π channel to couple to the 2π channel via ω ($A \neq 0$), as shown in Fig. 50, drastically improves the fit to an almost acceptable level ($\chi^2/\text{NDoF} = 55.1/33$, $pV = 0.0093$), in contrast to the simple-minded Breit-Wigner-sum model discussed previously (Fig. 46, $\chi^2/\text{NDoF} = 102.9/33$, $pV = 4 \times 10^{-9}$). The significance of the ω contribution can be calculated via Wilks theorem [40] from the fit χ^2 difference between the fits without and with $\hat{T}_{2\pi,3\pi}$ term in the amplitude, $n_\sigma = \sqrt{367.8 - 55.1} = 17.7$ standard deviations. We can also estimate the significance of the $\hat{T}_{2\pi,3\pi}$ term as, $A/\Delta A$, where A is the parameter controlling size of this term with respect to the $\hat{T}_{2\pi,2\pi}$ term (see Eq. 31), and ΔA is the fit error. This gives a similar significance to the ω term, 17.7σ .

Since the fit quality is not quite satisfactory, we now allow polynomial corrections to the 2π production coupling (Eq. 25). Already with a linear corrections, $\alpha_{2\pi}(s) = 1 - P_1 C_1(\hat{s})$ (Eqs. 26-29), an excellent fit quality, $\chi^2/\text{NDoF} = 24.7/32$ ($pV = 0.82$), is achieved with the ρ^0 and ω contributions (Fig. 52). The obtained P_1 coefficient is comfortably small, $P_1 = 0.226 \pm 0.045$. Because it gives the highest p -value, this is our default fit model. It gives the following fit fraction: $R_\omega^0 = 0.0193 \pm 0.0044$ and $R_\omega^{\text{all}} = 0.214 \pm 0.023$ ($1 - R_\omega^{\text{all}} = 0.786 \pm 0.023$ is the ρ^0 fit fraction), which are measures of fractional ω contributions with and without interference between the $\hat{T}_{2\pi,2\pi}$ and $\hat{T}_{2\pi,3\pi}$ terms (see Eqs. 35-36). The default fit gives, $A = (0.208 \pm 0.024) \times (m_\omega^2 - m_\rho^2)$, where the mass difference multiplier was introduced to make the fit parameter dimensionless (values of all floated and fixed parameters in the default fit are summarized in Table 10 in Appendix B). The significance of ω estimated as $A/\Delta A = 8.6\sigma$, is again similar as the one estimated via Wilks theorem, $\sqrt{\Delta\chi^2} = 8.1\sigma$. The fit with the ρ^0 term alone, has still unacceptably low p -value, 2×10^{-7} (Fig. 51).

Table 8: *Fits to the data with the coupled-channel model.*

$\alpha_{2\pi}(s)$	constant		linear (default)		quadratic	
	ρ^0	ρ^0, ω	ρ^0	ρ^0, ω	ρ^0	ρ^0, ω
χ^2/NDoF	367.8/34	55.1/33	90.5/33	24.7/32	54.9/32	24.6/31
pV	1×10^{-57}	0.0093	2×10^{-7}	0.82	0.0071	0.78
$A/(m_\omega^2 - m_\rho^2)$	—	0.287 ± 0.018	—	0.208 ± 0.024	—	0.197 ± 0.042
$A/\Delta A$	—	16.3σ	—	8.6σ	—	4.7σ
$\sqrt{\Delta\chi^2}$	—	17.7σ	—	8.1σ	—	5.5σ
P_1	—	—	0.497 ± 0.042	0.226 ± 0.045	0.163 ± 0.047	0.210 ± 0.066
P_2	—	—	—	—	0.166 ± 0.022	0.016 ± 0.047
R_ω^{all}	—	0.292 ± 0.015	—	0.214 ± 0.023	—	0.206 ± 0.035
R_ω^0	—	0.0397 ± 0.0041	—	0.0193 ± 0.0044	—	0.0178 ± 0.0062
$R_{\omega/\rho}^0$	—	0.0561 ± 0.0070	—	0.0246 ± 0.0062	—	0.0225 ± 0.0088

789 There is no improvement in $\rho^0 + \omega$ fit quality when allowing a quadratic term (see
790 Table 8). The fit shown in Fig. 54 has a p -value which dropped to 0.78, indicating that
791 the model is now over-tuned given statistical precision of the data. The P_2 polynomial
792 correction is consistent with zero, 0.016 ± 0.047 . The A , P_1 , R_ω^0 and R_ω^{all} values stay
793 within the statistical errors of the linear fit. The statistical errors are larger because of
794 the introduction of unnecessary nuisance parameter. The significance of ω term drops
795 correspondingly, though stays above 5σ from the Wilks theorem (the more proper way to
796 estimate significance than $A/\Delta A$).

797 The fit with ρ^0 term alone (Fig. 53), does not quite reach acceptable p -value (0.0071),
798 and has the quadratic polynomial term P_2 , which is more significant than the P_1 term.
799 This is not an expected behavior for a converging correction series. Since only the tail of
800 ω contributes to our data, it is not a surprise that higher order polynomial modification
801 of the ρ^0 term can start absorbing the ω contribution. Thus further increase in order of
802 polynomial is not very interesting.

803 It is interesting to display the fitted amplitude with an extended phase-space limit,

Figure 49: *Fit of the coupled-channel model with ρ^0 alone (i.e. $\alpha_{3\pi} = 0$) and constant $\alpha_{2\pi}(s)$. $\chi^2/\text{NDoF} = 367.8/34$, $pV = 1 \times 10^{-57}$. This fit is almost identical to the fit with ρ^0 Breit-Wigner amplitude (Fig. 45).*

804 which we achieve by setting $X(3872)$ mass to 4000 MeV. This is shown for the default
805 fit in Fig. 55. The phase-space limit imposed by the actual $X(3872)$ mass (the vertical
806 dashed line) is just below the ω mass peak. Prominent constructive $\rho^0 - \omega$ interference
807 is visible in the mass range available in the $X(3872)$ decays. The ratio of the integrals
808 of the ρ^0 and ω contributions, I_{ρ^0}/I_{ω} , is 41 ± 10 in actual phase-space, and 5.6 ± 1.6 in
809 the extended phase-space (the errors are statistical from the fit). After dividing I_{ω}
810 by the small $\mathcal{BR}(\omega \rightarrow \pi^+\pi^-)$, the ρ^0/ω intensity ratio in the extended phase-space is
811 0.086 ± 0.023 . Since both resonances are nearly fully contained, this ratio reflects the
812 ratio of the $X(3872)$ couplings to $\rho^0 J/\psi$ and $\omega J/\psi$, squared. Taking its square root, we
813 obtain a value of 0.29 ± 0.04 , which is very similar to the value of the $X(3872)$ coupling
814 constants extracted by Hanhart *et al.* [34] from the Belle and BaBar data under the
815 $J^{PC} = 1^{++}$ assignment to $X(3872)$, $R_X = 0.26_{-0.05}^{+0.08}$. This value, is an order of magnitude
816 larger than expected for a ratio of isospin violating to isospin conserving decays for an
817 ordinary charmonium state (see Sec. 4 and Ref. [34]).

Figure 50: *Fit of the coupled-channel model with the ρ^0 and ω contributions and constant $\alpha_{2\pi}$. $\chi^2/\text{NDoF} = 55.1/33$, $pV = 0.0093$.*

Figure 51: *Fit of the coupled-channel model with ρ^0 alone with linear $\alpha_{2\pi}$. $\chi^2/\text{NDoF} = 90.5/33$, $pV = 2 \times 10^{-7}$, and $P_1 = 0.50 \pm 0.04$.*

Figure 52: *Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. This is our default fit to the data. $\chi^2/\text{NDoF} = 24.7/32$, $pV = 0.82$, and $P_1 = 0.226 \pm 0.045$.*

Figure 53: *Fit of the coupled-channel model with ρ^0 alone and quadratic $\alpha_{2\pi}$. $\chi^2/\text{NDoF} = 54.9/32$, $pV = 0.0071$, $P_1 = 0.16 \pm 0.05$, and $P_2 = 0.17 \pm 0.02$.*

Figure 54: *Fit of the coupled-channel model with ρ^0 and ω and quadratic $\alpha_{2\pi}$. $\chi^2/\text{NDoF} = 24.6/31$, $pV = 0.78$, $P_1 = 0.21 \pm 0.07$, and $P_2 = 0.02 \pm 0.05$.*

Figure 55: The amplitude model obtained by the fit to the LHCb data, with the phase-space limit extended by setting $X(3872)$ mass to 4000 MeV. The actual phase-space limit imposed by the true $X(3872)$ mass is indicated by the vertical dashed line. No mass resolution, nor detector efficiency were included here.

14 Fit model variations

The ρ^0 mass and width values which we use in the nominal fit are the world average numbers over the determinations in e^+e^- experiments [22]. Since we use the same values when tuning the Blatt-Weisskopf form-factor parameter R to the isovector P -wave e^+e^- phase variation extracted from the scattering experiments, there is no strong motivation to vary these parameters. Nevertheless, as a cross-check we try to fit them to our data, one at a time (see Figs. 56-57). The fit quality changes insignificantly, as shown in Table 9, which summarizes all cross-checks and systematic studies. The fitted values, $m_\rho = 771.1 \pm 10.8$ MeV and $\Gamma_\rho = 144.2 \pm 12.4$ MeV, are consistent with the world average values. The ω fractional contributions, R_ω^{all} and R_ω^0 , remain consistent with the nominal results, however, they now have large statistical errors¹² reflecting that the ρ^0 mass and width are not well constrained by our data, as only about half of this resonance is within the available phase-space. Without external input on ρ^0 parameters the discrimination between ρ^0 and ω is difficult, as also reflected in low ω significance levels.

Since ω resonance peaks beyond the phase-space limit, our data are unable to probe for its mass and width. Since this is such a narrow resonance, its parameters are very well determined and don't vary across different production mechanisms.

The scattering data constrain the R parameter, to about $1.3 - 1.6$ GeV⁻¹ range. We use $R = 1.45$ GeV⁻¹ in the nominal fit. The variation of R in the interval given above, hardly yields any change in the results (Tab. 9, Fig. 58). The Gounaris-Sakurai model of ρ^0 , discussed in Sec. 21, offers an alternative approach to the Breit-Wigner amplitude with the R -dependent form-factor, and constitutes a more drastic systematic variation for related shape uncertainty.

In principle, the 2π production form-factor in $X(3872)$ decays (entering via $B_1(p)$ in Eq. 20) could be different than the one determined from the $\pi\pi$ scattering experiments. In the default fit, we use $R_{prod} = R = 1.45$ GeV⁻¹. If we consider R_{prod} to be an independent parameter of the $R = 1.45$ GeV⁻¹ in the denominator of Eq. 12, we find that the data are insensitive to its value. We vary it in a wide range, 0-30 GeV⁻¹, as shown in Table 9 and Fig. 59.

¹²They are not consistent when the ω term is excluded from the fit, $m_\rho = 831 \pm 16$ MeV and $\Gamma_\rho = 102 \pm 6$ MeV.

Figure 56: Fits of the coupled-channel model with ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. In this fit, m_ρ mass is a free parameter. $\chi^2/\text{NDoF} = 24.7/31$, $pV = 0.78$, $m_\rho = 777.1 \pm 10.8$ MeV and $P_1 = 0.23 \pm 0.06$.

847 As a variation of the production model, we add a non-resonant terms to the production
848 vector, via

$$\begin{pmatrix} \hat{A}_{2\pi} \\ \hat{A}_{3\pi} \end{pmatrix} = [1 - i K \rho]^{-1} \left[K \begin{pmatrix} \alpha_{2\pi} \\ \alpha_{3\pi} \end{pmatrix} + \begin{pmatrix} f_{2\pi} \\ f_{3\pi} \end{pmatrix} \right]. \quad (38)$$

849 Without $X(3872) \rightarrow 3\pi J/\psi$ data in the fit, we are unable to probe for $f_{3\pi}$, thus we set it
850 to zero. A constant $\alpha_{2\pi}$ suffices for a good fit in such approach, with the same fit quality
851 as the default model with the linearly corrected $\alpha_{2\pi}(s)$ and no non-resonant production
852 (Fig. 60). The NR production parameter is significant, $f_{2\pi} = (-9.7 \pm 1.6) \times 10^{-7}$. The
853 ω results are similar to the nominal fit (see Tab. 9). Adding non-resonant terms to the
854 K-matrix¹³ is known to affect the effective K-matrix pole positions. Without ability to
855 control ρ^0 and ω pole masses from our data, such exercise would not have had a well
856 defined meaning.

857 After the R parameter has been tuned to the scattering data, there is no strong

¹³This can be accomplished by adding a diagonal constant matrix to Eq. 11.

Figure 57: Fits of the coupled-channel model with ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. In this fit, Γ_ρ mass is a free parameter. $\chi^2/\text{NDoF} = 24.7/31$, $pV = 0.78$, $\Gamma_\rho = 144.2 \pm 12.4$ MeV and $P_1 = 0.21 \pm 0.08$.

858 motivation to include an excited ρ^0 to the K-matrix. Nevertheless, we try

$$K = K_0 + \frac{1}{m_{\rho'}^2 - s} \begin{pmatrix} g_{\rho' \rightarrow 2\pi}^2 & 0 \\ 0 & 0 \end{pmatrix}, \quad (39)$$

859 where $g_{\rho' \rightarrow 2\pi} = m_{\rho'} \Gamma_{\rho'} \mathcal{B}(\rho' \rightarrow 2\pi) / \rho_{2\pi}(m_{\rho'})$. We set $m_{\rho'} = 1465$ MeV, $\Gamma_{\rho'} = 400$ MeV [22].
 860 Assuming that 2π and 4π channels dominate ρ' width, and given $\mathcal{B}(\rho' \rightarrow 2\pi) / \mathcal{B}(\rho' \rightarrow$
 861 $4\pi) = 0.37 \pm 0.10$ [22], we derive $\mathcal{B}(\rho' \rightarrow 2\pi) = (27 \pm 6)\%$. It is necessary to allow for
 862 linear term in $\alpha_{2\pi}(s)$, which becomes larger $P_1 = 0.32 \pm 0.05$. The fit quality becomes
 863 insignificantly worse ($pV = 0.80$), and the ω results don't change much (Tab. 9, Fig. 61).

864 Changing the well motivated form of $\rho_{3\pi}(s)$ given by Eq. 17 to the simple approximation
 865 given by Eq. 16, changes the ω results very little (Tab. 9), since the ω width is rather
 866 small.

867 Even though, it would be hard to argue that approximations should be taken on par
 868 with more accurate formulae, it is interesting to check what happens to the fit results when
 869 $g_{\omega \rightarrow 2\pi}^2$ term in the K-matrix is dropped, resulting in Eqs. 24 and 30. As can be seen from

Figure 58: Fits of the coupled-channel model with ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. In these fits, $R = 1.3$ (1.6) GeV^{-1} at the top (bottom) displays. The P_1 coefficients are 0.21 ± 0.05 (0.24 ± 0.05), respectively.

Figure 59: *Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi^+\pi^-}^2$. The top (bottom) figures are obtained with $R_{prod} = 0$ (30) GeV^{-1} (see the text). The P_1 coefficients are 0.17 ± 0.04 (0.56 ± 0.05), respectively.*

Figure 60: *Fit of the coupled-channel model with ρ^0 and ω contributions and constant dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. Non-resonant $\pi^+\pi^-$ terms is added to the production vector. $\chi^2/\text{NDoF} = 24.5/32$ and $pV = 0.82$.*

870 Tab. 9, the fit results hardly change, which gives validity to the interpretation of $\hat{T}_{2\pi,2\pi}$
871 term as ρ^0 component, and $\hat{T}_{2\pi,3\pi}$ term as ω component, which is implied throughout this
872 work.

873 15 D-wave decay of $X(3872)$

874 In the default fit, we neglect D-wave decays by assuming that $X(3872)$ decays to J/ψ and
875 $\pi^+\pi^-$ in S-wave. This is well justified since the analysis of the angular correlations in
876 this decay set a tight limit on a fraction of D-wave decays, $f_D < 4\%$ at 95% confidence
877 level [3]. The likelihood function peaked at 10 times smaller value, $f_D \sim 0.004$, as shown
878 in Fig. 63.

879 In this section, we perform fits to the dipion mass distribution in which we allow for

Figure 61: *Fit of the coupled-channel model with ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. An excited ρ^0 is included in the K -matrix. $\chi^2/\text{NDoF} = 25.1/32$, $pV = 0.80$ and $P_1 = 0.32 \pm 0.05$.*

880 D-wave amplitude (A_D). We multiply the PDF function (Eq. 4) by a factor, S_D , given by:

$$S_D = 1 + [A_D F_2(p_{J/\psi}, p_{J/\psi}(m_\rho))]^2, \quad (40)$$

$$F_2(p_{J/\psi}, p_{J/\psi}(m_\rho)) = \sqrt{\frac{B_2(p_{J/\psi})}{B_2(p_{J/\psi}(m_\rho))}}, \quad (41)$$

$$B_2(p_{J/\psi}) = p_{J/\psi}^4 \frac{1}{9 + 3(R p_{J/\psi})^2 + (R p_{J/\psi})^4}, \quad (42)$$

881 where $B_2(p)$ is the Blatt-Weisskopf barrier factor for D-wave decay (we used the notation
 882 of Eqs. 7-8). With this normalization choice, A_D^2 expresses the ratio of D-wave to S-wave
 883 probabilities at the ρ^0 mass ($F_2 = 1$ at $m_{\pi\pi} = m_\rho$).

884 The χ^2 value changes from 24.7 with $A_D = 0$ to 24.5 when A_D is floated in the fit.
 885 Thus, D-wave contribution from the fit to the dipion mass distribution is completely
 886 insignificant (0.5σ from Wilks theorem). In fact, the fit p-value drops from 0.82 to
 887 0.79. The fitted value, $A_D = 0.13 \pm 0.41$, is consistent with zero within the large error
 888 ($A_D/\Delta A_D = 0.3\sigma$), and corresponds to a D-wave to S-wave fraction at $m_{\pi\pi} = m_\rho$ of

Figure 62: Fits of the coupled-channel model with ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi^+\pi^-}^2$. Fit result when $g_{\omega \rightarrow 2\pi}^2$. $\chi^2/\text{NDoF} = 24.7/32$, $pV = 0.82$ and $P_1 = 0.23 \pm 0.05$.

Figure 63: Likelihood-weighted distribution of the D -wave fraction as extracted from the analysis of angular correlations in $X(3872)$ decays to J/ψ and $\pi^+\pi^-$ (Fig. 2 from Ref. [3]).

889 $(1.7^{+27.2}_{-1.7})\%$. When integrating the probabilities in the full phase-space without efficiency
 890 and mass resolution, the corresponding D-wave fit fraction is $f_D = (2.2^{+26.6}_{-2.2})\%$. The
 891 significance of the ω contribution is still very high (7.8σ from Wilks theorem). The
 892 measures of ω fit fraction change only by about a quarter of the statistical errors in the
 893 default fit (see Table 9). The statistical errors on the ω fit fraction increase somewhat,
 894 however, they reflect the uncertainty in f_D from the dipion mass fit alone. From the
 895 analysis of the angular correlations discussed above, the uncertainty in f_D is an order
 896 of magnitude smaller. By using iterative procedure, we have found that $A_D = 0.176$
 897 corresponds to $f_D = 4\%$. Fixing A_D at this value restores the statistical errors on R_ω^{all}
 898 and R_ω^0 to the values from the default fit (Table 9). We use this fit, shown in Fig. 64, to
 899 bound the systematic uncertainty due to possible non-zero D-wave fraction.

Figure 64: *Fit of the coupled-channel model with the ρ^0 and ω contributions, linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$ and $A_D = 0.176$, which gives the D-wave fraction of 4%. $\chi^2/\text{NDoF} = 24.5/32$, $pV = 0.82$, and $P_1 = 0.313 \pm 0.046$.*

900 **16 Check for interference with other decays**

901 The final state we have selected, $B^+ \rightarrow J/\psi K^+ \pi^+ \pi^-$, is dominated by production of kaon
902 excitations. This a dominant component of the smooth background under the $X(3872)$
903 peak in the $J/\psi \pi^+ \pi^-$ distribution (Fig. 30), as fraction of non- B^+ candidates is rather
904 small (Fig. 31). The $X(3872)$ has a very narrow natural width [41], thus it is rather
905 unlikely for it to interfere with such contributions. Such interferences are neglected in our
906 analysis. As the composition of kaon resonances changes with $K^+ \pi^+ \pi^-$ mass, correlated
907 with the $X(3872)$ helicity angle, $\cos \theta_X$ (defined as an angle in the $X(3872)$ rest frame
908 between the J/ψ and K^+ directions), we can check for possible interference effects with the
909 kaon excitations by dividing the total sample into subsamples of $\cos \theta_X < 0$ and $\cos \theta_X > 0$
910 data. The $X(3872)$ is expected to be split approximately evenly by such subdivision. We
911 have performed independent extraction of the dipion mass distribution in each subsample,
912 by the method described in Sec. 6. While the mass resolution is consistent in the two
913 subsamples, the relative efficiency differ somewhat, as shown in Fig. 65. We then fitted
914 each subsample separately, as illustrated in Fig. 66. The results are compatible with
915 each other, proving that any potential interference effects are not significant and can be
916 neglected.

Figure 65: *Dipion mass efficiency for $\cos\theta_X > 0$ and $\cos\theta_X < 0$ samples.*

Figure 66: *Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ of $m_{\pi\pi}^2$. The top: fit sample is in the $\cos\theta_X > 0$ region, $\chi^2/\text{NDoF} = 42.2/32$, $pV = 0.11$. The bottom: fit sample is in the $\cos\theta_X < 0$ region, $\chi^2/\text{NDoF} = 26.9/32$ and $pV = 0.72$. θ_X is the helicity angle of $X(3872)$. The P_1 coefficients are 0.16 ± 0.05 and 0.31 ± 0.08 , respectively.*

17 Selection of data with multivariate discriminant

Our default data selection uses relatively loose cuts, since non- B^+ background are relatively small in the signal region (see Fig. 31), thanks to the narrowness of the B^+ and $X(3872)$ mass peaks. To check for possible systematic effects in the simulations of efficiency variation with $m_{\pi\pi}$ influencing our results, we perform a more sophisticated data selection, which makes a more aggressive use of hadron identification, and folds in information from other discriminating variables by the use of Boosted Decision Tree method. We perform this tighter data selection on top of our nominal data selection cuts.

The following variables have been used on input to BDT:

- A combined hadron ID variable: $\log[\text{K_ProbNNk}(1-\text{K_ProbNNpi}) \text{Pi1_ProbNNpi}(1-\text{Pi1_ProbNNk}) \text{Pi2_ProbNNpi}(1-\text{Pi2_ProbNNk})]$ (labeled kNN in Fig. 69),
- A log of B^+ vertex χ^2/NDoF (labeled as Bvc2),
- A log of the minimum of hadron χ_{IP}^2 (labeled as hIPc2min)
- A log of the minimum of hadron PT (labeled as hptmin)
- A log of B^+ χ_{IP}^2 (labeled as B_IPc2)
- A log of the minimum between $\mu^+\mu^- \chi_{\text{IP}}^2$ (labeled as Min_Mu1_IPchi2_Mu2_IPchi2)
- B^+ A log of B flight distance χ^2 (labeled B_FDchi2)
- A log of 1-B_DIRA (labeled as B_DIRA)

We utilize a large, clean sample of $B^+ \rightarrow \psi(2S)K^+$, $\psi(2S) \rightarrow \pi^+\pi^- J/\psi$ events in our preselected data sample (see Fig. 67) as a signal proxy, since it has a topology very similar to $B^+ \rightarrow X(8372)K^+$, $X(3872) \rightarrow \pi^+\pi^- J/\psi$. After 2σ cuts around the B^+ and $\psi(2S)$ masses, 120k events are used in training. Non- B background in the training sample is only 1%, as determined by the fit to the B^+ mass distribution (see Fig. 68), and it is simply ignored. The non- B background sample for training is taken from $4 - 10\sigma$ sidebands of the B^+ mass peak, which are also outside 4σ mass windows around the $\psi(2S)$ and $X(3872)$ signal peaks and have $\pi^+\pi^- J/\psi$ mass below 3950 MeV. The distributions of the BDT input variables for the signal and background training samples is shown in Fig. 69.

944 The cut on BDT output discriminant is -0.1091 , as determined from the optimization
 945 curve shown in Fig. 70. The distribution of the BDT output discriminant on the actual
 946 $X(3872)$ signal sample is shown in Fig. 73. About 8% of the events are removed by the cut.
 947 The total signal $X(3872)$ yield is 6761 ± 100 (see Fig. 71), which is 99.6% of our nominal
 948 yield, and close to the expectations from the simulations, 99.4% (Fig. 74). The non- B^+
 949 background has been reduced from 9.4% in our default sample to 3.1% (see Fig. 72).
 950 However, the gain in the background level under the $X(3872)$ peak, 17% vs. 23%, is very
 951 modest because of the irreducible background from the other $B^+ \rightarrow J/\psi K^+ \pi^+ \pi^-$ decays
 952 (kaon excitations).

953 The efficiency variation with $m_{\pi\pi}$ (Fig. 75) is similar to the one in the nominal analysis
 954 (Fig. 43). The mass resolution does not change.

955 The fit results to the dipion mass distribution (Fig. 76 and Table 9) are very consistent
 956 with the nominal result.

Figure 67: A fit to the $\psi(2S)$ peak in the $J/\psi\pi^+\pi^-$ mass distribution after the $\pm 2\sigma$ cut on the B^+ mass.

Figure 76: *Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. The BDT cut is applied to this sample. $\chi^2/\text{NDoF} = 24.6/32$, $pV = 0.82$ and $P_1 = 0.24 \pm 0.04$.*

18 Systematic uncertainty from hadron identification

The hadron identification cuts in our default analysis (Sec. 5) are very loose: $PIDK > -5$ for the kaon candidate, $PIDK < +5$ for the pion candidates. The kaon candidate must also have a larger $PIDK$ value, than any of the two pion candidates. In the default approach to the relative efficiency simulation, we rely on $PIDK$ values set by the simulations. Since the cuts are loose, this works fairly well, and the kinematic distributions in the data are well reproduced by the simulations (see Fig. 37), once the B^+ transverse momentum distribution is corrected for as discussed in Sec. 7.

A more aggressive use of hadron identification variables is employed in the BDT data selection performed as a cross-check (Sec. 17). A log of the product of ProbNN variables, $K_ProbNNk(1-K_ProbNNpi) Pi1_ProbNNpi(1-Pi1_ProbNNk) Pi2_ProbNNpi(1-Pi2_ProbNNk)$, is used as one of the inputs to the BDT discriminant. The relative efficiency hardly changes (Fig. 75) and the results from the fit to the dipion mass distribution in the data change very little (Table 9).

As an additional cross check on systematic uncertainty related to the simulations of hadron identification cuts, we replace $PIDK$ values in the simulated events by values sampled from the PDFs extracted for kaons and pions from the calibration data using PIDCalib package. It turns out that following this procedure, kaon transverse momenta in the data are not well reproduced by the simulations even after the $p_T(B^+)$ reweighting (Fig. 77). After additional reweighting of the Monte Carlo sample in $p_T(K)$ (the weight function is shown in Fig. 78), the agreement between the data and simulations is reasonable as shown in Fig. 79. The relative efficiency variation with the dipion mass, is very similar to the one obtained with the default simulations (see Fig. 80 for a comparison). The fit to the dipion mass distribution in the data (Fig. 81), with the relative efficiency simulated using PIDCalib package, is almost identical to the default fit results as shown in Table 9.

Figure 77: The distribution of $p_T(K)$ for the data (points with error bars) and for the MC (histogram). The distributions were corrected for the varying bin width. The data points were obtained by fitting the $X(3872)$ peak in the $J/\psi\pi^+\pi^-$ mass distributions for various bins. The MC events were weighted by the run-dependent, dipion-mass dependent, and $p_T(B^+)$ weights. The MC distribution was normalized to the same number of entries as the data.

Figure 78: *The ratio of the data and MC distributions of $p_T(K)$ when using PIDcalib package in MC. Fit of a smooth function, used as a correction weight for simulated events, is shown.*

Figure 79: The distributions of p_T of various reconstructed particles, and of $X(3872)$ helicity angle, for the data (points with error bars) and for the MC (histogram) with use of PIDcalib package. The distributions were corrected for the varying bin width. The data points were obtained by fitting the $X(3872)$ peak in the $J/\psi\pi^+\pi^-$ mass distributions for various bins. The MC events were weighted by the run-dependent, dipion-mass-dependent and $p_T(B^+)$ -dependent weights. The MC distributions were normalized to the same number of entries as the data.

Figure 80: Variation of the reconstruction efficiency with dipion mass obtained using PIDcalib in the simulations (blue points), compared to the efficiency with the default simulations (red points).

Figure 81: *Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. The BDT cut is applied to this sample. $\chi^2/\text{NDoF} = 24.6/32$, $pV = 0.82$ and $P_1 = 0.22 \pm 0.04$.*

982 19 Mass resolution systematics

983 By default, we scale the dipion resolution up by a factor of 1.06, as deduced from the
 984 visible $X(3872)$ widths in the data and and in the simulations, and discussed in Sec. 8.
 985 To explore uncertainty in the dipion mass resolution used in the fits, we vary the scaling
 986 factor from 1.0 (no corrections) to 1.14 derived from the ratio of B^+ mass resolutions in
 987 the data and in the MC (see Sec. 8). The fits are shown in Figs. 82-83 and the results are
 988 given in Tab. 9.

989 The dipion mass bin which is the most sensitive to the mass resolution effects is in
 990 775-780 MeV range. As an additional systematic variation, we exclude this bin from the
 991 fit. The results change by amount comparable to the statistical error from the fit (Fig. 84
 992 and Tab. 9).

Figure 82: *Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. This fit was performed with the dipion mass resolution taken from simulations without any correction factor. $\chi^2/\text{NDoF} = 26.6/32$, $pV = 0.74$, $P_1 = 0.23 \pm 0.05$.*

Figure 83: *Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. This fit was performed with the dipion mass resolution scaled up by 14%. $\chi^2/\text{NDoF} = 22.6/32$, $pV = 0.89$, $P_1 = 0.23 \pm 0.05$.*

Figure 84: *Fit of the coupled-channel model with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. This fit was performed in reduced mass range from 380MeV to 775MeV. $\chi^2/\text{NDoF} = 18.0/31$, $pV = 0.97$, $P_1 = 0.24 \pm 0.05$.*

993 20 $X(3872)$ lineshape systematics

994 In the default analysis, we use double-sided Crystal Ball lineshape as the $X(3872)$ signal
 995 PDF in $m_{J/\psi\pi\pi}$ mass distribution when extracting the dipion mass distribution from the
 996 data (Sec. 6). This shape describes the $X(3872)$ mass peak well in the data and in the
 997 simulations. In this section, we present results obtained with simple Gaussian lineshape.
 998 Even though this lineshape model does not describe the simulations well (Fig. 85), the
 999 results depend only on a ratio of $X(3872)$ signal yield in the data and in the simulations
 1000 (via efficiency corrections), thus some deficiencies of this model cancel out. This approach
 1001 sets a conservative bound on how much the lineshape assumptions can matter for the
 1002 physics results.

Figure 85: *Fit to the $J/\psi\pi^+\pi^-$ distribution in the signal simulations, after the 2σ B^+ mass cut, and with the PV , J/ψ and B^+ mass constraints. We used Gaussian function for the signal peak and flat background. The blue line represents the total fit. Compare to fit with the double-sided Crystal Ball lineshape shown in Fig. 42.*

1003 The Gaussian fit to the $X(3872)$ peak in the data is shown in Fig. 86. The peak
 1004 mass value and σ obtained in this fit, are used in 2D fits to $m_{J/\psi\pi\pi}$ vs. $m_{\pi\pi}$, in bins of
 1005 $m_{\pi\pi}$. A sample of such fits in projection onto $m_{J/\psi\pi\pi}$ is shown in Fig. 87. The efficiency

1006 dependence on $m_{\pi\pi}$ obtained by using Gaussian shape in 2D fits to MC is shown in Fig. 88.
 1007 The fit to such obtain dipion mass spectrum with ρ^0 and ω contributions is shown in
 1008 Fig. 89, and with ρ^0 contribution alone in Fig. 90. The numerical results are shown in
 1009 Table 9 and are on par with the other systematic uncertainties.

Figure 86: *The distribution of $m_{J/\psi\pi^+\pi^-}$ with the 2σ B^+ mass signal cut, with the PV , J/ψ and B^+ mass constraints, fit with a Gaussian for the signal, and quadratic polynomial for the background. The blue line represents the total fit, red is the signal component, and the dashed-green is the background. Compare to the fit with the double-sided Crystal Ball lineshape in Fig. 30.*

Figure 87: Projections of unbinned fits to $m_{J/\psi\pi\pi}$ vs. $m_{\pi\pi}$, with Gaussian $X(3872)$ shape, in different $m_{\pi\pi}$ bins, onto the $m_{J/\psi\pi\pi}$ axis. The total fit, the $X(3872)$ signal and the background components are shown by the green, red and blue lines, respectively. Compare to the fits shown done with double-sided *Crystal Ball* lineshape in Fig. 33.

Figure 88: Variation of the reconstruction efficiency with dipion mass obtained using Gaussian lineshape for $X(3872)$. Units of efficiency are arbitrarily chosen to be close to 1 near 700 MeV, as only the relative variation matters in this analysis. Compare to the efficiency obtained with the double-sided Crystal Ball lineshape in Fig. 43.

Figure 89: *Fit of the coupled-channel model to the mass spectrum obtained using Gaussian $X(3872)$ shape, with the ρ^0 and ω contributions and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. $\chi^2/\text{NDoF} = 20.0/32$, $pV = 0.95$, and $P_1 = 0.242 \pm 0.045$.*

Figure 90: *Fit of the coupled-channel model to the mass spectrum obtained using Gaussian $X(3872)$ shape, with the ρ^0 contribution alone and linear dependence of $\alpha_{2\pi}$ on $m_{\pi\pi}^2$. $\chi^2/\text{NDoF} = 72.8/33$, $pV = 8 \times 10^{-5}$, and $P_1 = 0.48 \pm 0.04$.*

21 Gounaris-Sakurai model

A high statistics data on $\rho^0 - \omega$ interference in $e^+e^- \rightarrow \pi^+\pi^-$ reaction was successfully described by the BaBar collaboration [4] by using Gounaris-Sakurai model of the ρ^0 resonance [2],

$$BW_\rho^{\text{GS}}(s, m_\rho, \Gamma_\rho) = \frac{m_\rho^2 [1 + d(m_\rho)\Gamma_\rho/m_\rho]}{m_\rho^2 - s + f(s, m_\rho, \Gamma_\rho) - i m_\rho \Gamma(s, m_\rho, \Gamma_\rho)}, \quad (43)$$

where,

$$\Gamma(s, m, \Gamma) = \Gamma \frac{m}{\sqrt{s}} \left[\frac{k(s)}{k(m^2)} \right]^3, \quad (44)$$

$$d(m) = \frac{3}{\pi} \frac{m_\pi^2}{k^2(m^2)} \log \left[\frac{m + 2k(m^2)}{2m_\pi} \right] + \frac{m}{2\pi k(m^2)} - \frac{m_\pi^2 m}{\pi k^3(m^2)}, \quad (45)$$

$$f(s, m, \Gamma) = \frac{\Gamma m^2}{k^3(m^2)} [k^2(s) [h(s) - h(m^2)] + (m^2 - s)k^2(m^2)h'(m^2)], \quad (46)$$

$$k(s) = p(s), \quad (47)$$

$$h(s) = \frac{2}{\pi} \frac{k(s)}{\sqrt{s}} \log \left[\frac{\sqrt{s} + 2k(s)}{2m_\pi} \right], \quad (48)$$

and $h'(s)$ is a derivative of $h(s)$, which we calculate numerically. This is an alternative formulation to the parameterization of the ρ^0 line shape with the mass-dependent width equipped with the Blatt-Weisskopf form-factor, which we used in Sections 10 and 11. To include the P -wave momentum barrier in ρ^0 decay, we set

$$M = \frac{k(s)}{k(m_\rho)} BW_\rho^{\text{GS}}(s, m_\rho, \Gamma_\rho). \quad (49)$$

Fit of this ρ^0 shape to our data, is better than the fit of the Breit-Wigner shape described in Sec. 10, however, it still fails to describe the data as illustrated in Fig. 91.

Including ω contribution by adding its Breit-Wigner amplitude improves the fit, but still gives a bad quality fit $pV = 3 \times 10^{-5}$ (see Fig. 92).

A good quality fit to the data is achieved following the prescription used by BaBar¹⁴ [4],

$$M = \frac{k(s)}{k(m_\rho)} BW_\rho^{\text{GS}}(s, m_\rho, \Gamma_\rho) [1 + A_\omega e^{i\phi_\omega} BW_\omega(s, m_\omega, \Gamma_\omega)], \quad (50)$$

$$BW_\omega(s, m_\omega, \Gamma_\omega) = \frac{m_\omega^2}{m_\omega^2 - s - i m_\omega \Gamma_\omega}. \quad (51)$$

¹⁴Following the work by BaBar, we use a simple Breit-Wigner amplitude for ω here, with mass dependence of the width neglected, which hardly matters for such a narrow resonance. We also use ρ^0 and ω masses and widths used by BaBar in their fit to $e^+e^- \rightarrow \pi^+\pi^-(\gamma)$ data (Table VI in Ref. [4]).

Figure 91: Fit of ρ^0 Gounaris-Sakurai model to the data. The fit qualities are $\chi^2/\text{NDoF} = 290.0/34$ and $pV = 2 \times 10^{-42}$.

1024 In fact, this form arises from the coupled-channel approach as discussed in Sec. 11, when
 1025 the diagonal coupling of ω to $\pi^+\pi^-$ is neglected. Using this approximate form of the
 1026 coupled-channel approach, allows us to use Gounaris-Sakurai model for the ρ shape,
 1027 instead of the ρ^0 pole with the Blatt-Weisskopf form factor. Production couplings are
 1028 expected to be real in the coupled-channel approach, thus we set ϕ_ω to zero. In fact, the
 1029 BaBar data were consistent with this expectation ($\phi_\omega = -0.011 \pm 0.037$ radians [4]). The
 1030 fit quality to our data is good with $\chi^2/\text{NDoF} = 34.3/33$ and $pV = 0.40$ (see Fig. 93). The
 1031 $A_\omega = 0.0232 \pm 0.0016$ is 15.0σ away from zero, and by an order of magnitude larger than
 1032 when ρ^0 and ω are produced in $e^+e^- \rightarrow \pi^+\pi^-$ reaction, 0.001644 ± 0.000061 [4], which is
 1033 perhaps not surprising given that the $X(3872) \rightarrow \rho^0 J/\psi$ decay violates isospin. Yet even
 1034 larger ρ^0 suppression had been expected in case the $X(3872)$ would have been an ordinary
 1035 isoscalar charmonium state (see Sec. 4 and 13). The ω fractional contributions, overall
 1036 $R_\omega^{all} = 0.272 \pm 0.014$, and excluding the interference of the two terms $R_\omega^0 = 0.034 \pm 0.004$,
 1037 are larger than in our default coupled-channel model (Sec. 13). The ω significance
 1038 determined from the χ^2 -difference method is 16.0σ .

Figure 92: *Fit of Gounaris-Sakurai model of ρ^0 plus a simple Breit-Wigner formula for ω (Eq. 51) to the data. The relative phase was set to 95° (the fit is insensitive to it as discussed in Sec. 10). The fit qualities are $\chi^2/\text{NDoF} = 90.0/33$ and $pV = 3 \times 10^{-7}$.*

1039 The results are fairly insensitive to the value of the ϕ_ω . They don't change at all when
 1040 its value is fixed to -0.011 radians. When we fit this parameter to our data, we obtain
 1041 a value consistent with zero, $-0.40^{+0.41}_{-0.33}$ rad, with no improvements to the fit quality
 1042 ($\chi^2/\text{NDoF} = 33.4/32$, $pV = 0.40$). In such a fit ω parameters are poorly determined
 1043 ($A_\omega = 0.026 \pm 0.005$, $R_\omega^{all} = 0.277 \pm 0.029$, $R_\omega^0 = 0.047 \pm 0.017$).

1044 The BaBar collaboration found a significant contribution of the ρ' resonance, $A_{\rho'} =$
 1045 0.158 ± 0.018 , $\phi_{\rho'} = 3.76 \pm 0.10$ rad, when adding the $A_{\rho'} e^{i\phi_{\rho'}} BW_{\rho'}^{\text{GS}}(s, m_{\rho'}, \Gamma_{\rho'})$ term to
 1046 Eq. 50 [4]. We fix the ρ' mass, width and phase to the values determined from the BaBar
 1047 data [4], and obtain a fit quality, $\chi^2/\text{NDoF} = 24.8/32$, $pV = 0.81$ (see Fig. 94), matching
 1048 the fit quality of our nominal fit. The ρ' significance is 3.1σ from the χ^2 -difference method
 1049 (Wilks theorem). The production parameter, $A_{\rho'} = 0.302 \pm 0.099$, is also 3.0σ away from
 1050 zero, and consistent within the large errors with the value obtained by the fit to the BaBar
 1051 data (see above). The ω significance is 7.8σ from the Wilks theorem. Its production
 1052 parameter, $A_\omega = 0.0171 \pm 0.0024$ is 7.2σ away from zero. The ω fractional contributions

Figure 93: *Fit of Gounaris-Sakurai model of ρ^0 coupled with ω via Eq. 50. The relative phase was set to zero. The fit qualities are $\chi^2/\text{NDoF} = 34.4/33$ and $pV = 0.40$.*

1053 are now more consistent with our default model, $R_\omega^{all} = 0.221 \pm 0.024$, $R_\omega^0 = 0.021 \pm 0.005$.
1054 In here, $R_\omega^{all} = 1 - R_{\rho+\rho'}$, where $R_{\rho+\rho'} = 0.780 \pm 0.023$ is the coherent fit fraction of ρ^0
1055 and $\rho^{0'}$ together. Individual fit fractions are $R_\rho = 0.833 \pm 0.037$ and $R_{\rho'} = 0.013 \pm 0.008$.
1056 We include this fit when evaluating the systematic uncertainty of our results (see Table 9).

Figure 94: *Fit of Gounaris-Sakurai (GS) model of ρ^0 coupled with ω via Eq. 50, and $\rho^{0'}$ in the GS representation added to the fit. The relative phase of ω was set to zero. The relative phase of $\rho^{0'}$ was set to 3.76 rad [4]. The fit qualities are $\chi^2/\text{NDoF} = 24.8/32$ and $pV = 0.81$.*

1057 **22 Summary of systematic variations**

1058 The summary of the results, including all systematic variations and cross-checks is given
1059 in Table 9. We set the systematic errors from the largest variations found in the table.
1060 For significance of the ω contribution, we take the smallest number found, excluding the
1061 division of the data into subsamples. The final result, including the systematic error is
1062 given in the last row.

Table 9: Summary of systematic studies and cross-checks. Numbers in italic font do not contribute to the total systematic uncertainties.

23 Conclusions

We have performed analysis of dipion mass distribution in $X(3872) \rightarrow \pi^+\pi^- J/\psi$ decays, reconstructed from $B^+ \rightarrow K^+ X(3872)$ decays, with the signal statistics which is 43 times larger than in the previous analysis of this type. The ρ^0 and ω contributions are resolved for the first time. The decay is dominated by $\rho^0 \rightarrow \pi^+\pi^-$ contribution, however this contribution alone fails to describe the data. We have developed a coupled-channel K-matrix model, which describes the data well once the ω contribution, coupling to both $\pi^+\pi^-$ and $\pi^+\pi^-\pi^0$ is allowed. The data can be equally well described with Gounaris-Sakurai model of ρ^0 , coupling to ω , with a small ρ^0 contribution, previously used to describe the high statistics $e^-e^+ \rightarrow \pi^+\pi^-(\gamma)$ data [4]. We establish a $\omega \rightarrow \pi^+\pi^-$ contribution with a high significance ($> 7.1\sigma$) for the first time. At present, this is a more significant observation of $X(3872) \rightarrow \omega J/\psi$ decays, than the observations with $\omega \rightarrow \pi^+\pi^-\pi^0$ decays.

Quantitatively, the $\omega \rightarrow \pi^+\pi^-$ contribution leaves a large impact on the overall $X(3872) \rightarrow \pi^+\pi^- J/\psi$ rate, by contributing as much as $(21.4 \pm 2.3 \pm 2.0)\%$, mostly via interference with the ρ^0 contribution. Without this interference, the dominant ω term in our coupled-channel model constitutes only $(1.9 \pm 0.4 \pm 0.3)\%$ of the total rate, which is consistent with the expectations based on $X(3872) \rightarrow \omega J/\psi$, $\omega \rightarrow \pi^+\pi^-\pi^0$ rate measurements and the known ω branching fractions to channels with two and three pions.

By providing a detailed explanation of the dipion mass distribution observed in the $X(3872) \rightarrow \pi^+\pi^- J/\psi$ decays, we properly quantify magnitude of isospin violating production of ρ^0 resonance for the first time. Relative to the isospin conserving $\omega J/\psi$ decay, $\rho^0 J/\psi$ rate is an order of magnitude larger than expected for an ordinary charmonium state.

Large isospin violation is naturally expected in models in which the $X(3872)$ state has a significant component of $D\bar{D}^*$ pairs, either as constituents (molecular model) or generated dynamically in the decay, which would preferentially be $D^0\bar{D}^{*0}$ combination, thanks to the proximity of the $X(3872)$ mass to the related threshold, rather than D^+D^{*-} combination, which is 8 MeV heavier [27–30, 33, 35, 42–45]. However, it has been also suggested that two, degenerate and mixed, neutral, compact tetraquark states could also give a raise to a large isospin violation in the $X(3872)$ decays [46–48]. The compact tetraquark model

¹⁰⁹⁴ predicts charged partners of $X(3872)$, which have not been observed.

Appendices

A Dipion mass distribution in the signal simulations

In this section we discuss in more detail the dipion mass distribution in the simulated sample of $B^+ \rightarrow X(3872)K^+$, $X(3872) \rightarrow J/\psi\rho^0$, $\rho^0 \rightarrow \pi^+\pi^-$, $J/\psi \rightarrow \mu^+\mu^-$ events.

In particular, we cover reweighting of this sample with the dipion mass, applied when comparing the simulated sample to the real data in variables other than the dipion mass.

We also present a test of the default matrix element model on this fully simulated sample.

The events were generated according to EventType 12145003, in which the B^+ decay chain is simulated using the helicity model in which 1^{++} $X(3872)$ decays in S-wave, which describes the angular distributions in the data well [3]. For convenience, we list here EvtGen dec-file directives:

The comparison between the reconstructed dipion mass distributions in the data and in the MC is shown in Fig. 95. Both were obtained by fitting the $X(3872)$ peak in the $J/\psi\pi^+\pi^-$ mass distribution in bins of the dipion mass as described in Sec. 6. Since the MC has very little combinatoric background under the $X(3872)$ peak, and no contribution from $B^+ \rightarrow J/\psi K^{*+}$, $K^{*+} \rightarrow K^+\pi^+\pi^-$ which are significant in the data, the background polynomial is reduced to a constant term when fitting the MC. The distributions track each other rather well, except for the highest mass values. However, this is an accident, since the data contains the significant ω contribution, which accounts for about 20% of the total rate (after interference with the ρ^0) present mostly at high dipion masses. The

1131 MC makes up for the lack of the ω contribution in the simulations by not implementing a
 1132 proper phase-space factor in the $X(3872) \rightarrow J/\psi\rho^0$ decay. We discuss this further below.
 1133 When projecting the simulations to other variables than the dipion mass, we correct for
 1134 the deviations between the data and MC seen in Fig. 95, by weighting the simulated
 1135 sample with the mass-dependent weight shown in Fig. 96.

Figure 95: *The reconstructed dipion mass distributions in the data (points with the error bars) and in the MC (histogram). The MC signal sample is 6.3 times larger than in the data and was scaled down to the same integral as the data.*

1136 An attempt to fit the dipion mass distribution in the MC with the ρ^0 contribution
 1137 alone, exposes the problem in the generation of the proper ρ^0 shape in the MC generation,
 1138 as illustrated in Fig. 97. The ρ^0 Breit-Wigner shape here is consistent with the ρ^0 shape
 1139 documented in the previous publication on this topic by the Belle Collaboration [38],
 1140 which rules out a possibility of a mistake in our formulae or coding. Therefore, the problem
 1141 is on the MC generation side. In fact, the MC distribution observed here is consistent
 1142 with the ρ^0 mass sampled from the ρ^0 Breit-Wigner formula and just truncated at the
 1143 upper kinematic bound, without taking into account the phase-space factor, $p_{J/\psi}$, in the
 1144 $X(3872) \rightarrow J/\psi\rho^0$ decay. The observed sharp drop off of the reconstructed dipion mass

Figure 96: *The ratio of the dipion mass distribution reconstructed in the data and in the simulations (points with error bars), with the smoothing weight function superimposed. p -value of the fit is 47%.*

1145 distribution in the MC near the upper kinematic bound is only due to the finite mass
1146 resolution.

1147 To make up for improper ρ^0 mass generation in the MC, we reweight the simulated
1148 sample according to the $p_{J/\psi}(m)/p_{J/\psi}(700 \text{ MeV})$ weight, where m is the true dipion mass
1149 (from the MC "truth" information), and 700 MeV is an arbitrary weight-normalization
1150 point. After reweighting, we fit the simulated sample with our default K-matrix model,
1151 which allows for ρ^0 , with a linear mass dependence of its production vector, and for ω
1152 contribution. The ρ^0 mass and width are fixed in the fit to the values used in the generation
1153 (768.5 MeV and 151 MeV, respectively). The mass resolution is not scaled up. It is not clear
1154 to us if EvtGen uses mass dependent width formula for ρ^0 , and if so, what is the effective
1155 hadron size parameter (R) used in the Blatt-Weisskopf form-factor. It is not even clear if
1156 the Breit-Wigner used in the generation is in a non-relativistic or relativistic form. Since
1157 it would be difficult to take relativity out of our K-matrix model, we stick to our default
1158 formulation and float the R value in the fit. The obtained value is $R = (5.8 \pm 1.5) \text{ GeV}^{-1}$.

Figure 97: The fit of ρ^0 Breit-Wigner shape to the dipion mass distribution reconstructed in the signal MC.

1159 The fit describes the reweighted simulations reasonably well as shown in Fig. 98. The
 1160 obtained ω contribution is consistent with zero, $A_\omega = (0.002 \pm 0.018) \times (m_\omega^2 - m_\rho^2)$,
 1161 $R_\omega^0 = R_{\omega/\rho}^0 = 0.0001 \pm 0.0002$ and $R_\omega^{all} = 0.002 \pm 0.018$. The ρ^0 production is consistent
 1162 with no dependence on the dipion mass, $P_1 = 0.102 \pm 0.052$, as in fact expected for these
 1163 simulations. This exercise validates our fitting approach and proves the lack of the $p_{J/\psi}$
 1164 phase-space factor in the ρ^0 shape generation in the simulations.

Figure 98: The fit of ρ^0 and ω contributions to the dipion mass distribution reconstructed in the signal MC after reweighting MC with $p_{J/\psi}$, as described in the text.

1165 B Various additional plots and information

1166 In this appendix we include various plots and information added on request, which do not fit other sections.

Figure 99: Dalitz plot for $X(3872) \rightarrow J/\psi\pi^+\pi^-$ decay. The pion candidate which has the same sign as B in the selected $B \rightarrow X(3872)K$ decay is labeled as π^+ .

1281 **Vita**

1282 Author's Name: Baasansuren Batsukh

1283 Place of Birth: Ulaanbaatar, Mongolia

1284 Date of Birth: January 22, 1994

1285 Degrees Awarded:

1286 Bachelor of Science, National University of Mongolia, 2015

1287 Professional Experience:

1288

1289 Teaching Assistant, Syracuse University Department of Physics, 2015-2017

1290 Research Assistant, Syracuse University Department of Physics, 2017-2021

1291 CERN User, Geneva, Switzerland, since 2017
