ABSTRACT

The Delaware Basin forms part of West Texas's and New Mexico's famous petroleum-generating Permian Basin. The Bone Spring Formation is a prolific hydrocarbon producer within this basin, creating one of the world's richest oil shales. This formation has lithological sequences that are characterized by repeating carbonate and siliciclastic intervals of a third-order cycle which can largely be correlated to highstand and lowstand systems tracts, respectively. Lithological complexity and facies change are manifested by debris flows, turbidites, and slumps. In addition to glacio-eustasy, both tectonism and broader Milankovitch cycles have influenced the depositional history.

Previous investigations have utilized cores and wireline logs to provide high-resolution chemo-facies segregation, which can be correlated with reservoir and rock properties; however, core and wireline logs are sporadically collected, whereas drill cuttings are available from most wells. For this study, XRF elemental data derived from drill cuttings collected at 30 – 60ft (9 – 18m) intervals have been compared to wireline well logs. XRF measurements were categorized using hierarchical cluster and principal component analysis based on chemical facies. Chemostratigraphic units and packages were applied to generate cross-sections and facies maps to understand depositional cyclicity, terrigenous influence, grain size,

mineralogy, organic content and rock property distribution. These data sets can be used to high-grade acreage for resource identification and storage to optimize drilling performance, completion designs and as a geosteering input.

ACKNOWLEDGMENTS

I would like to thank my advisor Julie Bloxson for her guidance and support throughout this master's program and thesis research and the geological department of Stephen F Austin for affording me the opportunity for an online learning experience. My wife Keyla, my children Katherine and Andrew, my in-laws Gilberto and Gredy for their support and assistance. To Ben Metz of Ascent Energy for allowing me to use the data from his field and his insights and guidance along the way. Science involves standing on tall shoulders. I would like to thank my thesis committee for their input, feedback and guidance Dr. Liane Stevens, Dr. Robert Friedfeld and Dr. Mindy Faulkner. Thanks to Simon Hughes, Meri McCully, and Andreina Liborius for the inputs and ideas. To my fellow students and co-workers throughout my academic and professional career, every experience and interaction lead and leads to enrichment.

Figure 8, Facies Model based on outcrop study in the Guadalupe Mountains, West Texas. From Walker (2021). 18

Figure 9, Photographs of outcrops and photomicrographs depicting the eight facies Facies pictures from outcrop (upper photo) and thin section (lower photo). A) Facies 1 is a thin-bedded laminated lime mudstone. The pencil is marking ripples. Detrital quartz grains are visible in thin section. B) Facies 2 is a thin to thick bedded deformed lime mudstone with form lines indicating deformation. Photomicrograph of Facies 2 with deformation-induced calcite-cemented fractures with background facies identical to Facies 1. C) Facies 3 is a thick-bedded bioclastic lime wackestone to packstone. Photomicrograph of Facies 3 shows an increase in mud content to the top interpreted as possible turbidity current. D) Facies 4 is an interbedded lime mudstone and bioclastic packstone with interbedded packstone indicated. Photomicrograph shows interbedded packstone beds with calcite cementation and lenticular to continuous nature. E) Facies 5 is a thick-bedded normal-graded bioclastic lime packstone to grainstone. Normal grading shown with finger placed on basal coarse-grain deposit. Thin section shows bryozoan (by), brachiopods (ba), and undifferentiated carbonate allochems with chert cement. F) Facies 6 is a thin-bedded laminated bioclastic quartz siltstone. Note different color and weathering pattern to Facies 1. Thin section shows noticeably higher detrital quartz present in comparison to Facies 1. G) Facies 7 is a thin-bedded laminated quartz lime mudstone. Interbedded with Facies 6 showing different weathering pattern. Note brown color in comparison to Facies 1. Photomicrograph of Facies 7 with detrital quartz content less than Facies 6 but greater than Facies 1. H) Facies 8 is a thick bedded bioclastic lime packstone to grainstone. Photomicrograph of Facies 8 reveals bryozoan (by), sponge spicules (sp), rugose corals (co), brachiopods (ba), and unidentified carbonate material, (Walker 2021). 19

(1.)INTRODUCTION

The Greater Permian Basin is a global leader in hydrocarbon production, with estimated remaining proven reserves in excess of 5 billion barrels of oil and 19.1 trillion cubic feet of natural gas, making it one of the largest hydrocarbon-producing basins in the United States and the world (EIA, 2017). It includes the Delaware Basin and Diablo platform to the west, the Central Basin Platform to the east, and the rocks of the Ancestral Rocky Mountains and the Northwest Shelf to the north-northwest (Figure 1.) (Hatcher et al., 1989). A thick section of up to 4,000 feet (1,000 m) of siliciclastic, carbonate, and evaporite sediments accumulated during the Pennsylvanian in a deep-water depositional setting, depositing the Leonardian Bone Spring Formation from 268-283 Ma, (Ewing, 1991, 2014). This formation is one of the most prolific hydrocarbon-producing unconventional reservoirs in the basin, and prior to 2010 was a prolific conventional reservoir in the sandstone intervals, consisting of heterogenous interbedded carbonates, mudstones, and sandstones, (Carr,2019). Eustatic and tectonic controls over Permian Basin evolution have resulted in the complex lithologies and structure of the Bone Spring Formation. This stratigraphic interval is characterized by a repeating third-order cycle of carbonate and siliciclastic intervals, which can largely be correlated to highstand and lowstand systems tracts, respectively (Carr, 2019). Furthermore, extensive debris flows caused by tectonic pulses and/or high frequency sea level fluctuations are found

throughout the basin, which resulted in increased vertical and lateral facies variability (Loucks and Ruppel, 2007; Driskell, 2018). Establishing relationships between the depositional cyclicity, terrigenous influence, grain size, mineralogy, and rock properties, and their geochemical elemental facies could provide a greater understanding of both the genesis and occurrence of these formations.

Figure 1, Regional structural features in West Texas and New Mexico. The study area is marked by the red dot. The Greater Permian Basin includes the Delaware Basin, Central Basin Platform, Midland Basin and Val Verde Basin. The study area is on the northern edge of the Delaware Basin. Modified from Pioneer Natural Resources (2013).

One method for analysis of mudstones is chemostratigraphy. Chemostratigraphy is a reservoir correlation technique utilizing geochemical data for characterization and correlation of sedimentary rocks. It is widely used in paleoclimatology and paleoceanography (Rothwell and Croudace, 2015a, 2015b; Algeo and Maynard, 2004;

Ratcliffe et al., 2004; Pearce et al., 1999), and has proven well suited to the study of fine-grained mudrock systems and tight reservoirs (Craigie, 2021). On first appearance, mudstones can appear to be homogenous; however, they can contain significant geochemical variability that is a result of depositional influences (Figure 2.) (Algeo and Maynard, 2004). Chemical proxies have been developed regarding several sediment properties including source, clay content, dolomitization, anoxia, organic richness, and terrigenous input (Algeo and Maynard, 2004; Ratcliffe et al., 2004; Pearce et al., 1999;

Figure 2, Geochemical data from the Buda, Woodbine Group, and Eagle Ford Formation. The elemental data can be interpreted as minerals, either by themselves or as ratios with other elements. In conjunction with X-ray diffraction measurements (XRD) as a calibration for minerals present. Oftentimes, the elemental data is also correlated to TOC to aid in interpretation of depositional setting. These can then be used to infer sediment type (Track 18), preservation potential (oxic vs. dysoxic conditions; Track 19), and productivity (EF Ni; Track 20). Track 18 consisting of carbonate vs. siliciclastics is a key signal in understanding Leonardian Permian depositional systems in this study. From Meyers (2019).

Tribovillard, 2006, 2010; Ratcliffe et al., 2010; Wright et al., 2010; Turner et al., 2015; Driskill et al., 2018). For example, while the increased solubility of redox-sensitive trace metals in oxic environments leads to trace metal depletion, in oxygen-deficient environments trace metals are enriched due to their lower solubility (Driskill et al., 2018). The influx of nutrient-rich waters (enriched in elements such as phosphorous and copper) promotes primary production, while subsequent anoxia encourages the preservation of organic matter (Brumsack, 1989). Furthermore, correlations have been established between certain trace metals, such as Ni, As, Co, Cu, Fe, Mo, Ni, S, Se, and Zn, with total organic carbon (TOC) in the Wolfcamp and Bone Spring formations (Driskill et al., 2018). From Driskill et al.'s work, uranium does not correlate well with TOC in these formations, which is often the case with "typical" organic rich shales such as the Devonian Marcellus Shale (Driskill et al., 2018). This can lead to inaccurate TOC estimations from the spectral gamma ray or traditional gamma ray logs. Overall, these fundamental principles of chemical elements as proxies for understanding evolving geologic conditions can be used to determine event extent, timing and spatial extent to expand upon a generalized model for basin mudstone deposition (Cortez, 2012).

Elemental data is used to understand depositional cyclicity (sea level changes), terrigenous influence, grain size, mineralogy, and rock mechanical properties. The work of Driskill et al. (2018) and Peng et al. (2022) utilizing core data illustrates the potential insights that can be obtained. Driskill et al. (2018) used core, log, and elemental data obtained via X-ray fluorescence (XRF) to demonstrate how silica/aluminum (Si/Al),

zirconium/aluminum (Zr/Al), and titanium/aluminum (Ti/Al) ratios identified fining upwards Bouma turbidite sequences in the 3rd Bone Spring and Wolfcamp A formations. Si is a proxy for quartz and Al is a proxy for clay mineral content. A decrease in the Si/Al ratio occurs in upward fining sequences, indicating a turbidite sequence. Their work was able to determine grain size using these elemental proxies, showcasing the heterogeneity of these formations throughout the region. Zr, Hf, Ti, Ta, Nb, Cr, Y, Th are considered high field strength detrital elements, their distributions being largely unaffected by post depositional weathering/diagenesis. For this reason alone, they tend to be utilized in isolation, or in the form of ratios, to place chemostratigraphic boundaries (Craigie, 2018).

Elemental data derived from core have been used to establish relationships with lithological facies as well (Larson, 2022). Principal Component Analysis and K Means Clustering were employed on the Wolfcamp Formation to develop statistical chemical facies that were then correlated with lithofacies to better predict reservoir quality. Stolz et al. (2015) also demonstrated a relationship between petrophysical properties and lithofacies in the bone spring and avalon formations overlying the Wolfcamp. Carbonate facies were determined by Ca and Mg concentrations, which negatively correlated with porosity and permeability measurements. The Ca and Mg concentrations could be taken as proxies for porosity and permeability rather than taking time consuming and expensive measurements. Ca and Mg, therefore, can be used to predict reservoir quality in these formations (Figure 3.). Walker (2021) worked on outcrops in the Guadelupe mountains and linked chemical facies to lithofacies and depositional environments using in situ XRF

measurements.

However, previous work, including that mentioned above, has primarily used core for chemostratigraphy studies (Driskill et al., 2018, Larson et al., 2021). While core can provide a complete picture of a formation in the subsurface, they are expensive, proprietary, and oftentimes widely spatially distributed. Drill cuttings and wireline logs are prolific across basins and can provide better spatial resolution across a region, although at the expense of depth resolution. Drill cuttings are often taken every 30 to 120 ft (9 to 36 m), rather than continuously, like core (Tonner, 2018). Well logs can have a depth resolution down to 2 ft (60 cm) (Nance and Rowe, 2010) sometimes even less, depending on the age and type of tool. Few chemostratigraphy studies have been conducted using cuttings because of the low depth resolution; however, the potential exists to “fill in the gaps” where cores are unavailable.

This study utilized cuttings and well logs to create a subsurface model of the Bone Spring Formation to determine depositional environmental conditions in the northern Delaware Basin. These results were then compared to results from previous core studies to determine if cuttings are a viable option for chemostratigraphy studies. This will provide a foundation for the usefulness of cuttings when core is unavailable or scarce in a region. The data sets is used to determine sequence stratigraphy and depositional cycles, whether eustatic or tectonic, within the Bone Spring Formation in Lea County, eastern New Mexico. Establishing relationships between drill cuttings and wireline data can aid in upscaling and application of data models across many wells and thus create a

better understanding of the subsurface as it relates to depositional cyclicity, terrigenous influence, grain size, mineralogy, and rock properties.

2. STUDY OBJECTIVES

The objectives for this study are listed below:

1. Describe the changes in depositional environments throughout the Bone Spring Formation, including the Avalon Formation and Big Lime using XRF data on cuttings in Lea County, NM.
2. Assign chemofacies to the ten wells in the study area based upon Principal Component Analysis (PCA) and Hierarchical Cluster Analysis (HCA) cluster assignments to show periods of similar depositional conditions across the region.
3. Link chemofacies to lithofacies to improve understanding of the influence of glacio-eustasy and tectonic events in the rock formation.
4. Showcase the utility of cuttings data for chemostratigraphy studies by comparing this study to previous core studies. Cuttings have a lower resolution (typically 9.1 m (30 ft) sampling intervals), compared to core or outcrop where an entire section could potentially be observed.
5. Calculate reservoir properties from the cuttings XRF data, including the Brittleness Index, Gamma Ray log, TOC and V_{clay} .
6. Compare the calculated reservoir properties to petrophysical analyses to see if correlations exist between either widely used petrophysical calculations or well logs. This would allow for easy interpretation of chemofacies once correlations are established.
7. Address if chemostratigraphy can identify formations on a well bore lateral and can be used for geosteering purposes.

3. GEOLOGIC HISTORY

The Permian Basin, also called the West Texas Super Basin, covers more than 75,000 mi², spanning west Texas and southern New Mexico (U.S. Energy Information Administration, 2019). It is bounded by the Ouachita-Marathon orogenic belt to the south, the Diablo Platform to the west, the Eastern Shelf to the east, and the Northwest Shelf and Matador Arch to the north, with several sub-basins and platforms within the basin itself (Ewing, 1991; Ewing, 2014; Ewing, 2016; Ewing, 2019) (Figure 1.). The basin has produced 28.9 billion barrels (bbl.) of oil and 203 Trillion Cubic Ft (TcF) of gas since the 1920's (63 billion barrels of oil equivalent (BOE), (1920–2019). The US Geological Survey and the Texas Bureau of Economic Geology estimate that this super basin has 120–137 billion BOE in place (Fairhurst, 2021).

The West Texas Super Basin is a complex Paleozoic basin built on a varied Proterozoic crust. Initial Neoproterozoic and Cambrian rifting were followed by regional subsidence, later forming the Tabosa Basin (Figure 3.) in which deposition began in the Middle Ordovician and continued into the Devonian. Early Paleozoic Tabosa Basin subsidence terminated during the Mississippian orogenic uplift derived from the convergence of the Laurentian and Gondwanan plates. (Galley, 1958; Ewing, 2016). This is known as the Ouachita Orogeny (Figure 4.). This event, known as the Ouchita orogeny, resulted in the closure of the Rheic Ocean, the creation of the Pangea supercontinent

(Nance, 2008), and the development of the orogen as the southern edge of the Laurentia plate was subducted beneath a northward-advancing Gondwanan (South American side) continental-margin arc. Large-scale faulting and folding accompanied later stage tectonic evolution during the Late Mississippian subsidence. Tectonic and structural development was controlled by compression related to the Ancestral Rocky Mountains and Ouachita-Marathon orogenic events. The Ouachita-Marathon tectonic event ended in the Wolfcampian (early Permian) (Figure 6.). Subsidence continued to the end of the Ochoan. Periodic subsidence during the Mesozoic was likely caused by Laramide deformation in the Rocky Mountains. Cenozoic Laramide western uplift tilted the basin towards the east (Fairhurst, 2021).

During the Wolfcampian of the Permian (299-280 Ma), shallow carbonate shelves accumulated on the edges of the basin. Late Paleozoic tectonism led to high amounts of subsidence and compressional stress uplifting the platforms, leading to increased turbidite deposition of clastic and carbonate sediment on the slope (Adams, 1965). High sedimentation rates during the Permian (265-230 Ma) filled the basin with deltaic siliciclastics and extensive reef carbonate ringed the basin and evaporite shelves (Figure 5.). Marine transgression led to massive deposits of the overlying fine-grained siliciclastics into the basin (Hill, 1972) (Figure 6.).

Figure 3, During the Cambrian through the Mississippian, carbonate and clastic sediments were deposited in a broad marine basin, creating the Tobosa Basin. Modified from Blakey (2016).

Figure 4, The Ouachita orogeny occurred as Laurentia collided with South America from the Early Pennsylvanian through the Early Permian. This orogeny caused basin differentiation into several deep basins surrounded by shallow shelves. Modified from Blakey (2016).

Figure 5, The collision of Laurentia and Gondwana resulted in the formation of the Pangea supercontinent. Large volume Sediment deposition was initiated when the basin became structurally stable. Large volumes of Permian clastic sediments were deposited in the deeper part of the basin and carbonates were deposited on the shelves. Modified from Blakey (2016).

Figure 6, Leonardian depositional environments across the region. Tropical marine depositional environment existed with fluctuating sea levels. The Delaware Basin and Midland Basin are circled in blue, and the study area is highlighted in red. From Blakey (2020).

4. STRATIGRAPHIC FRAMEWORK

4.1 General Stratigraphy and Lithology

The Bone Spring Formation unconformably underlies the Brushy Canyon formation consisting of silts, carbonates, and shale that were deposited during cyclical sea level changes, with an overall gradational transgression. The Bone Spring is often informally divided into eight members, in ascending order: 3rd Bone Spring sand, 3rd Bone Spring carbonate, 2nd Bone Spring sand, 2nd Bone Spring Carbonate, 1st Bone Spring sand, 1st Bone Spring carbonate, Avalon sandstone, Bone Spring lime (Figure 7.). This Leonardian series is present throughout the Delaware Basin and is laterally equivalent to the Wichita, Abo-Yeso and Clearfork formations on the Central Basin Platform, and the Dean and Spraberry formations in the Midland Basin (EIA, 2019). Together the Bone Spring and Avalon formations average in thickness from 2,500 feet to 3,500 feet, with the thickest region occurring in the eastern portion of the Delaware Basin. The Bone Spring formation represents the downdip equivalent to thick shelf and shelf-margin carbonates that rimmed the Delaware basin during deposition of Leonardian strata (Mazzullo, 1991). Across the northern Delaware Basin, the Leonardian Bones Spring Formation represents a general shelf-to-basin relationship, (Montgomery, 1997). Although labeled as “sands,” the 1st, 2nd and 3rd Bone Springs sands are mislabeled, these are mudstones with varying degrees of carbonate, siliceous and argillaceous composition.

The Bone Spring Formation is a repeated cycle of basal siliciclastics capped by carbonates (Figure 13.) (Carr, 2019; Nance and Hamlin, 2020), creating the 1st, 2nd, and 3rd Bone Spring cycles. The low stand siliciclastics were deposited in laterally continuous submarine fan systems on the basin floor (Nance and Hamlin, 2020), while the carbonate members were deposited during high stands. The carbonates consist of three types of facies. The spiculitic limestone facies consists of carbonaceous wackestone and mudstones, with sponge spicules found throughout, deposited in a deep basinal setting, and are the main carbonate in the 1st Bone Spring carbonate (Montgomery, 1997). The dolomitized breccia facies consists of several facies within the package. Varying sizes of angular grains create packstone and wackestone that have been altered. The clasts within these breccias consist of laminated siltstones, cross-bedded peloidal packstone and grainstone, bryozoan-rich bound stones, and skeletal debris. These are thought to have been derived from the shelf through upper slope, deposited during submarine debris flows that exhibit sharp erosional contacts with rip up clasts (Bienvenour, 2019). The dolomitized bioclast packstone facies consists of bioclast-peloid packstone, with occasional wackestone and grainstone. The grains consist of skeletal debris (crinoids, bivalves, sponges, etc.). This facies is the main constituent of the 2nd Bone Spring carbonate. Generally, the carbonates are composed of dark and dense carbonaceous wackestone, and mudstone. These mudstones are an important source rock (Montgomery, 1997). Carbonate-dominated Bone Spring units are typically thickest at the basin margins, and show subtle thickening in structural lows that are located in basinal

positions. The very thick, basinward thinning fan pattern emanating from the southern part of the NW Shelf suggests that highstand carbonates were shed into the basin episodically due to autocyclic and catastrophic processes by sediment current flows (Carr, 2019). The 1st Bone Spring Carbonate consists of the 1st Bone Spring Lime, The Avalon, and the Big Lime. The Avalon is often divided further into three informal intervals: Lower Avalon, Middle Avalon, and Upper Avalon. The Lower and Upper Avalon are generally the mudstone-rich intervals separated by the more carbonate-rich Middle Avalon. The Avalon is a fourth low stand fan system productive in the more siliciclastic northern basin (Fairhurst, 2021). The Avalon has a thickness in excess of 150ft, porosity that ranges from 4-17%, and TOC ranging from 4-8% in the shale intervals

Siliciclastic intervals in the Bone Spring Formation consist of three general types of facies: argillaceous facies, siliceous facies and carbonate facies. Sand strata in the Bone Spring Formation were deposited as submarine fans. The sand intervals of the Bone Spring are composed of dark, thinly bedded, calcareous shales and siltstones. Overall, the Bone Spring Formation has porosities ranging from 4.5 to 16%, and an estimated TOC of 1 to 8 %.

The Big Lime overlying the Avalon is a carbonate mudstone sequence which lies unconformably beneath the Brushy Canyon clastics. As described by (Walker, 2021), the Bone Spring Fm. upper slope is composed predominantly of fine-grained carbonate hemipelagites and sediment gravity flows containing a high biogenic silica content (i.e., chert). Interbedded within the carbonate slope facies at various scales are detrital

terrigenous hemipelagic and sediment gravity flow deposits, carbonate mass-transport deposits, and carbonate submarine channel deposits.

Work done by Wiley (2021), mapped outcrops of the Bone Spring Formation in the Guadalupe Mountains of West Texas, developed an eight facies classification scheme and, in addition, mapped the facies to chemofacies using XRF measurements, (Figure 8.). The principal objective was to link geomorphology and slope to lithofacies and chemofacies. The following facies were identified:

A. Facies 1 thin-bedded laminated lime mudstone with pencil-thin marking ripples. Thin section of facies 1 is predominantly lime mudstone, but detrital quartz grains are present. (Figure 9A.)

B. Facies 2, thin to thick bedded deformed lime mudstone with lines indicating deformation. Thin section of Facies 2 with deformation-induced calcite-cemented fractures with background facies identical to Facies 1. (Figure 9B.)

C. Facies 3, thick-bedded bioclastic lime wackestone to packstone. Thin section of Facies 3 shows an increase in mud content to the top interpreted as a possible turbidity current. (Figure 9C.)

D. Facies 4, interbedded lime mudstone and bioclastic packstone with interbedded packstone indicated. Thin section shows interbedded packstone beds with calcite cementation and lenticular to continuous nature. (Figure 9D.)

E. Facies 5 thick-bedded normal-graded bioclastic lime packstone to grainstone. Normal grading shown with finger placed on basal coarse-grain deposit. Thin section

shows bryozoan (by), brachiopods (ba), and undifferentiated carbonate allochems with chert cement.(Figure 9E.)

F. Facies 6 thin-bedded laminated bioclastic quartz siltstone. Note different color and weathering patterns to Facies 1. Thin section shows noticeably higher detrital quartz present in comparison to Facies 1.(Figure 9F.)

G. Facies 7 thin-bedded laminated quartz lime mudstone. Interbedded with Facies 6 showing different weathering patterns. Note brown color in comparison to Facies 1. Thin section of Facies 7 with detrital quartz content less than Facies 6 but greater than Facies 1.(Figure 9G.)

H. Facies 8, thick bedded bioclastic lime packstone to grainstone. Thin section of Facies 8 reveals bryozoan (by), sponge spicules (sp), rugose corals (co), brachiopods (ba), and unidentified carbonate material.(Figure 9H.).

B) Facies 2 is a thin to thick bedded deformed lime mudstone with form lines indicating deformation. Photomicrograph of Facies 2 with deformation-induced calcite-cemented fractures with background facies identical to Facies 1. C) Facies 3 is a thick-bedded bioclastic lime wackestone to packstone. Photomicrograph of Facies 3 shows an increase in mud content to the top interpreted as possible turbidity current. D) Facies 4 is an interbedded lime mudstone and bioclastic packstone with interbedded packstone indicated. Photomicrograph shows interbedded packstone beds with calcite cementation and lenticular to continuous nature. E) Facies 5 is a thick-bedded normal-graded bioclastic lime packstone to grainstone. Normal grading shown with finger placed on basal coarse-grain deposit. Thin section shows bryozoan (by), brachiopods (ba), and

undifferentiated carbonate allochems with chert cement. F) Facies 6 is a thin-bedded laminated bioclastic quartz siltstone. Note different color and weathering pattern to Facies 1. Thin section shows noticeably higher detrital quartz present in comparison to Facies. G) Facies 7 is a thin-bedded laminated quartz lime mudstone. Interbedded with Facies 6 showing different weathering pattern. Note brown color in comparison to Facies 1. Photomicrograph of Facies 7 with detrital quartz content less than Facies 6 but greater than Facies 1. H) Facies 8 is a thick bedded bioclastic lime packstone to grainstone. Photomicrograph of Facies 8 reveals bryozoan (by), sponge spicules (sp), rugose corals (co), brachiopods (ba), and unidentified carbonate material, (Walker 2021).

Bienvenour and Sonnenberg (2019) developed the following more detailed sub classifications that can be divided into nine discreet facies. Within each facies there are Argillaceous, calcareous and biogenic sub facies. Each facies has been described based on its formation. Ie turbiditic, hemipelagic and formed from debrites. Figure 10 depicts core photographs, thin section photomicrographs and XRD ternary diagrams for the Leonardian and Wolfcamp formations.

Table 1. Facies classification based on an integrated core and log study by Bienvenour and Sonnenberg (2019).

Facies #	Facies Name	Facies Group	Bulk Mineralogy	Common Facies Assemblage
1	Argillaceous Siliceous Mudstone	Siliceous Mudstone	Si > Ar > Ca	L.D. Turbidite / Hemipelagic / H.E.B.
2	Calcareous Siliceous Mudstone	Siliceous Mudstone	Si > Ca > Ar	L.D. Turbidite / H.E.B. / Hemipelagic
3	Biogenic Siliceous Mudstone	Siliceous Mudstone	Si > Ar > Ca	Hemipelagic
4	Argillaceous Siliceous Siltstone	Siltstone	Si > Ar > Ca	L.D. Turbidite
5	Calcareous Siliceous Siltstone	Siltstone	Si > Ca > Ar	H.E.B. / L.D. Turbidite
6	Siliceous Calcareous Siltstone	Siltstone	Ca > Si > Ar	H.E.B. / L.D. Turbidite / H.D. Turbidite
7	Skeletal Mud Dominated Wacke-Packstone	Carbonate	Ca > Si > Ar	Debrite / H.E.B. / H.D. Turbidite
8	Skeletal Grain Dominated Pack-Grainstone	Carbonate	Ca > Si > Ar	Debrite / H.D. Turbidite
9	Dolomitic Skeletal Packstone	Carbonate	Ca > Si > Ar	Debrite / H.D. Turbidite

A Depositional Model of the Delaware Basin during Leonardian Time was developed by Loucks et al., 1985. Characteristic depositional processes of the time include carbonate debris origination above the basin floor, and deposition of organic, pelagic siltstones and mudstones out onto the basin floor. (Figure 11.).

Figure 11, Depositional Model of the Delaware Basin during Leonardian Time. Characteristic depositional processes of the time include carbonate debris origination above the basin floor, and deposition of organic, pelagic siltstones and mudstones out onto the basin floor (Loucks et al., 1985).

4.2 Type Well Log

Well logs have historically identified the changes in facies in the Avalon, 1st, 2nd and 3rd Bone Spring (Carr, 2019). The repeated cycles of carbonates, clastics, and mudstones create cyclical patterns in well log data. The 1st Bone Spring carbonate sequence and the Avalon carbonates are characterized by low gamma ray (< 40 API), high photoelectric effect (PEF) (~4.7 barns/electron) and resistivity values (~ 1000 ohm), higher density readings (~2.65-2.8 g/cm³), and an increase in sonic travel times (~100

usec/ft) compared to the siliciclastic intervals. In the sandstone, Hamlin and Baumgardner (2012) utilized wireline logs to estimate the position and the contact of the facies in the Midland Basin. Carr (2019) applied gamma ray (GR) vs. deep resistivity (Rd) cross plot methodology to the Bone Spring BSPG in the Delaware Basin. He used a GR-Rd model and created wireline facies curves for approximately 1800 wells where top picks and GR-Rd log-curve suites were available. Carr observed that the base of Brushy Canyon/top of BSPG was not difficult to pick in wireline logs, however the other boundaries of the uppermost mapping units, "Cutoff" and "Avalon", as well as the top of the 1st Bone Spring Lime, can be comparatively difficult to identify. Isopach maps by Carr (2019) indicate that siliciclastic deposits are thickest in the basin center while carbonates are thickest at the basin margins (Figure 12.).

Figure 12, Gross interval isopach maps of the (A) 3rd Bone Spring sand and (B) 3rd Bone Spring carbonate with the unit basement faults in bold black from Ewing (1990). Siliciclastic-dominated Bone Spring units are typically thickest in basin-center positions with the carbonate's thickest on the rim. The thickest parts of the unit occur in the northern half of the basin, north of the east–west-striking Grisham fault (aka Mid-Basin fault), indicating that structure also influenced Bone Spring sedimentation. From Carr (2019).

Between the carbonate to the siliciclastic intervals in the study area, there is a slight increase in gamma ray (>50 API), a reduction in PEF (~2.4-2.6) and resistivity (20-200-ohm meters), and a decrease in density (2.4-2.5 g/cm³) and sonic (~50usec/ft) values. This repeated carbonate highstand and siliciclastic lowstand sequence is important because the changes in chemical stratigraphy will be identified using XRF element geochemistry. (Figure 13 & Figure 14.).

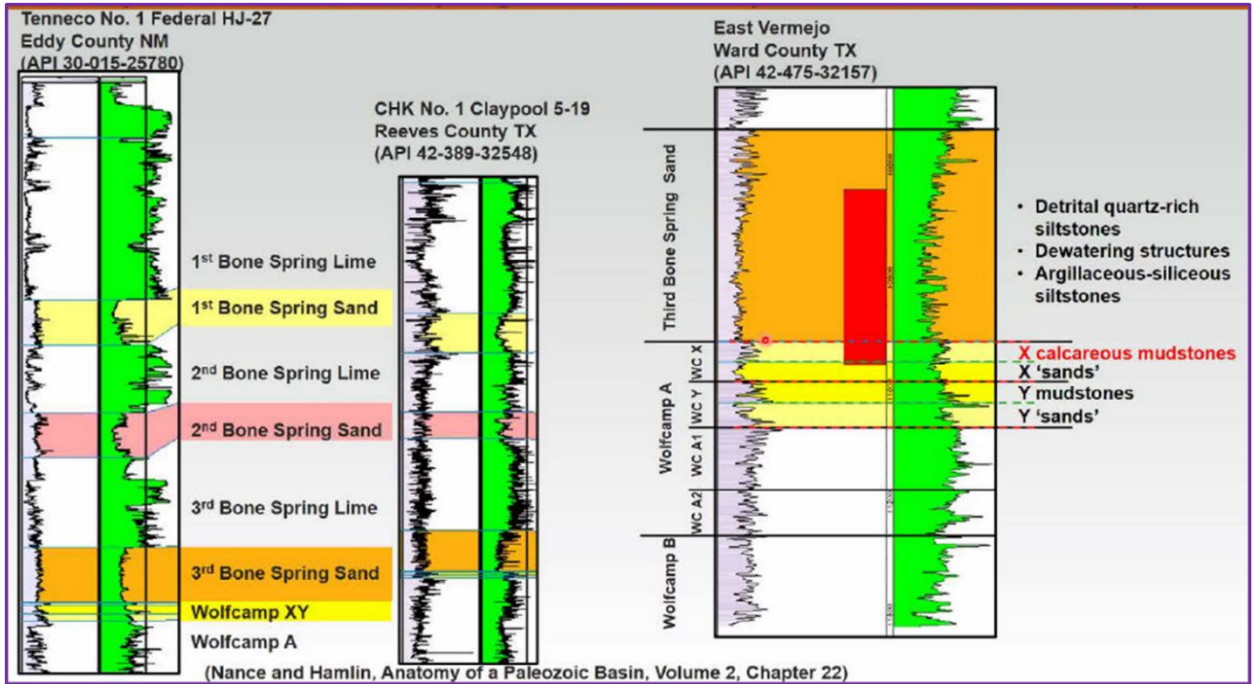

Figure 13, Repeated siliciclastics and carbonate sequences. Carbonates represent high stands and siliciclastics represent lowstands. From Nance and Hamlin (2020).

5. METHODOLOGY

5.1 Materials and Data

Elemental data were obtained from drill cuttings care of Ascent Energy. The XRF data was measured during the drilling of the well and the cuttings were disposed. Diversified Well Logging collected the samples at an average of 30-50 ft intervals and conducted the XRF analysis on 10 wells in the Delaware Basin (Figure 15., Table 2). The average number of samples per well is 200. All wells have gamma ray (GR) well log data, azimuth, and inclination information that were recorded during drilling. One well (Big Moose 604H) has a full suite of wireline logs, including gamma ray (GR), resistivity (RES), bulk density (RHOB), neutron porosity (NPHI), and Elemental Capture Spectroscopy (ECS), which measures the dry weight % of Si, Ca, Fe, S, Ti and Gd in a formation.

Table 2. List of wells used in this study from Lea County, New Mexico, and corresponding data.

	XRF	GR	Density	Sonic	Porosity	ECS	Resistivity	API	Start Depth Ft. MD	End Depth Ft. MD	Latitude	Longitude

Figure 15, (A) Map of the study area and well location in Lea County, New Mexico, Delaware Basin. (B) Inset map of the Texas-New Mexico border, with Texas in red, and the Delaware Basin shaded in yellow. (C) Map of the United States, with Texas in red and the Delaware Basin in yellow. Well locations are in red. Orange lines are perpendicular to the cross section line chosen.

The workflow (Figure 16.) consisted of first gathering the XRF measurements from the drill cuttings and the wire line logs. The XRF data were processed in the JMP statistical software package after Data QAQC. The software permits a combination of Hierarchical Cluster Analysis (HCA) and Principal Component Analysis (PCA) to characterize the data into seven chemical facies or chemofacies. Both sets of data were brought into Logscope® software for petrophysical analysis. Shapefiles were created of elements and algorithms of elements and imported into QGIS to plot concentrations across the region.

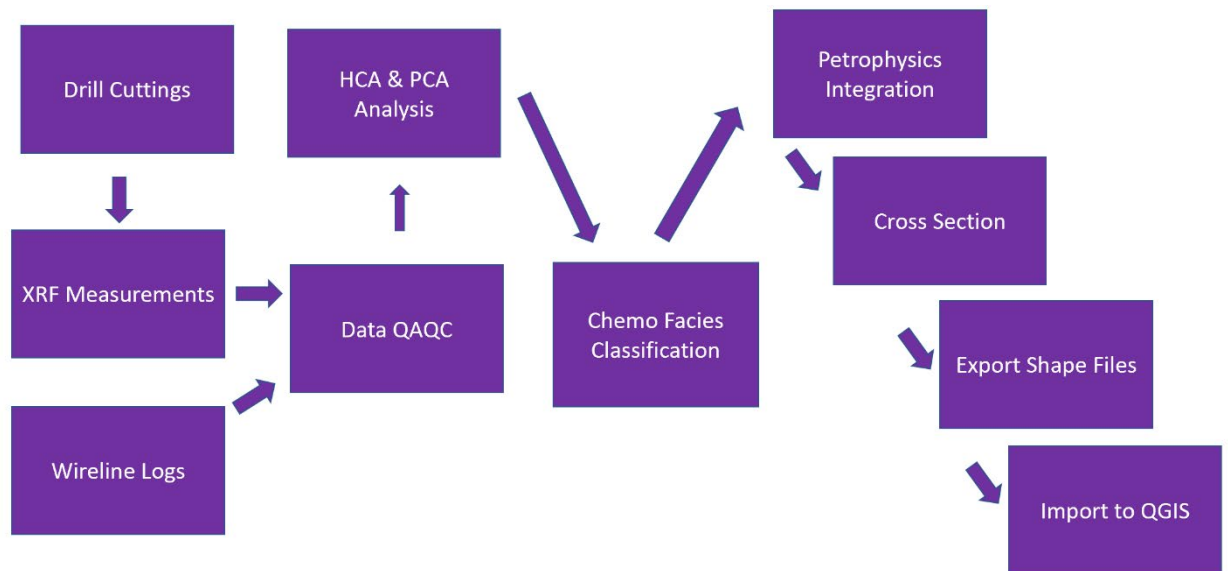

Figure 16, Drill cuttings and petrophysics workflow. XRF data from drill cuttings is merged into LogScope with downhole logs. Data is imported into an HCA/PCA analysis package and chemofacies are created. Cross sections are generated, and elemental attributes are geospatially mapped.

5.2 XRF

XRF was measured with a portable benchtop Spectro Scout at the well site while

drilling was taking place. Samples were collected during the drilling process using 10 (2mm), 80 (0.177mm) and 120 (0.125mm) mesh sieves. Mesh size refers to the number of openings per square inch. The samples were cleaned with diesel fuel and Dawn dish soap to remove oil-based mud contamination. They were then dried with a vacuum dryer (not heat). A small 5.5 g of the collected and cleaned sample was ground using a ball mill with 2 x 12 mm tungsten balls for 30 seconds. Samples were then placed into a vacuum cup and entered the XRF Portable Benchtop Spectroscout. A proprietary calibration method for mudrocks was used called “DWL Geo.” The samples were calibrated against the USGS SDC (Science Data Catalog) standard every 5th sample processed to ensure calibration of the instrument. Element concentrations were determined by cooperating laboratories using a variety of analytical methods (Table 3).

Table 3, SDC standard materials for XRF machine calibration. United States Geological Survey Certificate of Analysis Mica Schist, SDC-1.

Listed in mass % SDC Standard Brammer Standard Database	
Element	Concentration
SiO ₂	65.5
Al ₂ O ₃	15.8
CaO	1.4
FeO	3.93
Fe ₂ O ₃	6.32
K ₂ O	3.28
MgO	1.69
Na ₂ O	2.05
P ₂ O ₅	0.16

Specific elements used for proxies consisted of: redox sensitive trace elements

(RSTE's: Ni, Zn, V, Mo, U), detrital deposition (Si, Al, Ti, Zr, Rb), carbonate deposition (Ca, Mg, Sr), phosphate enrichment (P, Y), and sulfur enrichment (S) (Baumgartner and Rowe, 2017). Si/Al, Si/Zr ratios were calculated as a proxy for grain size (Driskill, 2018). The total set of elements used are listed in (Table 4).

Table 4, List of elements measured by the XRF.

Cl	Si	Ti	Al	Fe	Mn	Mg	Ca	K	P	S	V
Cr	Ni	Cu	Zn	Rb	Sr	Y	Zr	Mo	W	Tl	Pb
Th	U										

The XRF data were used to determine mineralogy using a proprietary, forward modelling logic, stoichiometric mineral model method developed by Diversified Well Logging but based on previous work by Cohen and Ward 1991 (Figure 17.). The order of calculations is listed in Table 5. The “Limiting Element” means that all of a particular element remaining at that calculation step is used to calculate the abundance of the mineral

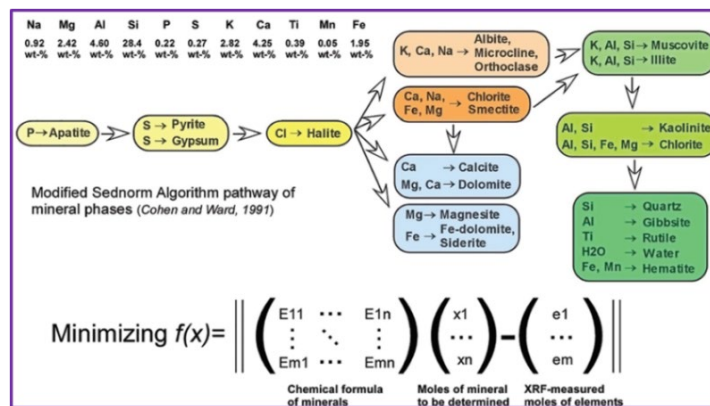

Figure 17, Sequence and algorithm for mineralogy calculation. (Cohen and Ward, 1991)

There are several key assumptions that were made during the mineralogy calculations. Fe and Mg are present in equal amounts in chlorite. All plagioclase is albite (sodic end member), although note Na is difficult to measure with the XRF instrument utilized. No K-feldspar is present. All K₂O present is found in illite. No mixed-layer illite/smectite is present. All K₂O is contained in illite. MnO is not significant and is not utilized in the calculation. The above assumptions are based on previous work calibrating the responses to mineralogy via X-ray diffraction in the Permian Basin.

Table 5, List of minerals and chemical formulas used in the normative calculations in this study.

Order of Calculation	Mineral Calculated	Mineral Formula	Limiting Element 1	Limiting Element 2	Limiting Element 3	Limiting Element 4
1	Rutile	TiO ₂	TiO ₂			
2	Fluorapatite	Ca ₅ (PO ₄) ₃ (F)	P ₂ O ₅	CaO		
3	Barite	BaSO ₄	BaO	SO ₃		
4	Pyrite	FeS ₂	SO ₃			
5	Chlorite	Mg ₃ Fe ₃ Si ₂ Al ₂ O ₁₀ (OH) ₈	Fe ₂ O ₃	MgO	Al ₂ O ₃	SiO ₂
6	Dolomite	Ca _{0.5} Mg _{0.5} CO ₃	MgO	CaO		
7	Calcite	CaCO ₃	CaO			
8	Halite	NaCl	Cl	Na ₂ O		

9	Albite	$\text{NaAlSi}_3\text{O}_8$	Na_2O	Al_2O_3	SiO_2	
10	Illite	$\text{KA1}_4(\text{Si}_7\text{AlO}_{20})(\text{OH})_4$	K_2O_4	Al_2O_3	SiO_2	
11	Kaolinite	$\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$	Al_2O_3	SiO_2		
12	Quartz	SiO_2	SiO_2			

5.2 XRF Analyses – PCA and Cluster Analysis

XRF measurements were grouped as chemical facies (chemofacies) using a combination of Hierarchical Cluster Analysis (HCA) and Principal Component Analysis (PCA). Cluster analysis groups the samples based on the degree of similarity to one another using Ward Euclidian distance. PCA is a statistical procedure that allows you to summarize the information content in large data tables by means of a smaller set of “summary indices” that can be more easily visualized and analyzed.

The workflow was to first upload raw XRF data files into JMP for analysis. The first step was to conduct Quality Assurance and Quality Control (QAQC) on the data set to remove outliers and missing data. Due to low or missing values, the following elements were used (Table 4). In addition, the JMP software has the option to also remove low or missing values automatically. This method was chosen, i.e., the missing or low data values were removed.

HCA was then run on the clean dataset. HCA separates the clusters using the Euclidean distance, which measures the distance between two centroids (Ward, 1963). The number of clusters chosen was based on the “Thorndike” method, which looks at the

cluster similarity at each stage based on the Euclidean distance (Thorndike, 1953). The most significant advantage of using HCA is that we can manually assign and adjust the number of final clusters based on geological background and compare clustering solutions for different values to determine an optimal number of clusters for the data sets. Seven clusters were chosen because the eigenvector results in the PCA indicated seven clusters with a number greater or close to 1 and visually allowed for reasonable cluster separation. The resultant PCA chemofacies were described based on their elemental composition using a combination of the bulk elements and the S-Core mudstone classification scheme and the trace elements.

5.4 Petrophysical Analysis

After clustering, each chemofacies was assigned a number based upon the results from the HCA and PCA and imported into Logscope petrophysical software package from Harvey Rock Geophysics along with the raw XRF and available well log data for further analyses. Logscope Software is a petrophysical software that allows for multiwell analysis of fluids and rock properties. These evaluations use well log data to analyze a formation for various reservoir characteristics, such as porosity, shale content, permeability, or clay minerals. Variables in the analyses can easily be modified to fit a region, which are then updated across the project. The evaluations are conducted through established cross plots (Schlumberger Log Interpretation Charts, 2013), that have been calibrated using laboratory measurements. Furthermore, it allows for visualization of changes across the

region. Cross sections can easily be created consisting of chemofacies, well log data, and petrophysical properties. The logs uploaded into Logscope for petrophysical evaluation include gamma ray (GR), resistivity (RES), bulk density (RHOB), neutron porosity (NPHI), and Elemental Capture Spectroscopy (ECS) (Table 1).

In Logscope, formations boundaries were determined using the gamma ray log and the type curve (Figure 14.). Next, the XRF data were used to calculate an elemental gamma ray (EGR) curve. This curve was used to compare the cuttings depth to the well log depth for proper correlation of information. The EGR was calculated using the following formula where K_2O , Th, and U were measured by the XRF. This equation was calibrated using other wells in the field and is based on the original formula after Ellis & Singer (1987):

$$\text{Equation 1 } GR = 16K_2O + 8U + 4Th$$

where K is potassium in wt. %, U is uranium in ppm, and Th is thorium in ppm. The Elemental Gamma Ray logs were compared to downhole Gamma Ray logs that were acquired both while drilling (MWD) and the downhole tools ran after drilling. This helped to ensure that the cuttings were assigned the correct depth and can represent the formation when compared to the well logs.

Lithology was interpreted from the wireline log using the Big Moose fed Com 604H well, which has a full suite of well logs. This was conducted primarily using the ECS log coupled with the gamma ray and density. The combination of these three tools provided downhole lithologies that were compared directly to the modeled mineralogy from the

XRF. This was then correlated based upon the gamma ray curve. Oftentimes, the only curves measured on well logs are the gamma ray curve. Establishing a model to extrapolate data is important to create regional correlations, especially where data is scarce.

The XRF mineralogy derived from the mineral model described above was compared to the wireline mineralogy estimated from Elemental Capture Spectroscopy ECS wireline tools. A visual estimate of covariance was used.

The volume of shale was calculated from the gamma ray curve using the following formula:

$$\text{Equation 2 } V_{CLAY} = \frac{GR - GR_{min}}{GR_{max} - GR_{min}}$$

where GR is the measured gamma ray value at a given depth, GR_{min} is the minimum gamma ray value for the location, interpreted as being a “clean” or shale-free zone, GR_{max} is the maximum gamma ray value for the location, interpreted as being 100% shale.

The XRF clay content (Equation 2) was compared to the V_{shale} calculated content. The petrophysical properties calculated were then compared to the elemental data to establish relationships to rock properties that could be extrapolated across the region. The GEMS Tool Total Organic Content (TOC) using the Passey Method was compared to modeled TOC from paleo redox elemental proxies in source rocks (mudstones in the Bone Spring Formation). The TOC calculation in LogScope used the Passey Method from Passey et al. (1990). They used the change in deep resistivity and porosity curves to highlight the

presence of organic-rich intervals in source rocks. In 'lean' source rocks, the curves overlie one another. Organic-rich intervals are highlighted by curve separation, indicating a low density and high resistivity. Using the gamma-ray curve, reservoir intervals were identified and eliminated from the analysis, based upon the low gamma ray values (<50 API). The separation in organic-rich intervals results from two effects: the porosity curve responds to the presence of low-density, low-velocity kerogen, and the resistivity curve responds to the formation fluid. In an immature organic-rich rock, where no hydrocarbons have been generated, the observed curve separation is due solely to the porosity curve response (Passey et al., 1990). The magnitude of the separation indicates amount of TOC, which has been calibrated from laboratory measured TOC values and maturity data. Although ideal, it is not necessary given the amount of data available, and assumptions which can be made based upon generalized worldwide source rock trends, which is done by default in Logscope.

The brittleness was calculated using the XRF data in Logscope, and compared to the Sonic log. The brittleness of a rock describes its failure behavior during exposure to increasing stress. Rocks characterized by a high brittleness index typically have a high Young's modulus (E) and low Poisson's ratio (P) (Rickman et al., 2008). While pressure and temperature can affect the brittleness index, a primary controlling factor that affects it is the composition of the material. For example, a clay or mudstone will tend to be more malleable or ductile. Quartz and calcite on the other hand, with a higher density and hardness, will be more brittle. Overall, in geologic materials, certain minerals are

mechanically more competent. Previous work by Wang and Gale (2009) used the following formulas:

Equation 3
$$BI = \frac{V_{QTZ}}{V_{QTZ} + V_{CL} + V_{CAL}}$$

Where V is the volume in weight percent of a given mineral or set of minerals. Wang and Gale (2009) also proposed a further modified version:

The equation used with the XRF elemental data was:

Equation 4
$$BI = \frac{V_{QTZ} + V_{DOL}}{V_{QTZ} + V_{DOL} + V_{CL} + V_{CAL} + V_{TOC}}$$

Equation 5
$$BI = \frac{Ca}{Si + Ca + Al}$$

The brittleness was also calculated using the formula below from the modeled mineralogy:

Equation 6
$$BI = \frac{V_{QTZ} + V_{CAL}}{V_{QTZ} + V_{CL} + V_{CAL}}$$

XRF brittleness was compared to the sonic log for geomechanical properties. Both a visual and R² comparison was performed. The sonic log is an important log because it can be used as a proxy for mechanical characteristics. Oftentimes, a faster travel time reflects a more competent rock because of the changes in density of the different lithologies. A mudstone or claystone is less dense and thus will have a longer travel time. A competent packstone carbonate will reflect the sonic wave very quickly because it is denser compared to mudstones or sandstones

The highest values with the coarsest grains can be found in the Toque State wells. This is also the wells with found within chemofacies 6 enriched in detrital and siliceous components Grain size can be estimated using elemental ratios such as Zr/Al (Driskill et al., 2018). There are two grain size formulas:

$$\text{Equation 7} \quad \textit{Grain Size} = \frac{\textit{Zr}}{\textit{Al}}$$

$$\text{Equation 8} \quad \textit{Grain Size Detrital} = \frac{\textit{Zr+Ti+Rb}}{\textit{Al}}$$

Here, I used equation 7 to calculate the relative grain size within the formations.

5.5 Mapping

Combinations of elemental measurements were mapped across the study area to assess spatial changes. Wells were first imported as CSV data files into Logscope. Using the solver feature in Logscope, derived parameters were calculated from the elemental data sets. The redox sensitive trace elements (RSTE) calculation was the average of the sum of the U, Cr, Ni, Zn elements. The grain size was estimated using the Zr/Al ratio. These data sets were averaged for each formation interval, 1st Bone Spring Lime, 1st Bone Spring Sand, 2nd Bone Spring Lime, etc., and were exported as shapefiles and imported into QGIS. The inverse distance weighting (IDW) interpolation was used to generate rasters and were contoured. IDW estimates unknown values within a specified search distance, closest points, power setting and barriers. It is mathematical (deterministic) and assumes closer

values are more related than further values with its function. Appropriate color properties were changed using the symbology and color ramps that best represented the data. Isochore and structure maps were not completed on these wells, as much of the lower section were laterals – the horizontal portion of the well.

6. RESULTS AND INTERPRETATION

6.1 XRF Analyses

Below is a summary of the XRF analyses performed.

6.1.1 Formation Mineralogy and Distribution

Based upon the modeled mineralogy and general trace elemental composition, the Big Lime has an average composition of calcite 60%, quartz 21%, illite 11%, dolomite 4%, pyrite 1% and chlorite 1%. The redox sensitive trace element (RSTE) score is 171. The calculated Brittle Index (BI) is 19 and the grain size Zr/Al ratio is 22.

The Avalon has an average calcite composition of 62%, quartz 30%, illite 11%, dolomite 4%, pyrite 1%, and chlorite 1%. The RSTE redox sensitive trace metal score is 314, suggesting it is more organic rich than the Bone Spring Lime. The BI is 20 and the grain size Zr/Al ratio of 24.

The 1st Bone Spring Lime has an average calcite composition of 53%, quartz 30%, illite 10%, dolomite 4%, pyrite 2%, and chlorite 1%. The RSTE redox sensitive trace metal score is 229, falling in between the Bone Spring Lime and Avalon. The BI is 26 and the grain size Zr/Al is 18.

The 1st Bone Spring Sand has an average calcite composition of 41%, quartz 46%, illite 9%, dolomite 2%, pyrite 2% and chlorite 0%. The RSTE redox sensitive trace metal score is 312, indicating a relatively high organic richness, the Brittle Index is 49, i.e., much more competent than the Big Lime, Avalon, and 1st BSPG Lime, and the grain size

Zr/Al is 22.

The 2nd Bone Spring Lime has an average calcite composition of 42%, quartz 41%, illite 10%, dolomite 4%, pyrite 1% and chlorite 1%. The RSTE redox sensitive trace metal score is 267 the Brittle Index is 39 and the grain size Zr/Al is 31.

The 2nd Bone Spring Sand has an average calcite composition of 20%, quartz 49%, illite 21%. Dolomite 5%, Pyrite 1% and Chlorite 3%, i.e. much higher quartz content and an increase in chlorite. The RSTE redox sensitive trace metal score is 232, the Brittle Index is 49 (increasingly more competent) and the grain size Zr/Al is 52, indicating a much coarser grain size.

The 3rd Bone Spring Lime has an average calcite composition of 27%, quartz 45%, illite 18%, dolomite 4%, pyrite 2%, and chlorite 3%. The RSTE redox sensitive trace metal score is 250, the Brittle Index is 45 and the grain size Zr/Al is 49.

The 3rd Bone Spring Sand has an average calcite composition of 3%, quartz 57%, illite 27%, dolomite 6%, pyrite 0%, and chlorite 5%. The RSTE redox sensitive trace metal score is 250, the Brittle Index is 45 and the grain size Zr/Al is 49. The clay content is higher in this formation. The calcite composition is significantly lower.

The cross section (Figure 18.) shows the modelled mineralogy for all 10 wells derived from the XRF drill cuttings measurements. The Big Lime carbonate is a clear marker across the study area. This is followed by the Avalon, 1st Bone Spring Lime, 1st Bone Spring Sand, 2nd Bone Spring Lime and 2nd Bone Spring Sand can be followed with the change in mineralogy from Calcite to Quartz across the area, indicating a change in

carbonate composition and facies. There is a general increase in the carbonate from the 3rd Bone Spring sand up to the Big Lime.

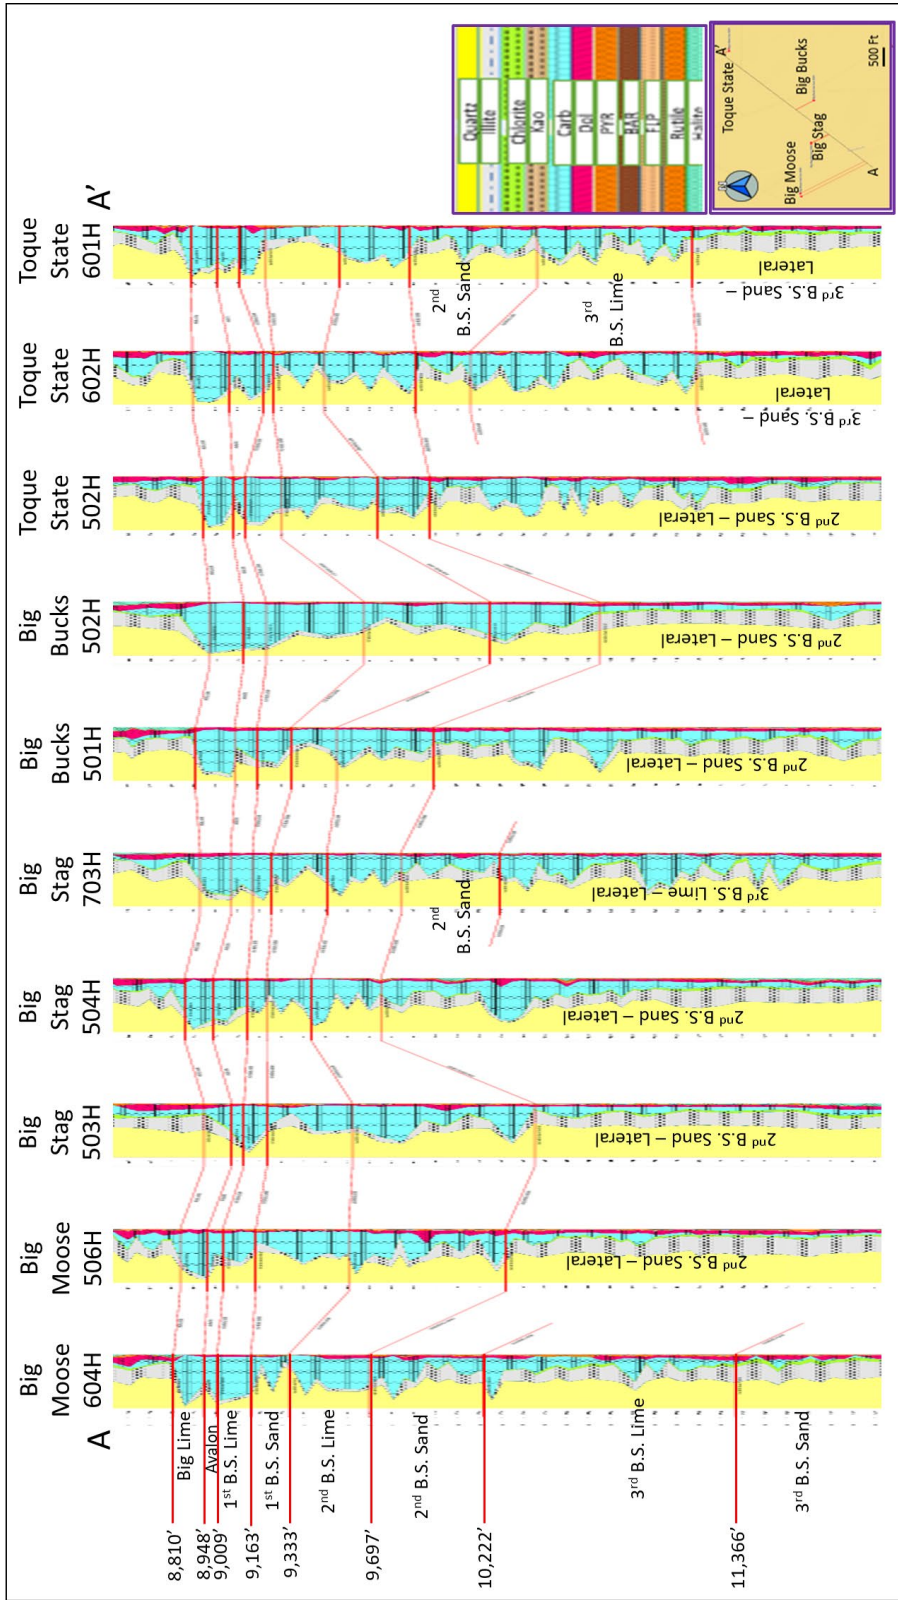

Figure 18, Plot of modelled mineralogy from XRF across the study area. The Big Stag Fed Com 703H has the highest carbonate composition in the lateral; this is a 3rd Bone Spring Lime well. Wells drilled in the Middle 2nd BSPG Lime (Big Stag Fed Com 504H and Big Bucks Fed Com 502H also have a higher carbonate composition.

6.1.2 PCA

Principal Component Analysis was run on the entire dataset after removing outliers and missing values. After removal of missing data, 26 of the elements were selected from the original 54 elements. There were seven components that had eigenvalues greater than 1, representing 80.395% of the total variance in the dataset (Table 6). This criterion also suggests that seven clusters should be used for the cluster analysis, and that seven clusters is statistically meaningful; more would create unnecessary groupings that would not be statistically different. Fewer clusters would group individual chemofacies that could be separated into meaningful geological units.

Table 6, Calculated eigenvalues for the principal components of the XRF data from all ten wells. The percent represents the amount of variance a component represents.

Eigenvalues							
Number	Eigenvalue	Percent	20	40	60	80	Cum Percent
1	8.7336	33.591					33.591
2	4.3223	16.624					50.215
3	2.2174	8.528					58.743

22	0.0510	0.196					100.974
23	0.0370	0.142					101.116
24	0.0202	0.078					101.194
25	0.0123	0.047					101.241

PC1 and PC2 were then used to determine the geological interpretation of the seven clusters. The Loading Scores (Table 7) indicate that Al, Rb, K, Ti, Si, Zr, Y, Fe, and Th

are strongly correlated, while negatively correlating with Tl, Sr, and Ca for PC1. This can be interpreted as the partitioning of the mineral-sensitive elements: high PC1 scores at a given depth indicates high values of Al, Rb, K, Ti, Si, Zr, Y, Fe, and Th, suggesting siliceous mudrocks, while low PC1 scores indicate high values of Tl, Sr, and Ca, suggesting carbonate lithofacies. PC 2 generally represents the enrichment of redox-sensitive Ni, U, Mo, Cu, and Cr; positive values indicate a given depth is redox-sensitive elements-rich, whereas negative values indicate that a depth is redox-sensitive element depleted (Figure 19.).

Table 7, Loading matrix for PC1 (Prin1) and PC2 (Prin2) for the 23 elements.

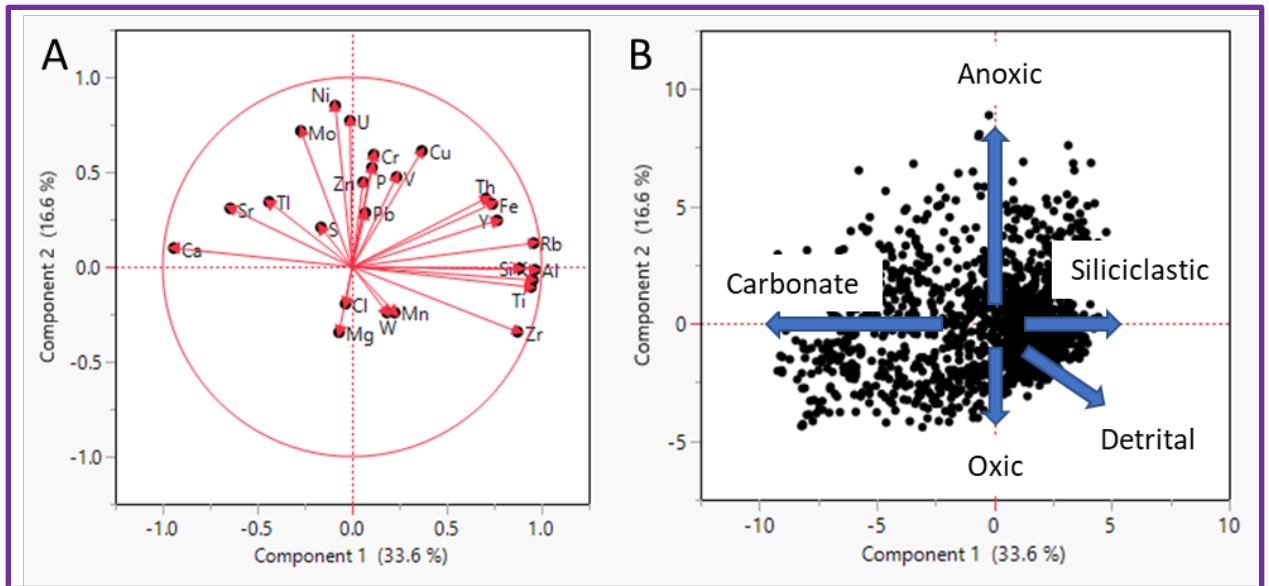

Figure 19, (A) Loading scores for Component 1 compared to the loading scores for Component 2. This shows clustering of similar elements. (B) Cross plot of component scores for Component 1 vs. Component 2 for all the downhole data, showing interpretations of the elements based upon correlations within each component where individual points down-well plot. These can be interpreted as chemofacies based upon the values in the loading matrix (Table 7).

6.1.3 Hierarchical Cluster Analysis

The HCA divided the data into seven clusters representing seven different chemofacies (

Figure 20). The component scores generated for every data point (here, depth in a well) by the PCA were also plotted on the PC1 vs. PC2, and color coded based upon the HCA chemofacies classification (Figure 21.). The data was also plotted on a S-Core ternary diagram, a mudrock classification system, to help with chemofacies interpretation. Generally, Ca and Sr elements provide an indication of the onset for carbonate deposition. Fe, Rb, Al, Zr, Ti all provide indication of a terrigenous input and are related to siliciclastic deposits. These Ca and Sr elements are indicative of transgressive higher sea level

depositional settings. The terrigenous elements are indicative of sea level falls i.e., regressive systems tracts. Redox sensitive trace elements U, Cr, Ni, Zn and V elements are indicative of increasing anoxia or flow restriction. Uranium is absent during high levels of carbonate deposition. Coupled, these can aid in interpreting depositional conditions for chemofacies.

Figure 20, (A) Dendrogram from the Hierarchical Cluster Analysis showing seven groupings of rocks with similar elemental chemical composition and (B) corresponding chemofacies described from the PCA results and correlations of elements.

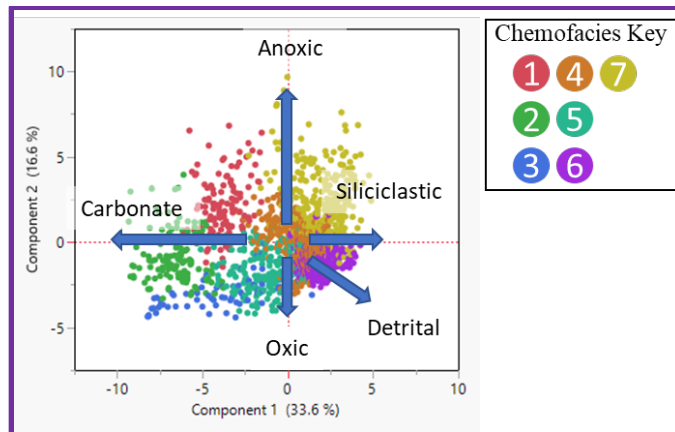

Figure 21, Loading scores for all data across the ten wells generated by the PCA and color coded based upon the seven chemofacies classification generated by the HCA. Chemofacies interpretation (lithofacies + redox conditions) are based upon the general bulk elemental composition (PC1) coupled with redox sensitive element enrichment or depletion (PC2).

Chemofacies 1 (CF1) is a carbonate-siliceous mixed mudstone. According to the modelled mineralogy, chemofacies 1 has an average of 44% quartz, 11% illite, 40% calcite, 3% dolomite and 2% pyrite. It falls on the negative side of PC1 indicating enrichment of Ca and Sr but not as enriched as Chemofacies 2 and 3 (Figure 19.). It is on the positive side of Chemofacies 2, indicative of slightly dysoxic to anoxic conditions with some enrichment in S and Zn (Figure 19.). This suggests a deeper water environment of deposition influenced by periodic siliceous sediment pulses.

Chemofacies 2 (CF2) is a silica rich carbonate mudstone coupled with carbonate dominated lithotype. CF2 has an average composition of 23% quartz, 6% illite, 66% calcite, 5% dolomite and 1% pyrite. It falls on the far negative side of PC1, with enrichment in Ca and Sr. It is on the negative side of PC2, indicative of oxic conditions of deposition (Figure 21.).

This suggests shallower water conditions with primarily carbonate deposition with a periodic influx of terrigenous sediments.

Chemofacies 3 (CF3) is predominantly a combination of mixed carbonate mudstone through carbonate-dominated lithotypes, although with some mixed siliceous mudstone. It falls on the negative side of PC1 with enrichment in Ca and Sr. It is on the negative side of PC2, indicative of oxic conditions of deposition. Magnesium is also associated with chemofacies 3, potentially indicating dolomitization. CF3 has an average composition of 24% quartz, 13% illite, 12% calcite, 47% dolomite and 2% pyrite. This chemofacies suggests shallower water conditions with primarily carbonate deposition, with a periodic influx of terrigenous sediments. It could potentially be “transitional facies” – a coupling between chemofacies 2 and chemofacies 4, with constant interbedding and mixing. Enrichment in dolomite could have been related to higher ambient temperatures during deposition or could also indicate higher levels of diagenesis with mg replacing calcite.

Chemofacies 4 (CF4) is a mixed siliceous carbonate mudstone. It falls in the middle of PC1 and PC2, indicating a mixed system deposited in oxic/dysoxic conditions. Here we have equal distribution of siliceous and carbonate elements. It has an average composition of 53% quartz, 27% illite, 12% calcite, 5% dolomite and 2% pyrite. This suggests also transitional facies between regressive and transgressive sea level with period tectonically induced gravity flows coupled with hemipelagic sedimentation.

Chemofacies 5 (CF5) is a mixed carbonate siliceous mudstone. It falls in the middle

of PC1 and slightly negative in PC2, indicating a mixed system deposited in oxic conditions. It has an average composition of 47% quartz, 20% illite, 22% calcite, 8% dolomite and 1% pyrite slightly more calcareous composition indicative of higher sea levels.

Figure 22, Ternary diagrams of each chemofacies linking the chemical composition with lithofacies.

Figure 23, An example well showing, from left to right, depth, elemental gamma ray (EGR) (U+K+Th), mineralogy, terrigenous Input (Fe, Rb, Al, K Si), carbonate (Ca, Sr), paleoredox indicators (Mo, V, U, Ni), and brittleness index (BI). This is from the Well Big Moose Fed

Com 604H. These enrichments or depletions in elements aid in interpretation of depositional conditions.

Chemofacies 6 (CF6) is a clay rich mixed siliceous mudstone. It falls in the positive side of PC1 and slightly negative in PC2 indicating a detrital composition enriched in Zr and Ti deposited in oxic conditions. It has an average composition of 56% quartz, 30% illite, 6% calcite, 6% dolomite and 1% pyrite. This would be indicative of lower sea levels, a regressive system with an increase in terrigenous detrital material. This has the highest quartz composition at 56%. These could be associated with silica-rich hemi-pelagic sediment gravity flows.

Chemofacies 7 (CF7) is a clay rich mixed siliceous mudstone. It falls in the positive side of PC1 and positive in PC2 indicating a siliceous composition enriched in RSTE's U, Cr, Ni, Zn and V deposited in anoxic conditions. It has an average composition of 50% quartz, 31% illite, 11% calcite, 5% dolomite and 2% pyrite. This would indicate a regressive sea level environment with sediment accumulating in a stagnant, lower energy and lower circulation environment. For a summary of the rock compositions for each chemofacies see (Table 8). , An example well showing, from left to right, depth, elemental gamma ray (EGR) (U+K+Th), mineralogy, terrigenous Input (Fe, Rb, Al, K Si), carbonate (Ca, Sr), paleoredox indicators (Mo, V, U, Ni), and brittleness index (BI). This is from the Well Big Moose Fed Com 604H. These enrichments or depletions in elements aid in interpretation of depositional conditions (Figure 23.).

Table 8, Summary of rock composition by chemofacies

6.1.4 Chemofacies Distribution

When compared to the general lithologies noted based upon elemental data, chemofacies can further subdivide the formation and show variations in depositional conditions across the study area (Figure 26.). The 3rd Bone Spring Sand is only located in three wells (Big Moose Fed Com 604H in the SW, and Toque State Com 602H and 601H in the northeast). Also, these were the “target” formation in horizontal wells, where these sections are horizontal. They represent spatial changes rather than changes through time. In the southwest (well Big Moose Fed Com 604H), chemofacies 4 is dominant, indicating a mixed siliceous mudstone deposited in fluctuating oxic to dysoxic conditions. In the northeast (wells Toque State Com 602H and 601H), the 3rd Bone Spring is dominated by chemofacies 6 and 7, indicating a mixed siliceous mudstone (chemofacies 6) deposited during oxic conditions with increasing clay content (chemofacies 7) deposited during fluctuations of anoxia.

The average RSTEs (U, Cr, Ni, Zr, V) increase in the Avalon, 2nd and 3rd Bone Spring Sand in the Big Stag Fed Com 503H, Big Stag Fed Com 703H, Big Bucks Fed Com 501H and the Toque State Com 601H. The relative increase can be seen in both map and cross section view. RSTE's correlate with higher TOC. The increase in the RSTE's indicative of higher TOC would also correlate well with the Mo/Ni plots shown previously where the wells with more restriction correlate with those with potentially higher TOC .

Given that there is a large potential for biogenic silica in the basin because of the

settling of sponge spicules it is important to review the Si/Zr ratio to gain insights into the source of silica. From work by Ratcliffe et al. (2012), biogenic and detrital silica can be differentiated using this Si/Zr ratio. For the Muskwa Formation in Canada a cross-plot of SiO₂ and Zr indicate a terrestrial trend of increasing SiO₂ with increasing Zr, and a biogenic trend with decreasing Zr with increasing SiO₂. The negative correlation is caused by an excess of Si due to an influx from biogenic sources. Parts of chemofacies 7, 4 and 6 exhibit some of this excess silica. In addition, the Zr/Al ratio is at its highest in the older 3rd Bone Springs sandstone sequence and then becomes increasingly lower i.e., finer grained up sequence to the Big Lime.

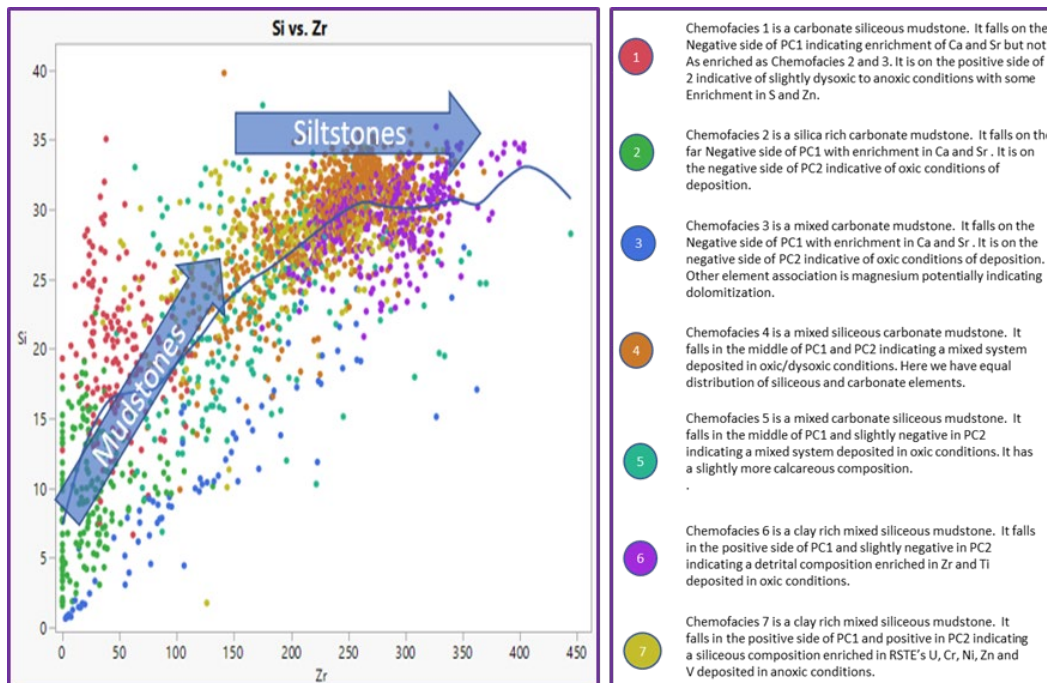

Figure 24, Biogenic silica proxies using the Si/Zr cross-plot coupled with Si/Al ratio to determine dstones and siltstones. Datapoints are color coded based upon chemofacies classification.

Figure 25, Cross Section Indicating change in chemofacies across the study area. Notable is the increase in detrital elements in the Toque State wells and the increase in Redox sensitive elements in the 2nd Bone Spring Sand members. Colors on right track of each log represent the chemofacies clusters coloring (see Fig 16). Middle track on each well represents changes from carbonate (blue) to siliciclastics (yellow) derived from Si and Ca compositions. The overlying Delaware group, Brushy and Cherry Canyon. Chemofacies 2,3 and 5 (Carbonate mudstones) are intercalated with chemofacies 4 (mixed siliceous mudstones) in these upper sequences.

The 3rd Bone Spring Lime is only found in the center of the study area (Big Stag Fed Com 703H). It too was the target formation, and this section is a lateral (horizontal well) representing horizontal changes in the vicinity. It consists of predominantly of chemofacies 4 and 7. There is slightly more argillaceous material and fluctuations of anoxia during time of deposition compared to the underlying 3rd Bone Spring Sand. This may indicate an increase in water depth to allow for increased clay deposition and anoxia.

6.1.5 Grain size

Zr/Al can be used to estimate grain size (Driskill et al., 2018), as Al is a proxy for clay in this system. Within the 3rd Bone Spring Sand, there are generally high Zr/Al ratios (Figure 28.), indicating coarser grain sizes. Up-section, the Zr/Al ratios continue to decrease, suggesting a grain size and composition decrease. The Avalon is an exception, with a slightly coarser grain size than the overlying Big Lime and underlying 1st Bone Spring Lime. Overall, the coarsest relative grains can be seen in the 3rd BSPG Lime and Sand. This would indicate an increasingly higher energy environment of deposition and shallower water conditions compared to the finer-grained sediments. The association with higher Ti would also indicate a detrital source. The Zr/Al ratio for the 3rd Bone Spring Sand is 56. Zr/Al ratio for the 3rd Bone Spring Lime is 55. Zr/Al ratio for the 2nd Bone Spring Sand is 44. Zr/Al ratio for the 2nd Bone Spring Lime is 26. Zr/Al ratio for the 1st Bone Spring Sand is 29. Zr/Al ratio for the 3rd Bone Spring Lime is 28. Zr/Al ratio for the Avalon is 35. Zr/Al ratio for the Big Lime is 28.

would have had more stagnant lower circulation conditions which would have led to organic enrichment. Coupled with the Zr/Al maps, we can see a relative negative correlation between RSTE and grain size. The RSTE's are higher in the finer grained rocks and the RSTE's are lower in the coarser grained rocks. This would make sense geologically since the conditions of stagnant water with low circulation would be conducive to the deposition of fine-grained sediments. Coarser material requires higher energy and would not have the stagnant conditions conducive to organic enrichment. environment.

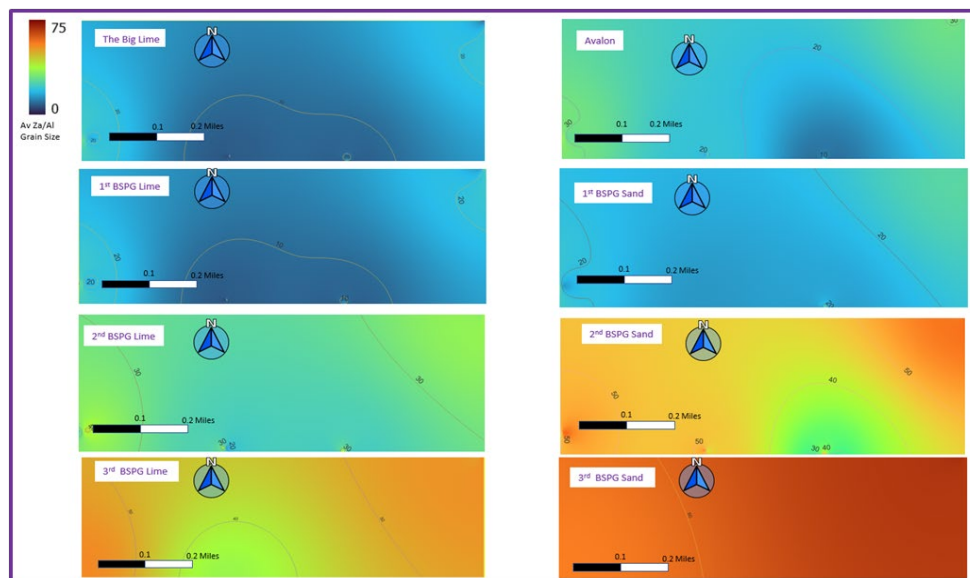

Figure 27, Average Zr/Al ratios (Grain size proxy) for the study area. Zr/Al ratios decrease from the 3rd Bone Spring Sand through the Big Lime, indicating a potential grain size decrease and or change in lithology. Also, the Zr/Al ratios generally decrease towards the center of the study area for all formations, indicating reduction in detrital material through that area. This could indicate lower energy flow environment.

Figure 28, Map of Average RSTEs Redox Sensitive Trace Elements, (U, Cr, Ni, Zi, V) is highest in the Avalon in the northeast. RSTEs typically correlate with higher TOC

6.2 Petrophysical Analysis and Cuttings Comparison

6.2.1 Drill Cuttings depth QA/QC

Elemental gamma ray (EGR) from the drill cuttings were calculated from the addition of U+K+Th and compared to the MWD gamma ray. R^2 correlations between the EGR and MWD GR for Toque State 602H is 0.72 (Figure 30.). Overall, the Gamma Ray has a 0.3 m (1 ft) resolution and is much higher than drill cuttings, which are at an average of 18.2 m (60 ft), or 200 samples per 3,048 m (10,000 ft) of section compared to 1ft on downhole Gamma Ray. When a Gaussian smoothing of 18.3 m (60 ft) is applied an R^2 of 0.94 for 1st BSPG Sand can be observed. Elemental Gamma Ray correlates reasonably well with the MWD gamma ray providing indication that the cuttings collected are both representative of the section drilled at that measured depth.

Figure 29, Example well of the calculated gamma ray curve in the Big Moose 604H well. Overall, there is good agreement with the cuttings data and well log data.

While the EGR is a combination of U, K, and Th, each element has insight into depositional and diagenetic conditions, and can dominate the EGR at various locations in a well. Uranium from wireline logs on the Big Moose 604H well compared to U measured on XRF drill cuttings for the section from the Big Lime down to the 3rd Bone Spring Sand returned R² of 0.36. Potassium from wireline logs compared to the K on XRF drill cuttings returned a regression of 0.45 for the section from the Big Lime down to the 3rd Bone Spring Sand. Thorium from wireline logs compared to Thorium on drill cuttings returned an R² of 0.46 for the section from the Big Lime down to the 3rd Bone Spring Sand (Figure 31 & Figure 32.).

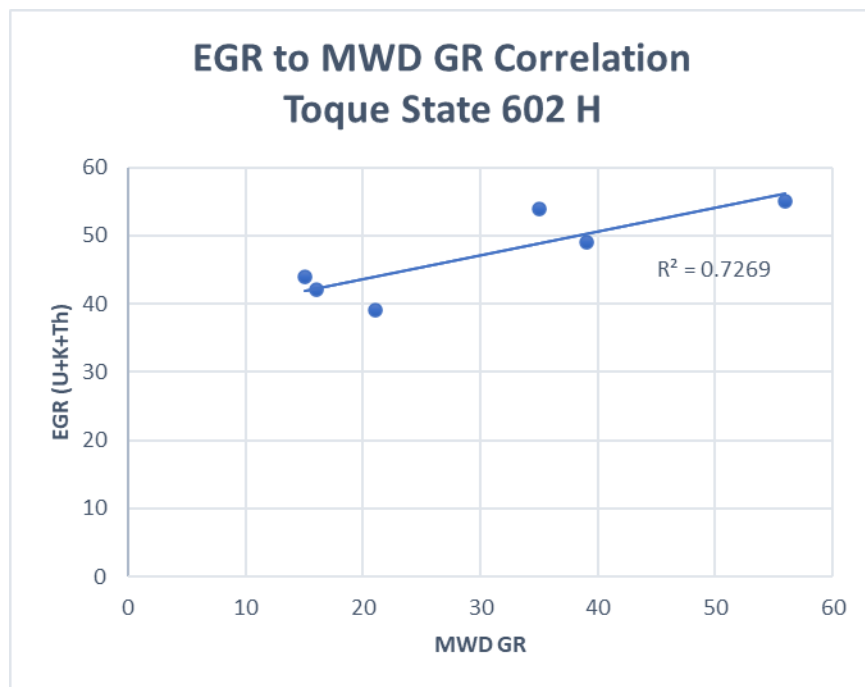

Figure 30, Average GR values vs MWD for Toque State 602H.

Figure 31, Comparison of the Uranium, Potassium, and Thorium wireline Logs to the U, K, and Th from The elements from XRF drill cuttings. Overall good visual correlation between the elements. Big Moose 604H well. The Th and the K from the XRF elemental data exhibit a good match throughout the sequence. The correlation improves in the siliclastics compared to the carbonates. The Uranium does not correlate well in the carbonates.

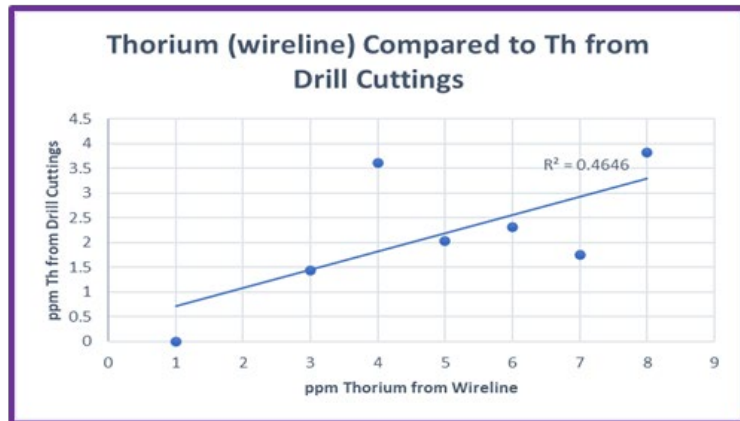

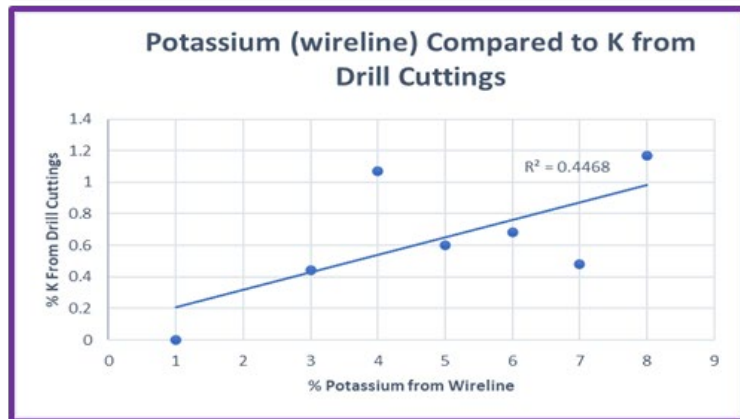

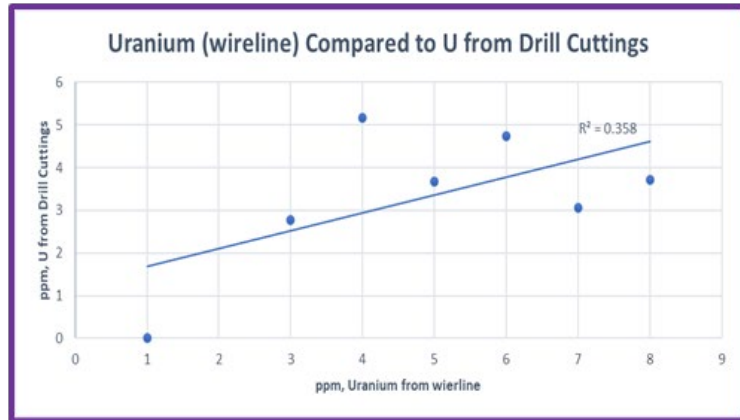

Figure 32, R^2 for U, K, and Th compared to wireline logs. Visually the correlation appears better than the statistical R^2 for each element. The reduction in correlation can be largely attributed to the difference in sample depth density. The lower correlation from the Uranium can be attributed to low U readings in the carbonate sections from the drill cuttings.

6.2.2 Mineralogy

The mineralogy derived from the XRF elemental mineral model was compared with the mineralogy generated by the Haliburton GEMS wireline logging tool. This was only done for the Big Moose Fed Com 604H well because it was the only well with a full suite of wireline logs provided (Figure 33.). The petrophysical mineralogy model is based upon known responses of the well logs, coupled with user inputs based upon the local geological formations. Overall, the two models can adequately determine similar ratios of clastics (sand) to clay content to carbonates. Note that both models exhibit highest levels of carbonate in the Big Lime and 1st Bone Spring Lime. As depth increases the carbonate composition reduces as the sand and clay contents increase. There are sections in the 2nd Bone Spring Sand and Lime where the well log mineralogy models greater amounts of dolomite. This could imply the XRF mineral model is apportioning too much magnesium to the clay. The XRF mineralogy model agrees with the petrophysical model in the Bone Spring Formation. Ca is normally concentrated in carbonate minerals, particularly calcite. Si may be linked with a variety of minerals but is most associated with quartz. Based on this, the silica and calcium ratios have been used in this study to understand the principal changes from siliciclastics deposits to carbonate deposition. The cyclicity which has been observed on well logs from previous studies (Carr, 2019) can be seen in this study. The carbonate deposition has been linked to transgressive high stand depositional environments and the siliciclastics linked to low stand regressive sea, level depositional environments. Stepping through the section we can see siliciclastics

predominate in the 3rd Bone Spring Sand. Carbonates predominate in the 3rd Bone Springs Lime. Siliciclastics are higher in the 2nd Bone Springs 2nd and the carbonate increases in the 2nd Bone Spring Lime. The siliciclastics reappear in the 1st Bone spring sand and the carbonates in the 1st Bone Spring Lime. The Avalon is both silica and carbonate rich and the Big Lime has higher carbonate composition. There is a general increase in Ca/Si ratio from oldest to youngest in the sequence.

the XRF data and compared to the sonic log (Figure 36.). Again, this was the only well that had a full suite of wireline data. Regression for the sonic log comparison to the XRF Brittleness Index returned a value of 0.59 (Figure 38.). There is a very good correlation in the carbonate rich sections. In the siliciclastics, there appears to be an underestimation of the competence compared to the sonic. This may indicate that the estimation of the quartz in the XRF mineral model could be slightly underestimated also. This BI was then applied to all the wells. The BI was highest in the older rocks in the sequence i.e., highest in the 3rd Bone Spring sand and becoming increasingly more ductile up to the Big Lime. In general, the siliciclastic-rich sequences exhibit the highest BI and therefore geomechanical competence.

BI for the 3rd Bone Spring Sand averaged 57, 3rd Bone Spring Lime averaged 45, 2nd Bone Spring Sand averaged 49, 2nd Bone Spring Lime averaged 39. The Brittleness Index BI for the 1st Bone Spring Sand averaged 49, 1st Bone Spring Lime averaged 26, 2nd Avalon averaged 22, and Big Lime averaged 17. Overall, the rock competence increases with depth and is geomechanically more competent in the siliciclastics rocks compared to the rocks with higher carbonate content. This seems to be linked to the quartz content throughout the formations, rather than the calcite content.

The BI is also reflected in the chemofacies. Chemofacies 2 appears to consistently have higher sonic values and BI, indicating that it is a more brittle rock compared to other chemofacies. It consists primarily of 65% calcite, 22% quartz 5.5% Illite and 4.5% dolomite. Conversely, chemofacies 4 appears to consistently have lower sonic values and BI,

indicating a more ductile formation, consisting of 27% Illite, 52% Quartz, 12% Calcite and 4.75% Dolomite and 1% Pyrite.

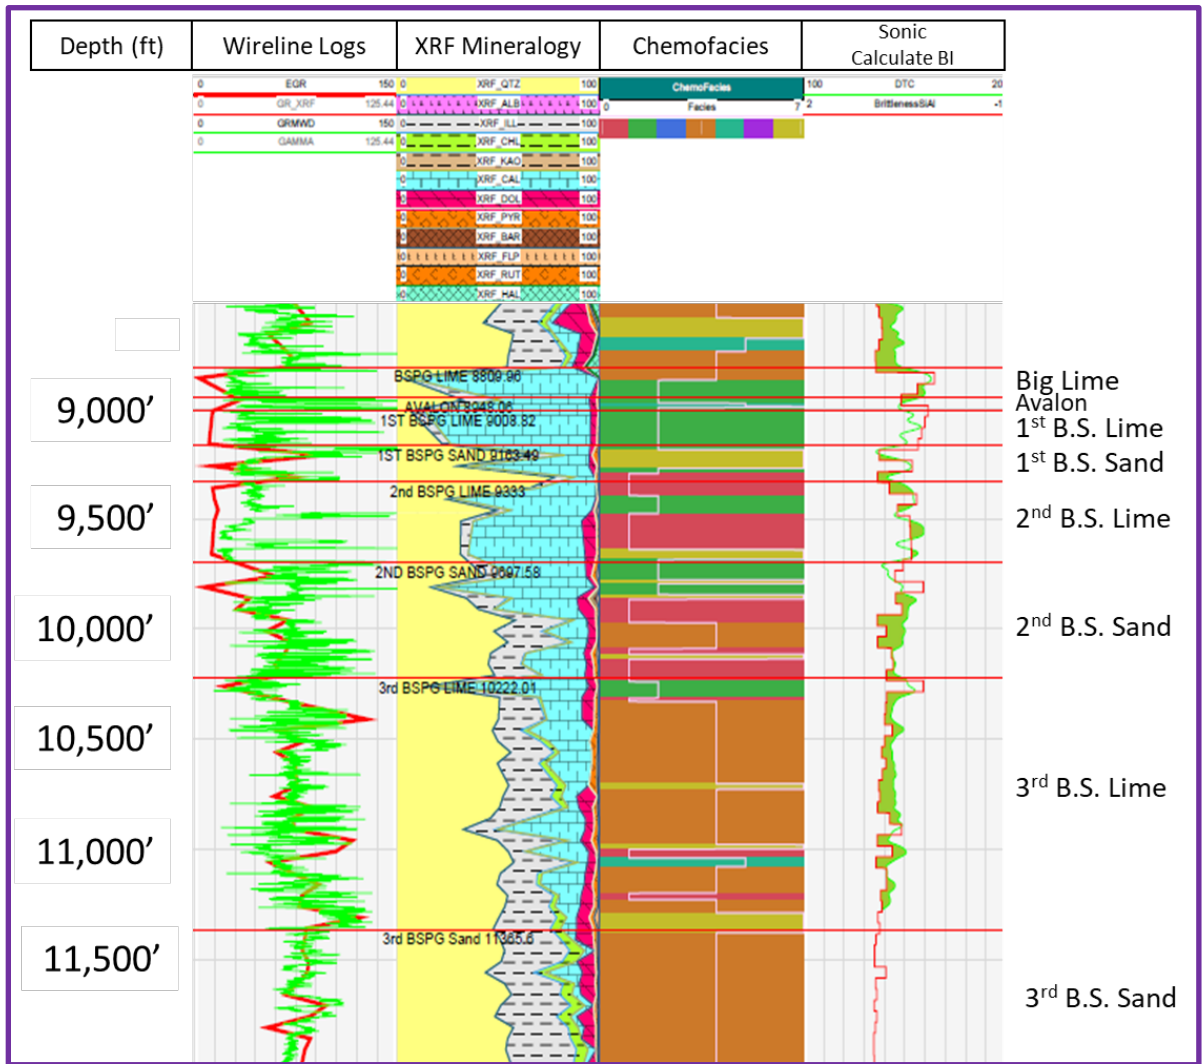

Figure 34, Example of the comparison of DTC sonic Log and Brittleness Index from XRF elemental data in well Big Moose Fed Com 604H (Track 5). The green filled in area shows the difference between the Sonic Log and calculated BI.

Figure 35, Cross plot of the BI vs Sonic Log (DTC)

6.2.4 XRF Mineralogy Comparison with Volume of Clay (V_{clay})

V_{clay} calculated from the Gamma Ray was compared with the Elemental Gamma Ray (U+K+Th) from the cuttings (Figure 36.). Given overall good correlation between the MWD GR and EGR, the V_{clay} follows similar positive correlation trends. There is greater offset in the carbonate rich sequences. There is the greatest positive correlation in the siliciclastic sequences, in particular, the 2nd and 3rd Bone Spring Sands. This could be due to mineralogy effects on the downhole tool response. For example, potassium-rich sand would have a high GR and lead to perhaps misinterpretation using a standard V_{shale} cut

off, resulting in bypassed pay. It may also be an artifact of drilling, drill rates and sample resolution. On the K, U and Th plots there appears to be an underestimation in Uranium from the XRF data, particularly in the carbonates, or overestimation on the downhole logs.

Figure 36, Example of the clay volume calculated from GR and compared to EGR (U+K+T). The area highlighted in green shows the difference between the XRF clay calculation and the Vclay calculation from the gamma ray. Well Log from Big Moose 604H.

6.2.5 Comparison with TOC from Logs

TOC was calculated from the resistivity and density logs using the Passey method, and compared the redox sensitive elements (Ni, V, U) (Figure 37.). This was only

completed on the Big Moose Fed Com 604H well because it was the only well with a full suite of well log data. Overall, all the three paleo-redox proxies exhibit positive correlation with the wireline log derived TOC. Figure 38 indicates an R^2 of 0.29 for the RSTE's compared to Log derived TOC using Resistivity and Density using the Passey method. The low correlation R^2 between the paleoredox proxies and the log derived TOC can be attributed to the differences in depth resolution nevertheless the low correlation should result in using these proxies with some caution.

The RSTE's were calculated for the other nine wells to show TOC variations across the study area and compared to the chemofacies. Note the increase in chemofacies seven (anoxic to sub-oxic siliciclastics enriched in RSTE's (U, Cr, Ni, Zn and V) in the 2nd Bone Spring Lime and 2nd Bone Spring Sand.

Figure 37, Comparison of log derived TOC from Resistivity and Density Logs and compared to drill cuttings XRF Paleo redox proxies of V, U and Ni for the Big Moose Fed Com 604H well.

Figure 38, TOC Comparison of TOC calculated from the resistivity/Density logs (Passey Method) compared to the TOC using (U+Cr+Ni+Zn+V) (Paleo-redox Proxy). R^2 of 0.29.

The RSTE for the 3rd Bone Spring Sand is 199. The RSTE for the 3rd Bone Spring Lime is 250. The RSTE for the 2nd Bone Spring Sand is 232. The RSTE for the 2nd Bone Spring Lime is 267. The RSTE for the 1st Bone Spring Sand is 312. The RSTE for the 1st Bone Spring Lime is 229. The RSTE for the Avalon is 343. The RSTE for the Big Lime is 142. The most organic rich zone is the Avalon, followed by 1st Bone Spring Sand. The leanest formation in organic richness is the Big Lime. In the Avalon, the Toque State wells in the northeast have the highest RSTE values of Toque State 502 (RSTE 789), Toque State 601 (RSTE 621) and Toque State 602 (RSTE 504).

7. DISCUSSION

7.1 Chemofacies to Lithofacies Comparison

Cuttings-based XRF measurements have been able to determine variations in the trace element composition across the study area. Within the Bone Spring Formation, seven chemofacies were determined using the cuttings, which described not only the basic lithology, but also gave indication into the depositional environment. For example, chemofacies 4, 6, and 7 have similar lithologies on the S-Core ternary diagrams (Figure 22.), suggesting clay-rich siliceous mudstones through mixed siliceous mudstones. However, these three chemofacies have varying RSTE's (Table 9). These variations in the average RSTE's indicate variations in redox conditions. Chemofacies 4, although very similar in average bulk element composition to chemofacies 6 and 7, is depleted in V and Ni, has average Zn and Mo, and slightly elevated U values compared to standard shale values as per (Wedepohl, 1971; Tribovillard et al., 2006) (Table 9).

The relative depletion of vanadium could be attributed to strongly reducing or euxinic environments of deposition. The presence of free H₂S produced by bacterial sulfate reduction causes V to be further reduced to V³⁺ which can be absorbed by geoporphyrins or precipitated as the solid oxide V₂O₃ or hydroxide V(OH)₃ phase (Craigie, 2018).

The relative enrichment of uranium occurs within the sediment, not the water column, so the oxygen penetration depth and the sedimentation rate may be significant.

A slower sedimentation rate, for instance, may enable more time for the diffusion of uranyl ions from the water column into the sediment (Crusius and Thompson 2000).

Craigie (2018) describes that the release of Zn to pore waters and the overlying water column may take place upon organic matter decay. The element may be incorporated as sphalerite ZnS as a solid solution phase in pyrite or, to a lesser degree, it may form its own sulfides, these processes occurring under anoxic conditions (Tribovillard et al., 2006). Molybdenum enrichment most probably occurs in association with a concentration in pyrite sediments deposited in anoxic environments, though the possibility of some being associated with organic matter should not be ignored (Craigie, 2018). The exact origin of molybdenum can be difficult to determine, however the association between this element and anoxic paleoenvironments has been observed in many studies (Craigie, 2018; Algeo and Tribovillard, 2009; Driskill et al., 2018).

Table 9, Average bulk and RSTE's for chemofacies 4, 6, and 7 compared to the average shale values.

Average	Si (%)	Ca (%)	Al (%)	V (ppm)	Ni (ppm)	Zn (ppm)	Mo (ppm)	U (ppm)
Chemofacies 4	29.4	4.52	4.36	40.5	23.1	62.5	3.26	3.37
Chemofacies 6	29.6	3.13	4.43	74.4	22.1	40.5	0.15	1.85
Chemofacies 7	27.8	4.95	4.59	85.3	54.1	156.7	6.74	4.27
Average Shale*	27.5	1.6	8.8	130	68	95	1.3	3

7.2 Chemofacies and depositional environment

Under oxic conditions, organic matter is broken down by methanogenic bacteria via an oxidative-reductive disproportionation of carbon (Tribovillard et al., 2006). Oxygen depleted conditions, and ultimately anoxia, may occur at the sediment-water interface or within sediments when the oxygen demand exceeds the supply. Anoxia may also develop in the water column of stagnant or confined water masses where there is a lack of circulation, or in places where intense organic matter degradation consumes O₂ faster than it is replenished, even in open-marine conditions. High levels of Mo, Cu, Co, Ni, Zn, Cr, U and V are often associated with anoxic paleoenvironments, and it may be possible to identify sediments deposited under these conditions where values of these elements exceed their average (Craigie 2018).

It has previously been shown that the RSTE's in the Bone Spring Formation can be directly linked to TOC (Driskill et al., 2018). Mo to Ni ratios can indicate a more restrictive flow environment based on work conducted by Algeo and Lyons (2006). Ni as a proxy for TOC and plotted against Mo. The 3rd Bone Springs Sand is predominantly more siliceous material (Chemofacies 4), indicating a low stand regressive sea-level depositional environment.

Notwithstanding, there are changes across the study area. The southeast area (Big Moose) has less detrital Zr and Ti than the northeast area (Toque State), which has more of chemofacies 6. This could indicate some localized silica-rich hemi-pelagic terrigenous

gravity flows. Fault orientation in the area primarily is in a NW-SE direction,(Figure 39.), and this could also be influencing the change across the area, which is abrupt given the small distance. It could also be a localized channel flow. The 3rd Bone Spring Lime in the northeast section of the study area indicates a mixed system with chemofacies 1,2,5 and 7 which are an indication of higher levels of carbonate deposition and oxygenation. This could be indicative of a calcium-rich hemipelagic sediment gravity flow.

The 3rd Bone Spring Lime in the southeast study area contains less carbonate and is more silica rich. This is more indicative of a silica rich hemipelagic sediment gravity flow. The 2nd Bone Spring Sand in Big Moose in the southeast is enriched in chemofacies 4 and 7 and increases in chemofacies 7 towards the center of the study area (Big Stag and Big Bucks). This would indicate an increase in anoxia towards the center, indicating a more stagnant, lower circulation depositional environment. The Bone Spring Sand towards the NE becomes more “limey”. This would indicate a potential carbonate-rich sediment gravity flow coming into this area.

The 2nd Bone Spring Lime is enriched in chemofacies 2, 1, and 7 interbedded, with increased 2 towards the NE again indicating a more carbonate-rich influence in this area also indicating potential carbonate gravity flow input. There are fluxes and pulses of interchanging chemofacies 2 and 7, indicating changes from siliciclastics to carbonates over time. The 1st Bone Spring Sand is interbedded with chemofacies 1, 3 with some 7 –

carbonates with periods of anoxia with increased anoxic siliciclastic input. There is a slight increase in anoxia chemofacies 7 to the northeast.

The 1st Bone Spring Lime is enriched with chemofacies 2 and 3, i.e., predominantly carbonate with periods of anoxia represented by chemofacies 7. The Avalon formation is a mixed system with chemofacies 1 and 2, carbonate floating between oxic to anoxic conditions, and siliciclastic input towards the northeast. This siliciclastic input is also anoxic chemofacies 7 in the Toque State 602H, which drives up the average RSTE's in this area. The Big Lime is predominantly chemofacies 2, calcite rich and deposited in an oxygenated, higher circulation depositional environment. This would correlate to chemofacies 1,3 or 8 in Walkers (2021) study, i.e. a calcium-rich hemipelagic

gravity flow lime mudstone to packstone.(Figure 43.).

Figure 39, Map of Study area with basement lineament faults care of USGS.

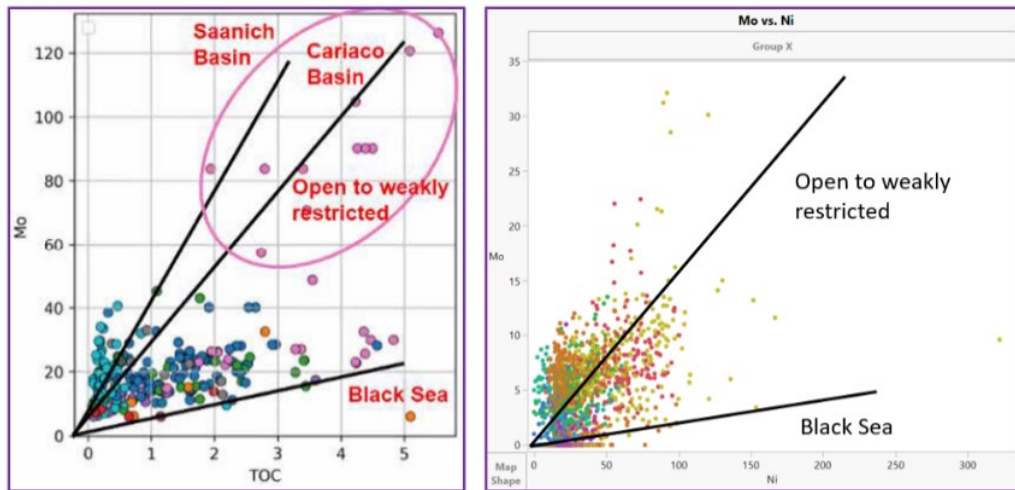

Figure 40, Molybdenum over TOC has been used to estimate depositional environment (Algeo and Lyons, 2006). The scatter plot to the left is from modern day analogs including the Black Sea, the Cariaco and Saanich basins. The scatter plot to the right is the data from the study area. Most of the data points fall within the open to weakly restricted area. With it being a mixed system it is difficult to resolve the depositional environments using these plots. Nevertheless chemofacies 5 does appear to be indicative of a more open circulatory environment compared to the other facies.

7.3 Core Studies vs. Cuttings Analyses.

Unfortunately, this study could not directly describe the cuttings to obtain general lithologies across the study area, which would have aided in lithofacies interpretation, this due to the cuttings being unavailable. Previous work done by Walker (2021) in the Bone Spring Formation based on measurements of outcrops in the Guadalupe mountains revealed a direct relationship between chemofacies and lithofacies related to the change in depositional setting. The same ratio plots have been applied to the data set in this study to draw potential parallels to this ground truth data set.

Lithofacies 6 from (Walker, 2021)(Figure 41.) indicates deposition of a silica-rich mudstone as a hemipelagic sediment gravity flow. This lithofacies appears to be similar

to chemofacies 4,6 and 7 based on the Ca/(Si+Ti) plots (Figure 44.). Lithofacies 1 and 2 from Walker (2021), which are Ca-rich hemipelagic sediment gravity flow deposits, correlate well with chemofacies 1,2 and 3 in this study. Facies 6 and 7 from (Walker, 2021) correlate with facies 4,6 and 7 from this study. This lithofacies is a thinly bedded laminated bioclastic quartz siltstone and thinly bedded quartz lime mudstone. These are therefore interpreted to be silica-rich hemipelagic sediment gravity flows. The changes in chemical facies and their associations thus provide evidence of relative sea level change and glacio-eustasy as we move from carbonate rich (Ca, Sr) elements to siliciclastics (Si, Rb, Ti, Al, Zr).

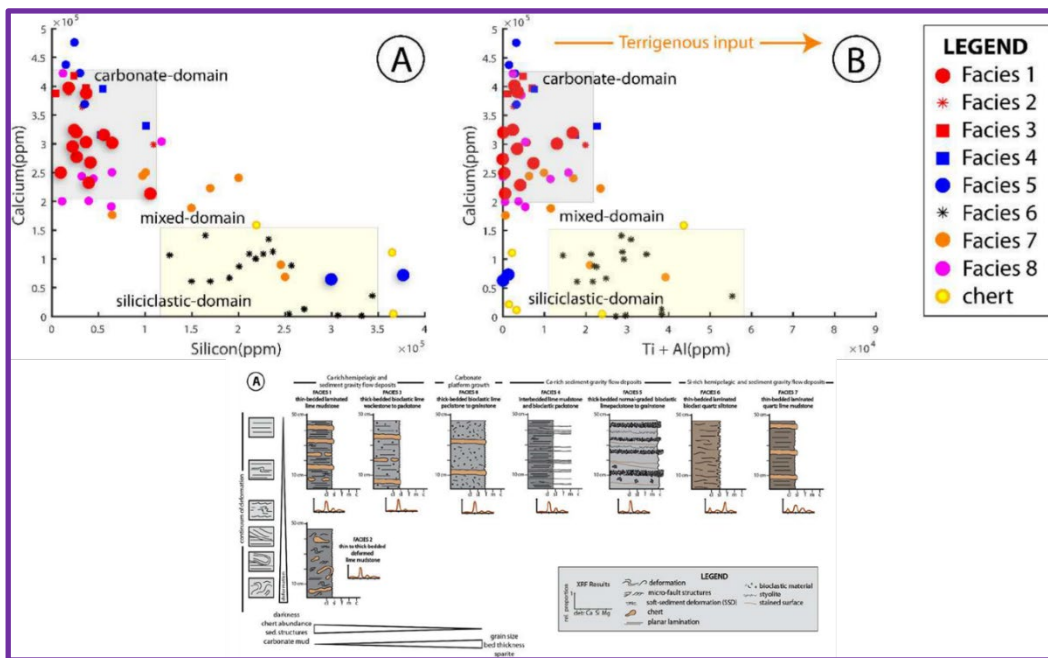

Figure 41, This is a figure from Wylie 2021 in which you can see the relationship between XRF data obtained from Outcrop in the Gudaloupe mountains. He has identified 8 facies and compared the XRF signatiures to those facies. He chose 4 main XRF data groupings, detrital, si, al and mg.

Figure 42, Molybdenum versus TOC cross-plot showing Wolfcamp and Leonard samples from the Greer 1 core in relation to several analogs. Blue arrow depicts an increase in basin restriction and deep-water age. From Cortez (2012).

Overall, using cuttings to determine chemofacies provided an adequate evaluation of the chemostratigraphy of the area. The limitation of drill cuttings analysis is primarily related to low depth resolution of sampling (on average 50 ft/17m). The implications of this are the inability to see fine scale changes in lithologies and facies. By studying outcrop, core and logs, we can see changes over cm scales; thus, cuttings-based studies can miss large sequences of important information. An additional challenge in this study area is the mixed nature of the lithofacies. A combination of sea level change, tectonism, and extraterrestrial influences (Milankovitch cycles) make this system complex and difficult to interpret. Nevertheless, broad changes in facies carbonate, siliciclastics, and argillaceous changes can be seen using chemofacies interpreted from XRF analysis of drill cuttings. The carbonate facies is characterized by high levels of Ca, Sr and Mg. The argillaceous facies

is enriched in Si and Al. The Siliceous facies is enriched with Si and Al with higher levels of Si than the argillaceous facies. Detrital facies are characterized by an increase in Zr and Ti. Subdivision of these facies when linked to core and outcrop studies can lead to further estimations of changes in depositional environments and gravity flows (Stolz et al., 2015). Figure 43 represents a depositional Model of the Delaware Basin during Leonardian Time. The Toque State 3rd Bone Spring Sand is enriched In detrital elements namely Zr, also with increased Si, Al, Rb, indicative of being derived from a Si rich hemipelagic sediment gravity flow. This would match with (Walker's 2021) chemofacies 6. The Big Moose 3rd Bone Spring Sand laterals by contrast is a thin bedded laminated bioclast quart siltstone derived from a Ca rich hemipelagic sediment gravity flow as can be seen represented as a debrite flow. The Big Stag and Big Bucks 2nd Bone Spring laterals have higher RSTEs indicative of anoxic low energy depositional environments. They are enriched in (Walker's 2021) chemofacies 7. 1st , 2nd & 3rd BSPG Lime depositional environment would have been on the carbonate fringe of the basin during highstands. 1st , 2nd & 3rd BSPG sands would have been deposited in the organic, pelagic, siltstone, mudstone setting. The Avalon with enriched organic content and clay would have been a lower energy and potentially more distal setting.

Figure 43, Depositional Model of the Delaware Basin during Leonardian Time. Characteristic depositional processes of the time include carbonate debris origination above the basin floor, and deposition of organic, pelagic siltstones and mudstones out onto the basin floor (modified from Loucks et al., 1985).

Ultimately, although inorganic elemental analysis is a powerful tool, the analysis itself is highly interpretive and, if used as the sole dataset, it can be highly subjective (Ratcliffe et al., 2004), (Craigie, 2018). Additional and preferred data sets would be core data, wireline log data on all wells, special core analysis, petrography and seismic.

- 1 Chemofacies 1 is a carbonate siliceous mudstone. It falls on the Negative side of PC1 indicating enrichment of Ca and Sr but not As enriched as Chemofacies 2 and 3. It is on the positive side of 2 indicative of slightly dysoxic to anoxic conditions with some Enrichment in S and Zn.
- 2 Chemofacies 2 is a silica rich carbonate mudstone. It falls on the far Negative side of PC1 with enrichment in Ca and Sr. It is on the negative side of PC2 indicative of oxic conditions of deposition.
- 3 Chemofacies 3 is a mixed carbonate mudstone. It falls on the Negative side of PC1 with enrichment in Ca and Sr. It is on the negative side of PC2 indicative of oxic conditions of deposition. Other element association is magnesium potentially indicating dolomitization.
- 4 Chemofacies 4 is a mixed siliceous carbonate mudstone. It falls in the middle of PC1 and PC2 indicating a mixed system deposited in oxic/dysoxic conditions. Here we have equal distribution of siliceous and carbonate elements.
- 5 Chemofacies 5 is a mixed carbonate siliceous mudstone. It falls in the middle of PC1 and slightly negative in PC2 indicating a mixed system deposited in oxic conditions. It has a slightly more calcareous composition.
- 6 Chemofacies 6 is a clay rich mixed siliceous mudstone. It falls in the positive side of PC1 and slightly negative in PC2 indicating a detrital composition enriched in Zr and Ti deposited in oxic conditions.
- 7 Chemofacies 7 is a clay rich mixed siliceous mudstone. It falls in the positive side of PC1 and positive in PC2 indicating a siliceous composition enriched in RSTE's U, Cr, Ni, Zn and V deposited in anoxic conditions.

Figure 44, Ca/Si and Ca/(Si+Ti) plots, associations exist between Walker 2021's chemofacies from outcrop and chemofacies derived from drill cuttings.

7.3 Practical implications

Chert zones can result in hard drilling, bit wear, tool failure, and non-productive drilling time. Identification of excess silica could provide input and assistance to improve drilling efficiency and performance. Near real time data being delivered within 2-30 minutes arriving at the surface could provide this drilling advisor input. Elemental chemostratigraphy can be used as an independent stratigraphic positioning tool and

therefore could be used for GeoSteering purposes. Scripts or formulas of these facies could be used and programmed into real-time GeoSteering software to predict wellbore position. In addition, the geomechanical data from the brittleness index BI and the chemofacies could be used to optimize completion design where stages can be linked to chemofacies, and this produces a frac recipe that is appropriate for each rock type. Big Stage Fed Com 703H for example, was initially classified as a Wolfcamp A well, but later review recategorized the well as a Lower 3rd Bone Spring Lime well. Using an extensive elemental data set can reduce the geological uncertainty and ensure that wells are drilled and geosteered in their target. Many have written that the key to unlocking unconventional resource plays is encountering the so-called Goldilocks rocks, the rocks that are just right. The combination of geomechanical competence (frackability) (BI), the organic richness indicative of the presence of hydrocarbons in the rock (RSTE), and the rock composition tied to core-based porosity and permeability (chemofacies) from drill cuttings can lead to this understanding. The author is deploying a patented robotic logging system that can analyze the elemental rock composition every 2 minutes while drilling to further push this envelope and explore the boundaries of possibilities.

8. CONCLUSIONS

Drill cuttings provide an important source of information for the geoscientist. XRF elemental data is a robust data set that can be collected relatively inexpensively and efficiently in the field while drilling or post well in the lab. The use of calibration rock standards (SDC) and comparing EGR to MWD GR at frequent intervals is an important part of the QA/QC process. Overall, the following can be concluded from this study:

Geospatial mapping of the chemofacies can lead to a greater understanding of changes in facies both laterally and over time. Here, they were able to showcase where increased RSTE enrichment or depletion occurred, and increased grain sizes are distributed across the region. In this study area the northeast corner had enrichment in RSTE in the northeast during the Avalon formation deposition. Through time the Zr/Al and BI index increased from the Big Lime through to the 3rd Bone Springs sand. The detrital elements Zr and Rb were increased in the northeast in the Toque state wells in the 3rd Bone Spring Sand.

Calibration to wireline logs, XRD, pyrolysis and other reservoir quality indicators are an important part of the model building process. The more rigorous this stage of the work, the better the modeled interpretation. The calculated reservoir properties were compared to petrophysical analyses to see if correlations exist between either widely used petrophysical calculations or well logs. This study has demonstrated some of the

relationships that exist between wireline log property measurements and that which can be derived from drill cuttings with XRF measurements.

Geochemical elements can be used to understand changes in lithology and the environment of deposition. The volume of clays can be loosely estimated using Illite composition. TOC can be estimated utilizing paleo redox proxies, although more calibration is required through direct pyrolysis measurements. Geomechanical rock properties can be estimated using a brittleness index derived from elemental rock compositions. Mineralogy can be estimated using stoichiometric mineral models.

Seven chemofacies were assigned to elemental cuttings data from ten study wells based on Principal Component Analysis (PCA) and Hierarchical Cluster Analysis (HCA) cluster assignments to show periods of similar depositional conditions across the region. The chemofacies were linked to lithofacies to improve understanding of the influence of glacio-eustasy and tectonic events in the rock formation. This has been achieved by working on the assumption that siliciclastics (Si, Al, Rb) predominate in lowstands and carbonates (Ca, Sr and Mg) in highstands. Linking outcrop studies chemofacies with XRF drill cuttings chemofacies provides further insights into carbonate and siliciclastic hemipelagic sediment gravity flow conditions.

The utility of cuttings data for chemostratigraphy studies by comparing this study to previous core and outcrop studies has been outlined. Cuttings have a lower resolution (typically 18.2 m (60 ft) sampling intervals), compared to core or outcrop where an entire section could be observed. The extrapolation of findings from core-based studies to this

drill cuttings study, particularly regarding the prediction of reservoir quality requires further work.

Future work could include more integration of cuttings, core data and petrology (thin sections and SEM work) with porosity and permeability measurements to utilize the chemofacies as a predictor of reservoir quality and to improve the correlations with lithofacies. In addition integration with seismic.
