Introduction

Detailed observations of velocity structure, salinity, and temperature in the Gulf Stream (GS) off Cape Hatteras, NC, are analyzed to quantify spatial and temporal variability and inform marine hydrokinetic energy (MHK) development. The observations are part of the North Carolina Renewable Ocean Energy Program's (NCROEP) (General Assembly of North Carolina, 2012) focus on MHK in the GS. We characterize the variability in the energy resource from the GS current and the average power available, describe the shear profile, and investigate the susceptibility to turbulent mixing along the Cape Hatteras Line shown in Figure 1 as well as introduce some recent physical insights that are relevant to MHK objectives.

Background: Physical Oceanography

The GS, the subtropical western boundary current of the North Atlantic that transports the largest volume of water close to the U.S. seaboard, makes its closest approach to the coastline off eastern Florida and off

ABSTRACT

Multi-year measurements of current velocity, salinity, and temperature from fixed and vessel-mounted sensors quantify Gulf Stream (GS) marine hydrokinetic energy (MHK) resource variability and inform development off Cape Hatteras, NC. Vessel transects across the GS demonstrate a jet-like velocity structure with speeds exceeding 2.5 m/s at the surface, persistent horizontal shear throughout the jet, and strongest vertical shears within the cyclonic shear zone. Persistent equatorward flow at the base of the GS associated with the Deep Western Boundary Current (DWBC) produces a local maximum in vertical shear where stratification is weak and is postulated to be a site of strong turbulent mixing. Repeated transects at the same location demonstrate that the velocity structure depends upon whether the GS abuts the shelf slope or is offshore.

Currents from a fixed acoustic Doppler current profiler (ADCP) deployed on the shoreward side of the GS exceed 1 m/s 64% of the time 40 m below the surface. The 3.75-year time series of currents from the ADCP mooring document large, roughly weekly variations in downstream and cross-stream speed (-0.5 to 2.5 m/s) and shear ($+ 0.05$ s $^{-1}$) over the entire water column due to passage of GS meanders and frontal eddies. Current reversals from the mean GS direction occur several times a month, and longer period variations in GS offshore position can result in reduced currents for weeks at a time. Unresolved small-scale shear is postulated to contribute significantly to turbulent mixing.

Keywords: western boundary current, Gulf Stream, marine hydrokinetic energy

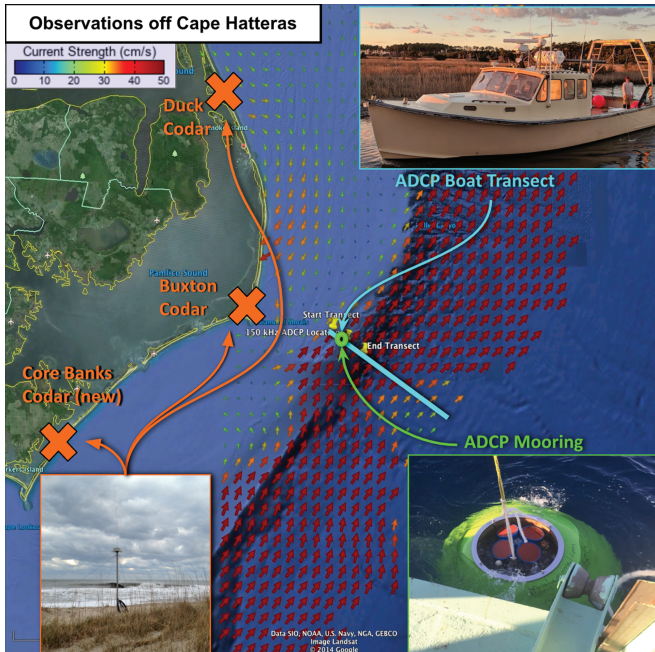

North Carolina (Miller, 1994). Off Cape Hatteras, GS velocities in the jet approach 3 m/s in the top 100 m of the water column, and volume transport estimates vary between 54.5 Sv (Heiderich & Todd, 2020) and 90 Sv (1 Sv = 1×10^6 m 3 /s) (Hogg, 1992). A complex confluence of several different water masses occurs in this region, from convergent shelf water masses (Flagg et al., 2002) and from the intersection of the Deep Western Boundary Current (DWBC) with the GS at greater depths (Andres et al., 2017).

GS structure between Cape Hatteras and 55°W has been studied extensively in multiple field experiments (Halkin &

Rosby, 1985; Hall & Bryden, 1985; Hogg, 1991; Meinen et al., 2009; Watts et al., 1995). The baroclinic structure of sloping isopycnals on the shoreward side of the GS, as well as horizontal and vertical scales, is thought to remain quite consistent in this area (Johns et al., 1995), notably maintaining structural consistency despite regular variations in GS position. A GS “wiggly garden hose” analogy was provided in Halkin and Rossby (1985), which refers to the stream structure being relatively consistent at their “Pegasus Line” north of Cape Hatteras between 35°13' and 36°27' despite varying regularly in position. Measured currents east of Cape Hatteras

FIGURE 1

Observation focus area off Cape Hatteras, NC, along the “Cape Hatteras Line” (cyan line across the GS) at $\sim 35^\circ\text{N}$. Orange Xs mark coastal ocean radar locations that produce the hourly averaged surface current measurements shown by arrows in the background where hotter colors represent faster currents, and three yellow push pins indicate the beginning of small vessel transects to measure currents, mooring location to measure currents, and offshore extent of small vessel transect, respectively. Transects currently extend ~ 70 km offshore from the 100-m isobath, to the eastern edge of the GS where currents are less than 50 cm/s. The green circle is the location of the 150-kHz ADCP mooring shown in the insert.

1994). Downstream of the Cape Hat- 140
teras Line, the stream separates from 141
the continental margin. Essentially un- 142
constrained by bottom topography, me- 143
ander variance doubles every 50 km, 144
with the most energetic meanders hav- 145
ing wavelengths of 180–460 km with 146
periods of 4–100 days (Andres et al., 147
2016; Tracey & Watts, 1986). Thus, 148 Q6
although the Cape Hatteras Line 149
may be an optimal place for energy 150
extraction because of its proximity 151
to land and access to swift currents 152
in relatively shallow water, these 153
long-term measurements are essential 154
because they are in a location not pre- 155
viously observed by other extended 156
studies. 157

Background: GS MHK

MHK is an often-used industry 158
term that refers to the kinetic energy 159
available from the marine environment. 160
Some examples include energy from 161
boundary currents, waves, and tidal cur- 162
rents. Preliminary results from region- 163
specific models indicate that variability 164
in GS position is the main cause of vari- 165
ability in the available MHK resource at 166
a given location. Observations and 167
model estimates at the acoustic Doppler 168
current profiler (ADCP) mooring site in 169
Figure 1 suggest the 271-day average 170
power density is 798 and 641 W/m^2 , 171
respectively, 75 m below the surface 172
between August 1, 2013, and April 173
28, 2014. Annual model power density 174
estimates at different locations along 175
the ~ 70 km Cape Hatteras Line at a 176
depth of 75 m vary from ~ 10 to nearly 177
1,200 W/m^2 (Lowcher et al., 2014). 178
The marked variability in power den- 179 Q7
sity at a given location from year to 180
year accentuates the importance of loca- 181
tion consideration for GS MHK har- 182
vesting and the annual variability at a 183
single location. The power densities 184
along the Cape Hatteras Line are like 185
186

100 show the stream’s influence on the ve- 120
101 locity structure extends to about 1,000 121
102 m, with maximum surface currents in 122
103 the jet confined to the top 100 m of the 123
104 water column (Figure 3). 124
105 The observations on the Cape Hat- 125
106 teras Line presented herein (Figure 1) 126
107 are slightly north and south of previous 127
108 long-term observation campaigns like 128
109 the GS Deflection And Meander Ener- 129
110 getics Experiment (DAMEX) (Bane & 130
111 Dewar, 1988), Frontal Eddy Dynam- 131
112 ics (FRED) (Glenn & Ebbesmeyer, 132
113 1994), and SYNoptic Ocean Predic- 133
114 tion Experiment (SYNOP) (Watts 134
115 et al., 1995) and occur at a location 135
116 where stream meander dynamics transi- 136
117 tion. The potential vorticity constraints 137
118 on GS meander amplitude caused by 138
119 the steep gradient of the continental 139

slope limit GS position variability 120
(Savidge, 2004). Upstream of the 121
Cape Hatteras Line, meander dynam- 122
ics are thought to be dominated by 123
stream deflections caused by the 124
Charleston Bump, causing meander 125
waves that can vary by as much as 126
40 km laterally from the mean (Bane 127
& Brooks, 1979). Downstream of 128
the bump, empirical orthogonal func- 129
tion analysis indicates the meanders 130
tend to degrade in amplitude as the 131
stream approaches Cape Hatteras. GS 132
meanders off Hatteras just prior to the 133
GS separation from the continental 134
margin cause the stream position to 135
vary by up to 10 km (Savidge, 2004), 136
nearly the same as that off the coast of 137
northern Florida where the stream 138
exits the Florida Straits (Miller, 139

187 those found in other western boundary
188 currents such as the Agulhas, Brazil,
189 and Kuroshio, which range from 0.5
190 to 2.0 kW/m² (Bane et al., 2017).

191 The observations presented herein
192 identify several vital engineering consid-
193 erations required for turbine and moor-
194 ing design along the Cape Hatteras
195 Line. Strong onshore flow and frequent
196 flow reversals that occur with meander
197 troughs suggest a turbine will be re-
198 quired to withstand multidirectional
199 flow. The enhanced current resource
200 closer to the ocean surface implies tur-
201 bines will have to be engineered to pre-
202 vent damage from surface waves. Strong
203 shears at depth and unresolved
204 small-scale shears that enhance the
205 shear profile (Winkel et al., 2002)
206 will demonstrate significant mooring
207 design challenges.

208 The GS edge is, on average, 40 km
209 offshore of Cape Hatteras based on
210 U.S. Navy frontal analysis charts
211 (Miller, 1994). The relatively small
212 variability in stream position, resource
213 proximity to land, and access to high
214 current velocities in relatively shallow
215 water have made the Cape Hatteras
216 Line the focus of the NCROEP ob-
217 servation and modeling efforts to ex-
218 plore the potential for harvesting
219 energy from the GS.

220 Observations

221 GS observations for the NCROEP
222 began in 2013. Several different types
223 of long-term consistent measurements
224 have been made off of Cape Hatteras,
225 NC (Figure 1): hourly surface currents
226 from a land-based HF radar network,
227 moored current measurements span-
228 ning nearly the entire water column
229 from a 150-kHz ADCP at 35.14
230 north latitude and 75.11 west longi-
231 tude in water 226 m deep, several
232 cross-stream current velocity measure-

233 ments from vessel-mounted ADCPs,
234 and water conductivity temperature
235 depth (CTD) measurements from
236 fixed-point moorings and vessel casts
237 throughout the water column that
238 characterize different water masses
239 present. The observations reveal the
240 GS flow field helps determine the
241 skill of an existing Mid-Atlantic
242 Bight/South Atlantic Bight Regional
243 Ocean Model (Chen & He, 2010) in
244 estimating the temporal and spatial
245 variability of the GS resource and elu-
246 cidate the engineering challenges in-
247 herent in turbine and mooring
248 deployment for energy extraction
249 from the GS. This manuscript pre-
250 sents observations from CTDs and
251 ADCPs that were both moored and
252 vessel mounted.

253 Current Velocity Measurements 254 and CTD Casts From Vessels

255 Shipboard current measurements
256 and CTD casts on a cross-stream sec-
257 tion have been gathered as weather
258 and vessel opportunity allowed, since
259 2013. The vessel measurements pro-
260 vide information about the GS velocity
261 structure, the variability in MHK ener-
262 gy with water depth and location, and
263 baroclinic structure near 35° north lat-
264 itude. Early velocity measurements
265 along a 14-km-long cross-stream/
266 cross-isobath transect were collected
267 with a downward-looking Teledyne
268 300-kHz Sentinel ADCP mounted
269 on a small vessel. The transect inter-
270 sected the moored ADCP location
271 and spanned isobaths from 100 to
272 1,000 m in depth. The small vessel
273 measures currents in the top 100 m
274 of the water column with 1-m vertical
275 resolution, with the shallowest current
276 measurement 7 m below the surface.
277 Qualitatively, measurements com-
278 pared well with the moored ADCP
279 current observations where they over-

280 lapped in space and time with good
281 agreement in the current velocity
282 structure from both instruments.

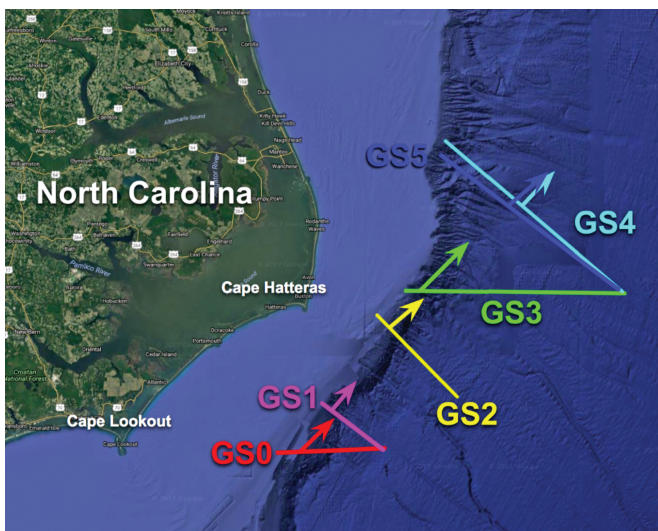

283 In 2016, we extended our measure-
284 ments on the Cape Hatteras Line
285 across the GS into the offshore anticy-
286 clonic shear zone where GS current
287 speeds were less than 1 m/s, a distance
288 of ~70 km, on the *R/V Armstrong's* first
289 Science Verification Cruise (SVC1).
290 Later, as part of a larger National Sci-
291 ence Foundation project—Processes
292 driving Exchange At Cape Hatteras
293 (PEACH), we explored several cross-
294 stream transects (Figure 2) using the
295 same vessel.

296 The *R/V Armstrong* has three hull-
297 mounted Teledyne RDI ADCPs—
298 300, 150, and 38 kHz with vertical
299 resolutions of 2, 5, and 20 m, respec-
300 tively. All vessel-mounted ADCP cur-
301 rent velocity measurements were made
302 absolute by using ancillary systems to
303 measure vessel heading, velocity,
304 pitch, and roll and remove them
305 from measurements. The vessel also
306 has a rosette sampler with a Seabird
307 911 CTD capable of making full
308 water column casts at stations along
309 the transects with processed data re-
310 turned at 1-m vertical resolution. Cur-
311 rent measurements made during casts,
312 while the vessel was not underway, are
313 of poor quality and not used for analy-
314 sis. Deep CTD casts, below 1,600 m,
315 take multiple hours to complete. Thus,
316 the velocity and shear profiles at the
317 cast location were estimated using the
318 average of the current measurements
319 made immediately preceding and fol-
320 lowing the cast.

321 In 2017, we outfitted the 42' ves-
322 sel *Miss Caroline* to continue to make
323 70-km GS crossings along the Cape
324 Hatteras Line (GS2 in Figure 2) mea-
325 suring currents to depths in excess of
326 400 m using hull-mounted 300- and
327 75-kHz ADCPs, with 2- and 16-m

FIGURE 2

Large vessel cross-stream current transects made in April 2017 at six different locations off Cape Hatteras, NC. Currents were measured to water depths of 1,500 m along these transects. Figures below use the labels given on this figure. Arrows indicate the downstream direction chosen to be the direction of the maximum velocity vector.

328 resolution, respectively. We have made 354 over most of the water column every
329 three GS crossings along GS2 on Feb- 355 10 min—excluding only the bottom
330 ruary 20, February 27, and August 31, 356 8 m and top ~28 m. The 10-min
331 2018, with the new vessel and contin- 357 measurements are then quality con-
332 ue to do so. Additionally, a Seabird 358 trolled to Integrated Ocean Observing
333 thermosalinograph continuously mea- 359 System Quality Assurance/Quality
334 sures (1 Hz) surface temperature and 360 Control of Real Time Oceanographic
335 salinity along the ship track. Presently, 361 Data (QARTOD) standards and
336 these measurements are planned to 362 averaged hourly.
337 continue as long as funding for them
338 is available.

363 Methods

364 150-kHz ADCP and CTD Mooring 365 GS Transect Current 366 Measurements and CTD 367 Casts From Vessels

368 We have maintained a mooring 368 measurements made from the *R/V*
369 on the upper slope in water depths 369 *Armstrong's* three hull-mounted
370 of ~230 m since August 1, 2013 370 ADCPs and a CTD cast made from
371 (Figure 1). The mooring contains a 371 that vessel in 1,900 m of water at
372 150-kHz Teledyne Sentinel ADCP, 372 35.072 north latitude and 75.023
373 Seabird SBE 37SM CTD, and 373 west longitude. Vessel current mea-
374 Multi-Electronique passive acoustic 374 surements were rotated into stream-
375 hydrophone. Initially, it was recover- 375 wise coordinates specific to each
376 ed and replaced every 6–9 months. 376 transect. For each transect, streamwise
377 More recently, we have recovered and 377 coordinates were defined such that
378 replaced the mooring annually, taking 378 the positive downstream direction

379 (y) was that of the maximum velocity 379
380 vector over the transect, taken to be 380
381 the direction of the GS jet. The 381
382 depth of the maximum velocity vector 382
383 on the Cape Hatteras Line used in 383
384 subsequent analysis was 13 m. The 384
385 cross-stream direction (x) selected is 385
386 positive clockwise perpendicular to 386
387 the downstream direction or nearly 387
388 cross-isobath offshore. 388

389 Vertical and cross-stream shears in 389
390 downstream velocity (v) with depth 390
391 and cross-stream distance, v/z and 391
392 v/x , respectively, were derived. The 392
393 resolutions of the vertical shear mea- 393
394 surements presented are the same as 394
395 individual ADCP velocity resolutions: 395
396 2, 5, and 20 m for 300, 150, and 396
397 38 kHz, respectively. The horizontal 397
398 resolution is approximately $3.7 \pm$ 398
399 1.3 km, estimated from the average 399
400 vessel speed. The white curves running 400
401 offshore in Figure 3 identify different 401
402 ADCP coverage from the 300-kHz 402
403 ADCP near the surface to the deepest 403
404 coverage from the 38-kHz ADCP. Ex- 404
405 ample velocity profiles from each 405
406 ADCP at the CTD cast location are 406
407 shown in Figure 4A. 407

408 From the ADCP velocities at the 408
409 CTD cast (Figure 4B), the shear 409
410 squared profile, where u is the cross- 410
411 stream velocity, v is the downstream 411
412 velocity, and z is the water depth, is 412
determined.

$$S^2 = \left(\frac{\partial u}{\partial z}\right)^2 + \left(\frac{\partial v}{\partial z}\right)^2$$

413 The CTD cast is used to quantify 413
414 the density stratification in the water 414
415 column. To do so, the potential density 415
416 was calculated from the salinity, tem- 416
417 perature, and depth measurements 417
418 made on the cast. From the potential 418
419 density “ ρ ” profile, we calculate the 419
420 buoyancy frequency squared, N^2 , that 420

FIGURE 3

From left to right: downstream velocity, shear with depth (vertical shear, $\partial v/\partial z$), and shear with cross-stream distance (horizontal shear, $\partial v/\partial x$). The vertical black line denotes the location of the analyzed CTD cast, from surface to bottom, and white curves delineate measurements made by each of three ADCPs—300, 150, and 38 kHz, respectively.

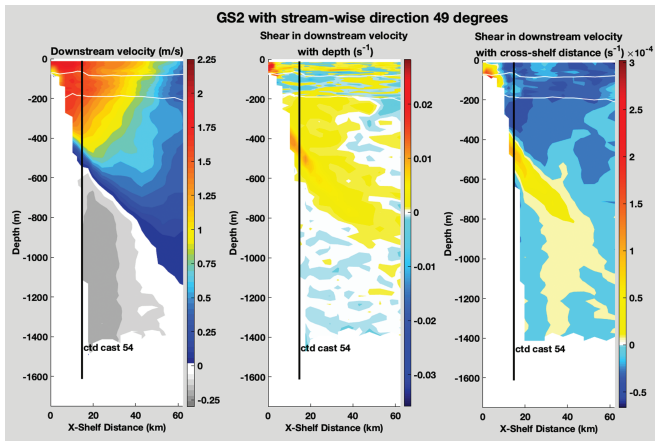

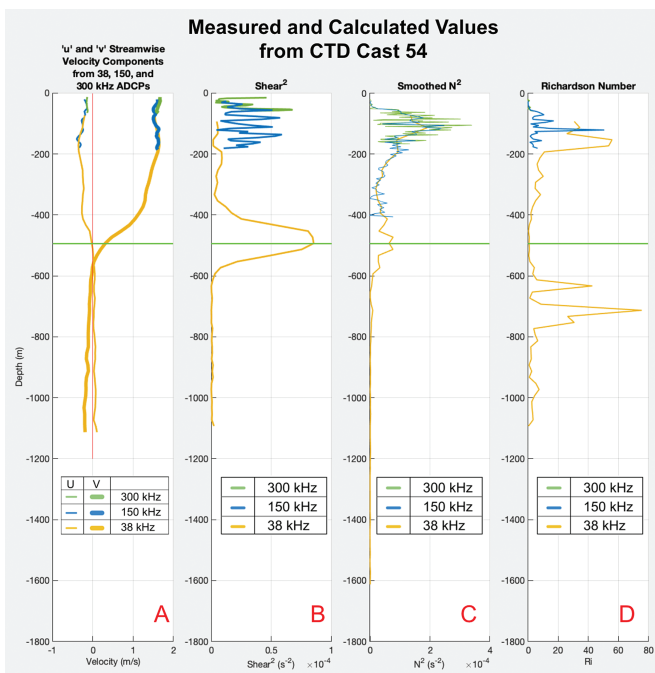

FIGURE 4

(A) The downstream “ v ” and cross stream “ u ” velocity components measured from the Armstrong’s 38-, 150-, and 300-kHz ADCPs at the CTD 54 cast location at 35.0720°N, 75.0230°W. The water depth at the cast is 1,613 m, as shown in Figure 3. (B) Profiles of the shear squared derived directly from the cast 54 velocity measurements in Figure 3 from each ADCP. (C) Smoothed profiles of the buoyancy frequency squared derived directly from the potential density measured on CTD cast 54 (Figure 3). (D) Richardson number profile derived from ADCP velocity measurements and CTD 54 cast. The bright green horizontal line marks the depth where mixing occurs between the GS and the DWBC—visible in Figure 3 along the CTD cast 54 line.

characterizes the stratification of the water column such that

$$N^2 = \frac{-g}{\rho} \frac{\partial \rho}{\partial z}$$

where g is the local acceleration due to gravity. N^2 was then smoothed to the resolution of each ADCP, namely, 2, 5, and 20 m, by convolving salinity and temperature used for density derivations from the CTD cast with 4-, 10-, and 40-point Bartlett windows, respectively (Figure 4C), to use in further analysis with the S^2 profiles from each ADCP with those resolutions.

To assess susceptibility to shear instabilities where the shears are high, the Richardson number, Ri , was calculated.

$$Ri = \frac{N^2}{S^2}$$

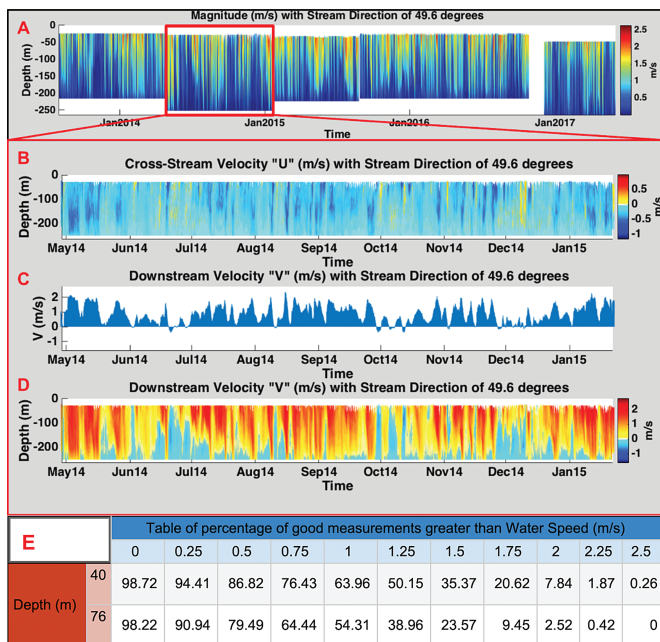

The Richardson number profile is shown in Figure 4D, with a vertical line at $1/4$, a value indicative of shear necessary to mix the stratification (Mack & Schoeberlein, 2004).

150-kHz ADCP and CTD Mooring

A different streamwise velocity coordinate system was chosen for the current velocity measurements over the water column at one location from the fixed mooring. The streamwise velocity for the moored ADCP current record was chosen to be the principal axis of the hourly depth averaged velocity vector for a 45-month time series. Positive downstream is 40° from true north, and positive cross-stream is 90° clockwise to the downstream, or approximately offshore relative to the isobaths. The mean depth of the maximum current speed during the time series is 56 m

FIGURE 5

Water speed from 3 years and 9 months (A) of current measurements made from the NCR0EP 150-kHz ADCP moorings (approximate location shown in Figure 1) with May 2014–January 2015 highlighted, the second deployment showing cross stream velocity “*u*” (B), direction of the maximum current (C), and downstream velocity “*v*” (D). Positive downstream is toward the northeast at 49°, positive. (E) Comparison of 3 years and 9 months of measured current speeds at different depths from the ADCP mooring location in Figure 1.

459 and the mode is 28 m, with the latter 479 transects have now been made from
 460 being the shallowest velocity measure- 480 that vessel along the Cape Hatteras
 461 ment made from the ADCP mooring 481 Line and at other locations off
 462 shown in Figure 1. Water depth varies 482 Cape Hatteras.
 463 slightly over the time series from 483 The *R/V Armstrong* vessel transects
 464 a minimum of 224 m to a maximum 484 also measure the counterflow below
 465 of 260 m. Individual mooring 485 the GS from the upper limb of the
 466 deployments were not always at the 486 DWBC, which is Upper Labrador

Results

MHK: Current Measurements and CTD Casts From Vessel Cross-Stream Vertical Section

472 In 2016, we began making cur- 498 stream on the Cape Hatteras Line
 473 rent observations from the *R/V* 499 March 2016, May 2017, August
 474 *Neil Armstrong*. Several cross-stream 500 2018, and November 2018.

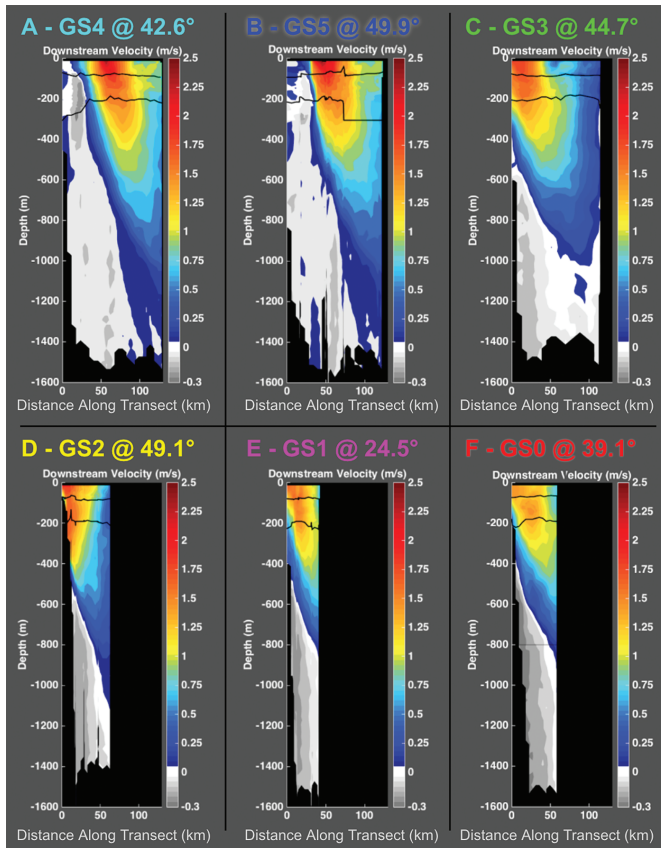

501 Several full water-column CTD 501
 502 casts were made during the *R/V Neil* 502
 503 *Armstrong* cruises. Vertical shear pres- 503
 504 ent where the ULSW flows counter to 504
 505 the GS is greatest beginning at a 505
 506 depth of 400 m beneath the GS jet, 506
 507 decreases in magnitude, and deepens 507
 508 offshore. Shears from the counterflow 508
 509 reach nearly the magnitude of those 509
 510 in the upper water column within 510
 511 the stream’s cyclonic shear zone (Fig- 511
 512 ure 4B). Analysis of the current veloc- 512
 513 ity (Figure 4A) and density structure 513
 514 at the cast locations provides valuable 514
 515 insights about the susceptibility of a 515
 516 mooring line or turbine to reversals 516
 517 in current direction, shear, and turbu- 517
 518 lence. The following are the results 518
 519 from further analysis of the observa- 519
 520 tions made at the cast location 520
 521 shown in Figure 3. Recall the resolu- 521
 522 tion for each instrument is 2, 5, and 522
 523 20 m for the 300-, 150-, and 38-kHz 523
 524 ADCPs, respectively. 524

525 The greatest shears appear in the 525
 526 upper 200 m of the water column— 526
 527 in and beneath the jet—and again at 527
 528 the base of the stream, where the flow 528
 529 reverses from the northeastward stream 529
 530 flow to the ULSW in the upper limb of 530
 531 the DWBC, which is towards the 531
 532 south/southwest (Figure 4B). Quan- 532
 533 tifying the shear in these zones is 533
 534 essential for successful turbine and 534
 535 mooring development in the upper 535
 536 200 m and for mooring design in deeper 536
 537 water. 537

538 The N^2 profiles (Figure 4C) show 538
 539 high stratification in the upper 200 m 539
 540 of the water column in the jet and 540
 541 again at depth where stream flow 541
 542 transitions to DWBC flow in the op- 542
 543 posite direction. Note that the same 543
 544 zones that exhibit high stratification 544
 545 also exhibit higher shears. Further- 545
 546 more, although there is much vari- 546
 547 ability in the buoyancy frequency in 547

FIGURE 6

Current measurements made at the transects shown in Figure 2 from north to south, A–F. The label colors of each figure coincide with the transect color in Figure 2. Black contours mark transitions between different ADCPs; black areas are locations where data are not available. Cross-stream scales are the same for all figures.

three ADCPs agree. This is not the case with individual S^2 profiles from each ADCP, a point investigated further in the discussion.

Where the Richardson number is $\frac{1}{4}$ or less, the velocity shear is significant enough to provide the necessary conditions for mixing to occur in the water column. Indeed, Richardson numbers less than 1 have been shown to provide the necessary conditions to induce mixing in the Subtropical Atlantic (Mack & Schoeberlein, 2004). Note that this occurs both in the top 100-m surface layer and in the transition zone between the GS and ULSW (Figure 4D), between depths of 400–600 m (Andres et al., 2017).

150-kHz ADCP and CTD Mooring

The percentage of exceedance for different speeds from the first 3 years and 9 months of mooring measurements, at 40 and 76 m below the surface, is given in Figure 5E. The depths were chosen for comparison because they are potentially viable water column locations for a turbine and to contrast the difference in the frequency of occurrence of current speeds between 1 and 2 m/s at both depths. Previous analysis by Bane et al. (2017) focused only on 76 m below the surface.

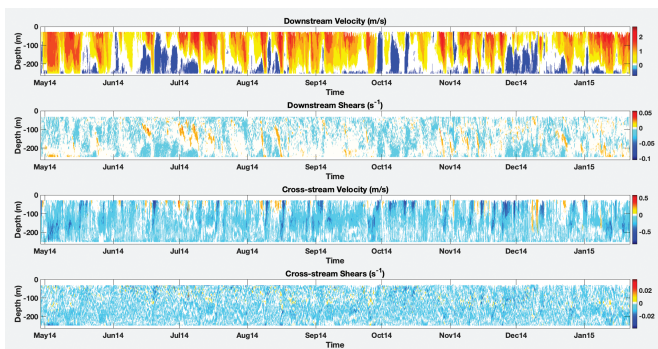

The currents exhibit much variability at the mooring location in Figure 1 as the GS meanders over the mooring and back offshore. A consid-

erable amount of vertical shear during times when the currents exceed 2 m/s is also apparent in the current speeds. Note the high percentage of the time when current speeds are less than 1 m/s. Slower current speeds over the mooring are likely the result of frequent meander passages that occur with a period of 3–8 days (Savidge, 2004), and GS path shifts that position of the GS offshore of the mooring for a week or more (Figure 5). Focusing on the second mooring deployment time series, outlined in red in Figure 5, several flow reversals are notable during the 9 months, with the first occurrence in June 2014 and several thereafter including three in October 2014 (Figure 5C). Most of these occurrences exhibit shoreward cross-stream current and near-zero or reversal, south/southwest flow, of the downstream current. These instances likely accompany the existence of a meander trough offshore of the mooring.

The vertical shear in the downstream and cross-stream directions, v/z and u/z , respectively, for the second ADCP deployment are shown in Figure 7, subplots 2 and 4 from top to bottom, respectively, along with downstream and cross-stream velocities. The magnitudes of shear maxima in the downstream direction from the mooring agree with the magnitudes of the downstream shear maxima seen in the vessel transect in Figure 3. The currents and shears seen during the second deployment have many notable events. Early in May, when downstream and onshore cross-stream velocities are both high throughout the entire water column (Figure 7), large positive downstream and onshore shears occur close to the bottom. The kinematics likely coincide with meander crest incursions over the mooring and repeat several times over the time series.

FIGURE 7

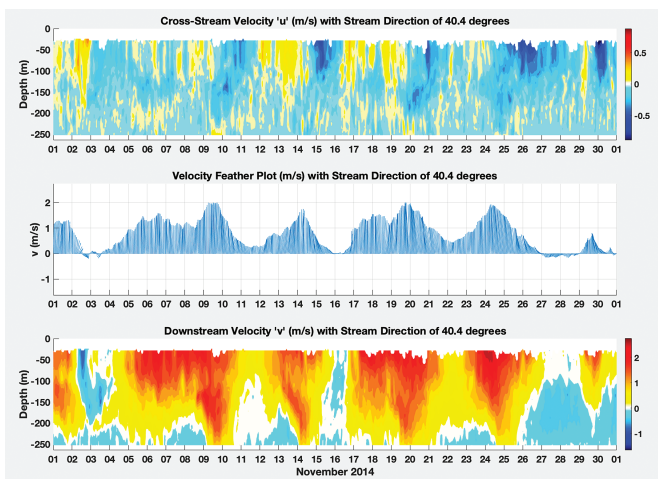

Downstream and cross-stream velocities and shears during the second mooring deployment from May 2014 to January 2015.

635 During periods when downstream 647 with lower shears (Figure 7) in the
636 currents approach 2 m/s in the top 648 water column typical of the GS
637 half of the water column, like the 649 being absent at the mooring.
638 first week of July, downstream and 650 A closer look at the time series of
639 offshore cross-stream shear maxima 651 the currents from November 2014
640 are apparent mid-water column. 652 (Figure 8) further explores the character
641 This occurs when the downstream di- 653 of the currents as meanders propagate
642 rection is very close to the mean of 654 past the mooring. Note the gradual
643 40°. Flow reversals that occur when 655 deepening and rapid shallowing, from
644 the stream is offshore of the mooring, 656 about 100 to 200 m, of the faster cur-
645 like those seen in October in the 657 rent speeds in excess of 1 m/s as the
646 feather plot in Figure 5C, coincide 658 current veers counterclockwise on

FIGURE 8

ADCP observations from November 2014 from top to bottom: downstream direction for the maximum velocity vector with the red line being the mean of 40° from true north, cross-stream velocity as a function of depth and time, top ADCP bin velocity vector, and the downstream velocity as a function of depth and time.

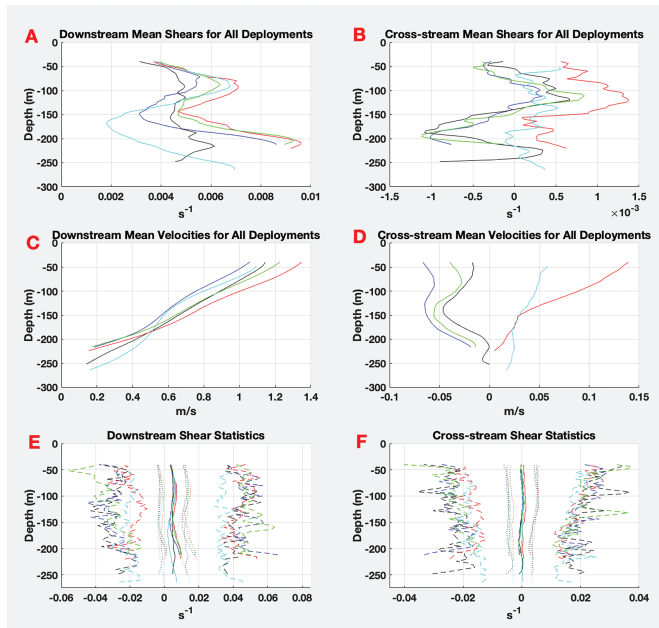

several occasions during the month. 659
Also, note the character of the current 660
during the flow reversal events on 661
November 3, 16, and 27–29. During 662
the reversal, the current veers from the 663
mean northeastward direction to a 664
south/southwestward flow of about 665
50 cm/s. The flow reversal likely re- 666
sults from the cyclonic circulation as- 667
sociated with the inshore side of a 668
passing meander trough (Brooks & 669
Bane, 1983). This is also evident in 670
the strong onshore currents that pre- 671
cede the flow reversal on November 3, 672
indicative of the approach of a mean- 673
der trough. The reversal events around 674
November 16 and 28 are not as pro- 675
nounced, with lesser negative 676
downstream speeds relative to the 677
November 3 event and less pro- 678
nounced onshore currents. 679

The mean velocities and shears for 680
each ADCP mooring deployment 681
time series are shown in Figure 9. 682
Downstream velocities have a gradual 683
nearly linear decrease from near sur- 684
face to bottom. Cross-stream veloci- 685
ties vary significantly by deployment 686
with cross-stream means for Deploy- 687
ments 3 and 5 being positive and neg- 688
ative for Deployments 1, 2, and 4. Note 689
the inflection point in the cross-stream 690
velocities that exists for all deploy- 691
ments beneath about 75 m. Although 692
the bottom moorings are not all de- 693
ployed at the same depth, with depths 694
ranging from 220 to 265 m, they do 695
have consistent downstream velocity 696
and shear profiles. The largest down- 697
stream velocity means are seen in De- 698
ployment 3. Deployment 3 also has 699
the largest offshore cross-stream mean 700
velocity near the surface. Two down- 701
stream shear maxima are present in 702
all deployment means, one at the 703
base of the jet at a depth of about 704
100 m and another sometimes larger 705
secondary maxima between 200 and 706

FIGURE 9

(A–D) Mean downstream and cross-stream velocities and shears for each ADCP mooring deployment. Deployments 1–5 are blue, black, red, green, and cyan, respectively. Deployment 5 (cyan) is the deepest in a water depth of 260 m. (E–F) Mean downstream (left) and cross-stream (right) shear profiles for the five ADCP deployments. The curve in the middle is the mean, the dotted curves on either side are ± 1 SD from the mean, and the outer curves are the maxima and minima for each deployment time series.

250 m. The largest shoreward and off-shore cross-stream mean velocities occur 50 m below the surface for three-fifths of the deployments, with Deployments 2 and 4 being the exceptions having half the mean shoreward current speeds at that depth. Cross-stream shears have two speed minima between about 50 and 100 m, and another beneath 150 m, with most having smaller minima at depth. The deepest deployment, the fifth, is an exception. There is an inflection point in the cross-stream shear profile that exists between 100 and 150 m for all deployments.

Cape Hatteras Transect velocity profiles, despite being nearly instantaneous velocity measurements rather than long-term means, demonstrate the same character as the long-term velocity and shear means seen in the mooring measurements. The Cape

Hatteras Transect (Figure 3A) has shoreward cross-stream velocity on the inshore side of the transect at the depths of the moorings. The center panel, v/z , in Figure 3B exhibits two downstream shear maxima beneath the jet and closer to the bottom at the mooring depth. The same mean downstream and cross-stream shears from the middle subplot in Figure 3 are shown below in Figure 9, with plots including ± 1 SD and their associated maxima and minima for each mooring deployment. The standard deviation for the downstream is nearly twice that for the cross-stream, 7.9×10^{-3} versus $4.3 \times 10^{-3} s^{-1}$. The depth averaged mean shear for all deployments is $4.7 \times 10^{-3} s^{-1}$ and $2.3 \times 10^{-4} s^{-1}$ in the downstream and cross-stream, respectively. Furthermore, the mean shear maxima of the downstream are

more than twice that of the cross-stream, $4.9 \times 10^{-2} s^{-1}$ versus $2.4 \times 10^{-2} s^{-1}$.

Discussion

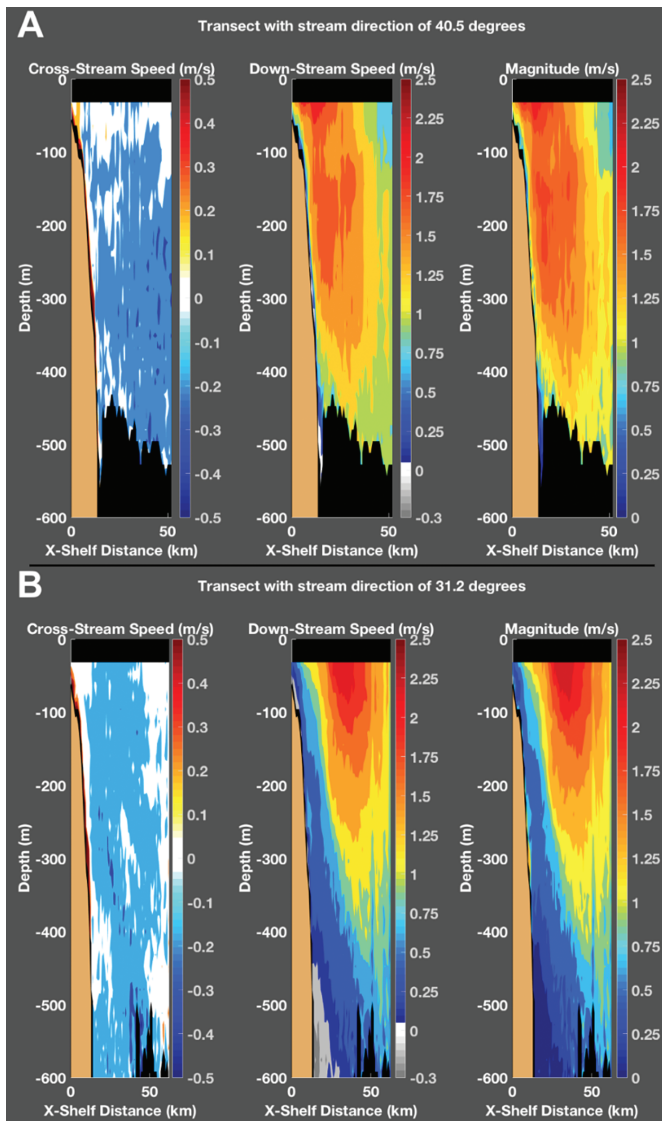

The observations presented herein provide several valuable insights about GS dynamics off Cape Hatteras and inform the MHK community considering engineering solutions for energy extraction in this region. They also begin to explore phenomena seen here for the first time.

Oceanography

The vessel transects made off Cape Hatteras provide several insights about the GS variability in velocity structure off Cape Hatteras, flow of ULSW south of the cape, potential instabilities caused by shearing in the stream and where the stream meets the ULSW at depth, and the potential existence of internal waves. Repeated measurements along the Cape Hatteras Line demonstrate that the velocity structure may vary along the same transect depending on whether the stream lies along the continental slope or offshore of it. The GS “wiggly garden hose” analogy provided in Halkin and Rossby (1985) may not be germane here where the stream regularly interacts with the continental margin. Along the Cape Hatteras Line, cross-stream vessel transects suggest the velocity structure may be quite different when the stream abuts the shelf break relative to instances when it is more offshore (Figure 10). Figure 10 shows the currents measured by *Miss Caroline’s* 75-kHz ADCP on separate dates along the Cape Hatteras Transect. The deepening of currents above 1 m/s by about 100 m in Figure 10A, when the current abuts the continental margin, is strikingly different from those in Figure 10B. Also, the skewing of higher

FIGURE 10

Velocity structure of the GS on the Cape Hatteras Line when it abutted the shelf break on February 20, 2018 (A), and when the GS was offshore of the continental margin on February 27, 2018 (B).

798 currents toward the shelf break is more
799 apparent in Figure 10A, with current
800 structure in Figure 10B tending to be
801 more symmetric.

802 Flow of ULSW past Cape Hatteras
803 was not thought to continue south of
804 Cape Hatteras prior to the observa-
805 tions made in the vessel transects pre-
806 sented here and in Andres et al.
807 (2017). Rather, the lower potential
808 density ULSW first seen in SVC1 as
809 a continuous southwestward flow be-

810 neath the GS was thought to be sheared
811 off the upper limb of the DWBC and
812 advected northeast with the GS (Pickart
813 & Smethie, 1993). CTD casts in this re-
814 gion verified that both lighter ULSW of
815 neutral density (γ), $27.800 \text{ kg/m}^3 < \gamma$
816 $< 27.897 \text{ kg/m}^3$, and denser Classical
817 Labrador Sea Water, $27.897 \text{ kg/m}^3 <$
818 $\gamma < 27.983 \text{ kg/m}^3$, continued to the
819 southwest beneath the stream (Andres
820 et al., 2017). The persistence of this
821 flow over time is uncertain. It has

822 been measured on three separate
823 cruises, and from two different vessels,
824 along the Cape Hatteras transect to
825 date: in March 2016, May 2017, Au-
826 gust 2018, and November 2018 and
827 from several glider cross-sections
828 south of Cape Hatteras (Heiderich &
829 Todd, 2020).

830 Velocity shear where ULSW
831 passes beneath the stream can reach
832 the same magnitude as that seen in
833 the upper 200 m of the water column
834 in the GS jet. An increase in thermal
835 wind shear caused by the difference
836 in potential density across sloping iso-
837 pycnals between the GS and ULSW
838 may contribute to the high shear be-
839 tween 400 and 600 m. From vessel ve-
840 locity measurements and CTD casts,
841 two zones were identified where both
842 high shear and stratification exist si-
843 multaneously, and the Richardson
844 number approaches a value low en-
845 ough to promote turbulent mixing of
846 the stratification: one between 50 and
847 200 m beneath the jet and the other
848 where stream water meets ULSW be-
849 tween 400 and 600 m.

850 The rich current measurements
851 made at the mooring site over 3 years
852 and 9 months provide the longest time
853 series of current measurements avail-
854 able at this location. The shear maxima
855 that exist beneath 150 m in both the
856 downstream and cross-stream currents
857 demonstrate the influence of frequent
858 meanders over the mooring, with the
859 strong shoreward cross-shelf velocity
860 component means suggesting the
861 mooring was influenced often by
862 stream meanders. The agreement be-
863 tween Deployments 1, 2, and 4, and
864 the discrepancy between them and De-
865 ployments 3 and 5, with the latter two
866 having lower cross-stream velocities
867 and shear beneath 150 m, is worth
868 consideration. Deployment 5 is the
869 deepest mooring depth at ~ 265 m,
869

870 yet the means agree well with Deploy- 917
871 ment 3, which is in 224 m of water, 918
872 both having the largest downstream 919
873 velocity, and smallest cross-stream ve- 920
874 locity means near the surface suggest 921
875 these deployments spent more time 922
876 in the jet, with less influence from me- 923
877 anders. Meander trough approaches 924
878 are led by significant increases in 925
879 cross-stream velocity and increased 926
880 shear in the water column. The differ- 927
881 ence in mean cross-stream velocity 928
882 during Deployments 3 and 5 relative 929
883 to the other three deployments may 930
884 be indicative of GS path shifts caused 931
885 by interannual variability that is not 932
886 yet well understood. 933

887 **MHK**

888 All of the aforementioned oceanographic 936
889 dynamics discussed also provide 937
890 valuable information to the 938
891 engineering community considering 939
892 MHK development. The vessel tran- 940
893 sects and CTD casts are valuable for 941
894 optimizing the depth of mooring 942
895 locations based on available MHK cur- 943
896 rent resource, velocity and shear 944
897 characterization, and water column 945
898 stability. The effects of the enhanced 946
899 velocity shear from unresolved small- 947
900 scale shear on moorings require more 948
901 observations, like lowering a higher 949
902 frequency ADCP on a cast through 950
903 this zone (Visbeck, 2002). The high 951
904 shears between 400 and 600 m 952
905 where the base of the stream meets 953
906 the counterflow of the ULSW may 954
907 be greater than that measured and is 955
908 already significant for mooring design 956
909 consideration at these depths. Shear 957
910 magnitudes in the downstream direc- 958
911 tion from the mooring are more than 959
912 twice those seen in the vessel transects 960
913 in deeper waters. The transects do 961
914 show shears of up to $\sim 0.03 \text{ s}^{-1}$ up 962
915 on the shelf in the vicinity of the 963
916 mooring, while downstream shear 964

917 maxima in the mooring are $\sim 0.04 \text{ s}^{-1}$,
918 suggesting the highest shears are
919 caused by the interaction of the high
920 GS currents with the bottom. These
921 agree with shear maxima seen in the
922 mooring current measurements.
923 Long-term currents measured by
924 the mooring help to characterize the
925 expected resource in greater detail
926 than previously available. A compari-
927 son between the velocity available at
928 40 and 75 m below the surface from
929 the long mooring time series eluci-
930 dates the expected differences in the
931 available MHK resource at different
932 depths—an important consideration
933 for optimizing turbine location in
934 the water column. About a 10%
935 greater occurrence of exceedance for
936 speeds between 1 and 1.75 m/s exists
937 between the two depths. Turbines
938 located closer to the surface will nec-
939 essarily require engineering to with-
940 stand the higher stresses caused by
941 greater exposure to the surface wave
942 field to take advantage of the greater
943 resource. The frequent current rota-
944 tions and flow reversals caused by
945 the passage of meander troughs seen
946 in the moored measurements will
947 add increased torques to turbines
948 here, and moorings will not exist as
949 simple catenaries but as more compli-
950 cated profiles with depth that will ne-
951 cessitate thoughtful engineering
952 solutions. Additionally, the means
953 from the mooring time series character-
954 ize the expected velocity shear in the
955 water column and quantify maximum
956 velocity and shear experienced by any
957 device at this location. The long-term
958 mean cross-shelf velocities are all shore-
959 ward, with shear maxima at depths
960 greater than 150 m (Figure 9). Also no-
961 table are the maxima and minima for
962 the long-term mooring mean shears—
963 about an order of magnitude greater
964 than the mean values, up to 0.06 s^{-1}

for the downstream and 0.04 s^{-1} for 965
the cross-stream. 966

967 **Summary and** 968 **Future Work**

969 Detailed observations have been 969
970 presented that provide in-situ views 970
971 of the velocity structure in the GS 971
972 off Cape Hatteras, NC. They quan- 972
973 tify spatial and temporal variability in 973
974 the velocity and baroclinic structure 974
975 along the Cape Hatteras Line and 975
976 provide a necessary basis for future 976
977 MHK or even traditional utility devel- 977
978 opment in the area. 978

979 Several vessel crossings of the Cape 979
980 Hatteras Transect demonstrate the 980
981 difference in velocity structure when 981
982 the GS flows closer to the shelf 982
983 break or is offshore of it. They quan- 983
984 tify shearing, stratification, and water 984
985 column stability from current mea- 985
986 surements and CTD casts along the 986
987 Cape Hatteras Transect and identify 987
988 new features at this location like the 988
989 possibly persistent ULSW flow be- 989
990 neath the stream and near inertial in- 990
991 ternal waves. 991

992 Analyses of a 3-year-and-9-month 992
993 time series of current, salinity, and 993
994 temperature measurements from a 994
995 mooring that contains a 150-kHz 995
996 ADCP were presented that summa- 996
997 rize the exceedance of currents at spe- 997
998 cific speeds at depths of 40 and 75 m 998
999 below the surface for future device de- 999
1000 sign consideration. The measured 1000
1001 currents show the influence of fre- 1001
1002 quent GS meander propagation and 1002
1003 path shifts over the mooring that pro- 1003
1004 duce flow reversals and strong shears 1004
1005 throughout the water column. Down- 1005
1006 stream and cross-stream velocities as 1006
1007 well as long-term means demon- 1007
1008 strate the persistent shoreward flow 1008
1009 at the mooring that may be caused 1009

1010 by the frequent approach of mean- 1058 changes with frequently upwelled
1011 der troughs. Several specific occur- 1059 GS water.
1012 rences were noted for the month of
1013 November 2014.

1014 The observations presently sup- 1060
1015 port several collaborative and con- 1061
1016 tinuing engineering efforts on 1062
1017 turbine, kite, and mooring design 1063
1018 (Bin-Karim et al., 2018; Divi et al., 1064
1019 2017), economic assessment of GS 1065
1020 MHK (Li et al., 2017; Neary et al., 1066
1021 2014), subsurface ADCP mooring 1067
1022 design with National Oceanic and At- 1068
1023 mospheric Administration's Center 1069
1024 for Operational Products and Services 1070
1025 division, and research with Dr. Lind-
1026 say Dubb's group (Coastal Studies In-
1027 stitute, 2020) to understand marine 1071
1028 mammal abundance relative to GS 1072
1029 variability off Cape Hatteras. Future 1073
1030 work will use hourly HF radar surface 1074
1031 velocity measurements in conjunction 1075
1032 with the moored ADCP currents to
1033 provide detailed examination and
1034 analysis of GS meander propagation 1076

1035 at the mooring site. Further analysis 1077
1036 of CTD and ADCP observations 1078
1037 may enhance understanding of the 1079
1038 complex interplay between shelf 1080
1039 water masses of the South Atlantic 1081
1040 Bight, Mid-Atlantic Bight, and Slope 1082
1041 Sea, as well as deeper waters down 1083
1042 the continental slope like the ULSW, 1084
1043 with GS variability. Observations 1085
1044 also identify new phenomena that 1086
1045 warrant further research like the po- 1087
1046 tentially persistent flow of ULSW be- 1088
1047 neath the GS (Andres et al., 2017; 1089
1048 Heiderich & Todd, 2020), variability 1090
1049 in GS velocity structure dependence 1091
1050 on stream location relative to the con- 1092
1051 tinental margin, and the effects of un- 1093
1052 resolved small-scale shear on the shear 1094
1053 profiles within and beneath the 1095
1054 stream, as well as their influence on 1096
1055 important exchange processes like 1097
1056 CO₂ fluxes at strong mixing zones be- 1098
1057 tween differing water masses and ex-
