COVID-19- coronavirus disease 2019

ICU- intensive care unit

ABSTRACT

Background: Major gaps exist in our understanding of the relationship between obesity and clinical outcomes in patients with severe COVID-19.

Research Question: Is obesity independently associated with major adverse clinical outcomes in critically ill patients with COVID-19?

Study Design and Methods: We used data from a multicenter cohort study of 4925 critically ill patients with COVID-19 admitted to ICUs at 68 hospitals across the US between XXX and XXX. The primary exposure was body mass index (BMI). The primary outcome was in-hospital mortality. Secondary outcomes included acute respiratory distress syndrome (ARDS), acute kidney injury requiring renal replacement therapy (AKI-RRT), thrombotic events, and seven circulating markers of inflammation and thrombosis (interleukin-6, C-reactive protein, albumin, ferritin, procalcitonin, fibrinogen, d-dimer). Unadjusted and multivariable-adjusted models were used.

Results: Among the 4908 patients included in the analysis, the mean (SD) age was 60.9 (14.7) years, 3095 (62.8%) were male, 1930 (39.2%) were white, 1496 (30.4%) were black, and 2552 (52.0%) were obese. A total of 1933 patients (39.4%) died during hospitalization. BMI was not independently associated with mortality. In contrast, higher BMI beginning at 25 kg/m² was associated with a greater risk of ARDS and AKI-RRT. BMI was also not associated with risk of thrombotic events. Of the seven markers of inflammation and thrombosis examined, only serum albumin was associated with BMI albeit in a clinically marginal manner.

Interpretation: In a large population of critically ill patients with COVID-19, higher BMI was not associated with a higher risk of death. BMI throughout the range of overweight and obese was, however, linked to greater risk of ARDS and AKI-RRT. The absence of any clinically

significant association between BMI and circulating biomarkers of inflammation and thrombosis challenges their hypothesized links with obesity and adverse outcomes in COVID-19.

INTRODUCTION

Over the course of the coronavirus disease 2019 (COVID-19) pandemic, obesity has emerged as an issue of great interest due to its prognostic significance. Several observational studies have identified obesity, particularly in its more severe forms, as an independent risk factor for hospitalization, critical illness, mechanical ventilation, and death.¹⁻⁶ The importance of obesity as a predictor of outcomes cannot be understated given its wide prevalence in the US and worldwide and its modifiable nature.⁷ Nevertheless, major gaps exist in our understanding of the interplay between obesity and COVID-19.

One such gap involves the relationship between obesity and outcomes in the sickest cohort of patients—those admitted to intensive care units (ICUs). With few exceptions,^{6,8} most analyses of this topic have been single center, limited by small sample size, or lacking in detailed descriptive data.⁹⁻¹² Moreover, most studies focused solely on the relationship between obesity and death without examining other major clinical outcomes. It is therefore not well understood if obesity is an independent risk factor for mortality and other major clinical outcomes like acute kidney injury requiring renal replacement therapy (AKI-RRT), acute respiratory distress syndrome (ARDS), and thrombotic events in critically ill patients with COVID-19.

The mechanisms underlying obesity's potential link with adverse outcomes in patients with COVID-19 are also poorly understood. Several postulated mechanisms include excess fat as a source of upregulated inflammation, a reservoir for viral replication, and/or a trigger for hypercoagulability.¹³⁻¹⁷ However, there is a dearth of biochemical evidence in humans directly linking obesity to increased systemic inflammation or thrombosis.

To address these knowledge gaps, we used data from a multicenter cohort study of 4877 well-characterized critically ill adults admitted to ICUs at hospitals across the US. We examined the relationship between obesity and major clinical outcomes (mortality, ARDS, AKI-RRT, and thrombotic events). We also studied the relationship between body mass index (BMI) and circulating inflammatory and thrombotic markers to better understand how obesity may exert its detrimental effects.

METHODS

Study Design, Oversight, and Patient Population

The Study of the Treatment and Outcomes in Critically Ill Patients with COVID-19 (STOP-COVID) is a multicenter cohort study that enrolled consecutive adults (≥ 18 years old) with laboratory-confirmed COVID-19 who were admitted to ICUs at 68 hospitals across the United States between March 4 and June 30, 2020. Patients were followed until the first of hospital discharge, death, or August 1, 2020, the date on which the database for the current analysis was locked. STOP-COVID only included ICU patients in an effort to focus on patients at highest risk of acute organ injury or death. For the current analysis, we excluded patients with missing data for BMI ($n=228$). For the AKI-RRT analysis, we also excluded patients with end-stage renal disease (ESRD) ESRD (eFigure 1). The study was approved with a waiver of informed consent by the Institutional Review Board at each participating site. Further information on STOP-COVID and its primary findings are reported elsewhere.⁶

Data Collection

Study personnel at each site collected data by detailed chart review and used a standardized case report form to enter data into a secure online database (REDCap). Patient-level data included: demographics and comorbidities; longitudinal laboratory values and physiologic parameters collected during the first 14 days of ICU admission; medications, treatments, organ support (including RRT) following ICU admission; and clinical outcomes, including acute organ injury and death. We also collected hospital-level data, including hospital size (assessed by the number of pre-COVID ICU beds, not including surge capacity beds). A complete list of variables is provided in the Case Report Form available elsewhere.⁶

Exposure and Outcomes

The primary exposure was body mass index (BMI), assessed at time of ICU admission and categorized in the following manner: <18.5, 18.5-24.9, 25-29.9, 30-34.9, 35-39.9, ≥ 40 kg/m². BMI of 18.5-24.9 was used as a reference category. The primary outcome was in-hospital death. Secondary outcomes included clinical outcomes and biomarker analyses. Clinical outcomes included the development of ARDS, AKI-RRT, or thrombotic events during the first 14 days of ICU admission. The presence of ARDS was defined using the following modified Berlin criteria:¹⁸ partial pressure of arterial oxygen:fractional inspired oxygen (PaO₂:FiO₂)<300 mmHg, the need for invasive mechanical ventilation, and a diagnosis of ARDS per chart review. AKI-RRT was defined as receiving any form of RRT, including intermittent hemodialysis, continuous renal replacement therapy, or peritoneal dialysis. Thrombotic events were defined as any of the following: deep vein thrombosis, pulmonary embolus, stroke, or other thrombotic event per chart review.

Secondary outcome biomarker analyses included the relationships between BMI and seven circulating markers of inflammation and thrombosis: interleukin (IL)-6, C-reactive protein (CRP), albumin, ferritin, procalcitonin, fibrinogen, and D-dimer,¹⁹⁻²⁴ measured during the first 14 days of ICU admission. Only the first value in any one day was used for this analysis.

Statistical Analyses

The population was described using univariable analysis with continuous variables expressed as mean (standard deviation) and median (interquartile ranges), and categorical variables as count

and percentage. We used unadjusted and multivariable-adjusted models to examine the association between BMI and the primary and secondary outcomes. The covariates selected for the multivariable models were tailored on the basis of prior knowledge and biological plausibility (further details are shown in the eMethods).^{6,25}

For the primary outcome of mortality, we used time-to-event analysis involving Cox Proportional-Hazards modeling that included time-varying covariates to account for the non-proportionality of the hazards.²⁶ The other three clinical outcomes (ARDS, AKI-RRT, and thrombotic events) were assessed only during the first 14 days following ICU admission, and mortality was assumed to be a competing outcome. Individuals who had no outcomes or were discharged from the hospital were censored using a competing risk model based on the Fine and Gray method.²⁷⁻²⁹ To account for the correlation of patients in the same hospital we used clustered robust standard error using health facility as the clustering variable.³⁰ For each BMI category, we presented unadjusted and multivariable-adjusted hazard ratios for mortality and competing risk subhazard ratios for predicting other clinical outcomes. In all outcome models, missing or unknown data were coded as a separate missing/unknown category.

When analyzing the relationship between BMI and circulating biomarkers during the first 14 days following ICU admission, we developed unadjusted and multivariable adjusted models using a generalized estimating equation (GEE) with an assumption of an exchangeable correlation structure whereby daily observations for the markers within a subject are assumed to be equally correlated. A repeated measure design helped to account for variability between subject measurements and allowed us to focus primarily on the effect due to the difference in

BMI.³¹ All multivariable models included the same variables listed in the eMethods. The GEE allowed us to account for incomplete data for each biomarker.³²

The following sensitivity analyses were performed that limited the analysis to: (1) biomarkers assessed during the first 3 days following ICU admission to limit additional influencing factors that could arise later during the ICU stay; (2) patients without diabetes to exclude the additional influence of the pro-inflammatory diabetic milieu;³³ and (3) patients admitted to the ICU within 72 hours of hospitalization to avoid major changes in BMI prior to ICU admission. Additional details on definitions, the GEE model, and biomarker analyses are found in the eMethods. Hypotheses were tested at 0.05 level of significance and the analyses were performed using Stata/MP 16.1.³⁴

RESULTS

Baseline Characteristics

Baseline characteristics of the 4925 patients included (eFigure 1) stratified by categories of BMI categories are shown in Table 1 (abbreviated) and eTable 1 (complete). Mean (SD) age was 60.9 (14.7) years, 3095 (62.8%) were male, 1930 (39.2%) were white, and 1496 (30.4%) were black. The most common comorbidities were hypertension (61.6%) and diabetes (42.2%). A total of 2552 patients (52.0%) were obese, defined as a BMI >30 kg/m² (eFigure 2). Univariate relationships between obesity and patient characteristics and clinical factors are shown in Table 1. A total of 1933 of 4908 patients (39.4%) died during hospitalization (eFigure 1), and the median time to death was 10 days (IQR, 5-18) after ICU admission.

BMI and Major Adverse Clinical Outcomes

In the unadjusted model, a BMI of 30-34.9, 35-39.9, and 40 or higher kg/m² were each associated with a lower risk of death, while a BMI of <18.5 kg/m² was associated with a higher risk of death. However, in the multivariable adjusted model there was no association between BMI and mortality (Figure 1, eTables 2-3).

ARDS was observed in 3545 of 4907 patients (72.2%) (eFigure 1). Results from the unadjusted competing risk analysis were very similar to that of the multivariable analysis, which showed an independent increase in risk of ARDS for BMI starting at 25 kg/m² (25-29.9 kg/m²: 1.21 (1.11, 1.33); 30-34.9 kg/m²: 1.40 (1.24, 1.58); 35-39.9 kg/m²: 1.36 (1.24, 1.48); ≥40 kg/m²: 1.34 (1.15, 1.56)) (Figure 2; eTables 4,5).

AKI-RRT developed in 900 of 4739 patients (19.0%) (eFigure 1). Unadjusted and multivariable competing risk models were similar in that risk for AKI-RRT progressively rose beginning at a BMI of 25 (multivariable model, 25-29.9 kg/m², 1.46 (1.10, 1.94); 30-34.9 kg/m², 1.83 (1.37, 2.43); 35-39.9 kg/m², 2.01 (1.44, 2.79); ≥40 kg/m², 2.27 (1.56, 3.31)) (Figure 2; eTables 6, 7).

Thrombotic events occurred in 552 of 4907 (11.2%) (eFigure 1). In both unadjusted and multivariable analyses BMI was not associated with a higher risk of thrombosis (Figure 2; eTables 8, 9).

BMI and Circulating Biomarkers of Inflammation and Thrombosis

The number of patients with missing biomarker data ranged from 2.9% (platelets) to 62.3% (IL-6) (Table 1). The multivariable-adjusted relationship between BMI and each circulating biomarker during ICU admission appears in Figure 3. With the exception of serum albumin, which had a statistically significant and positive association with BMI, no association with BMI was observed using the other six biomarkers. Results did not change regardless of whether BMI was examined as a continuous or categorical variable. Of note, the relationship between BMI and albumin was clinically marginal (for every 10 kg/m² increase in BMI, serum albumin rose by 0.1 g/dL). Sensitivity analyses that only included data from the first 72 hours of ICU admission (n=4925) (eFigure 3), in the subgroup of patients without diabetes during the first 72 hours of ICU admission (n=2845) (eFigure 4), or only including patients admitted to the ICU within 72 hours of hospital admission (n=3978) (eFigure 5) did not have qualitatively different results.

DISCUSSION

Our study examined whether the previously identified association between obesity and mortality also applied to the sickest population of patients with COVID-19 and extended beyond just mortality to include other major adverse COVID-associated complications like ARDS, AKI-RRT, and thrombotic events. We also evaluated possible underlying mechanisms of the obesity-COVID-19 link by assessing the relationship between BMI and commonly used blood biomarkers of inflammation and thrombotic risk. Our results provide new insights into the obesity-COVID connection.

The pathophysiological link between excess adiposity and adverse COVID-19 outcomes is incompletely understood though several mechanisms have been hypothesized. Visceral adipose tissue promotes low grade inflammation through infiltration of macrophages and secretion of pro-inflammatory mediators including interleukin-6 (IL-6).¹³ By expressing relatively high levels of angiotensin converting enzyme-2 (ACE2), adipocytes can become reservoirs for COVID-19, thereby leading to amplification of the infection and possibly the inflammatory cascade.^{14,15} Obesity can also promote a hypercoagulable state through several mechanisms including upregulation of pro-coagulant factors (e.g., plasminogen activator inhibitor-1, tissue factor), enhanced platelet activation, and inhibition of fibrinolysis and thus potentiate the pro-thrombotic effects of COVID-19.^{16,17}

In our analyses the only independent association between obesity and adverse events were seen with ARDS and AKI-RRT. ARDS is a relatively common and deadly complication of COVID-19.³⁵ Risk of ARDS increased beginning at a BMI of 25 kg/m² independent of other factors.

Similar findings have been reported in other studies of patients with COVID-19^{36,37} and are contrary to the “obesity-ARDS paradox” observation that describes a lower incidence of ARDS in individuals with obesity.³⁸ Some proposed reasons why obesity is an independent risk factor for ARDS include increased inflammation, immune system dysfunction, decreased wound healing, accumulation of lipofibroblasts that differentiate into fibrosis-promoting myofibroblasts, and associated restrictive lung disease.^{39,40}

We previously reported that AKI-RRT is relatively frequent in critically ill patients with COVID-19 and carries a poor prognosis.²⁵ In this study BMI was strongly and progressively associated with increased risk of AKI-RRT starting at a BMI of 25 kg/m². Obesity is a known predictor for AKI in critically individuals without COVID-19.⁴¹ Possible mechanisms making individuals with obesity particularly susceptible to COVID-19 related injury include underlying glomerular hyperfiltration and shear-related stress, podocyte damage with segmental sclerosis, fatty kidney, pulmonary hypertension, and secretory products like leptin that may have nephrotoxic effects.⁴²⁻⁴⁵

We found that obesity was not independently associated with a higher risk for mortality. Our result is slightly different than our previous report, which found that obesity was linked to higher mortality but only in the highest BMI range (≥ 40 kg/m²).⁶ We suspect the minor difference between the two results is due to this study’s much larger sample size and its accounting for interventions that have, subsequent to the earlier publication, been proven to influence outcomes.^{46,47}

Critically ill patients with COVID-19 have a very high incidence of thrombotic events.⁴⁸⁻⁵⁰

Despite the documented association between obesity, hypercoagulability, and thrombotic risk in the general and ICU populations^{16,51-53} we found no independent association between obesity and an increased risk of thrombotic events in our ICU patients. Perhaps any prothrombotic contribution of obesity was subsumed by a much larger risk associated with COVID-19.

To better understand the underlying pathophysiology between the putative relationship between excess adipose tissue and upregulation of pro-inflammatory and pro-thrombotic pathways in the COVID population,¹³⁻¹⁷ we examined the relationship between BMI and seven circulating inflammatory and thrombotic markers. To our surprise we found no clinically significant relationship between the two, despite that fact that several of the biomarkers are known to be secreted by adipocytes (i.e. IL-6, C-reactive protein, fibrinogen).^{13,54-56} Our analysis also accounted for extraneous factors that could have influenced inflammation or BMI such as diabetes or long pre-ICU hospital stays. While serum albumin was positively associated with BMI, the relationship was marginal in terms of clinical significance. Though often considered a good indicator of nutritional status, reductions in serum albumin are far more reflective of inflammation or illness, including in patients with severe COVID-19.^{20,57} An obvious explanation for the albumin-BMI relationship we observed is not available but could be explained by the fact that production of serum albumin by adipocytes can be independent of the inflammatory process.⁵⁸ Our preliminary findings raise into question the paradigm that obesity contributes to poor outcomes in critically ill patients with COVID-19 by upregulating systemic inflammatory and prothrombotic pathways. However, further research in this area is clearly

required. Of note, our study could not exclude upregulation of these pathways in ways that could not be directly measured by blood sampling (i.e. intra-organ signaling).

Our study has several strengths. It was performed in the largest and best characterized cohort of critically ill patients with COVID-19 to date. It is the first to examine the relationship between BMI and several of the most common and serious clinical outcomes in that population, including death. It is also the first to evaluate the link between BMI and markers of inflammation and thrombosis to try and better understand the mechanistic underpinnings between adiposity and COVID-19 that until this point has lacked direct correlation in humans. We chose to examine these questions in the critically ill population because we thought the relationship between obesity and biomarkers would be more easily discernible. However, this strategy also limited the generalizability of our findings and could have obscured pathophysiological mechanisms that would have been more apparent earlier in the course of the illness. Other limitations include missing data, lack of serial biomarker measurements, lack of a single study laboratory, and the insensitivity of BMI in differentiating visceral from subcutaneous fat.

In summary, in a large population of critically ill patients with COVID-19, obesity was not associated with mortality or thrombotic events but was consistently linked to a higher risk of developing ARDS and AKI-RRT throughout the range of elevated BMI. The absence of an association between BMI and circulating biomarkers of inflammation and thrombosis challenges their hypothesized links with obesity and adverse outcomes in COVID-19.

ACKNOWLEDGMENTS

ANF is responsible for the content of the manuscript, including data and analysis. ANF, RK, SG, JG, and DEL generated the data. ANF conceived of the project and was the primary author of the manuscript. LRT performed the statistical analyses. DEL and LRT contributed equally. All authors critically revised the final manuscript. A full list of the STOP-COVID investigators is provided in the Supplemental Appendix.

Abbreviations: ACE-I, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker; BiPAP, bilevel positive airway pressure; BMI, body mass index, in kg/m²; COPD, chronic obstructive lung disease; CPAP, continuous positive airway pressure; ECMO, extracorporeal membrane oxygenation; HFNC, high-flow nasal cannula; NSAID, non-steroidal anti-inflammatory drug

^aDefinitions are described more completely in ⁶.

^bData for white blood cell count were missing in 317 patients (6.4%)

^cData for lymphocyte count were missing in 999 patients (20.3%)

^dData for platelet count were missing in 142 patients (2.9%)

^eData for D-dimer were missing in 787 patients (16%)

^fData for fibrinogen were missing in 2405 patients (48.8%)

^gData for interleukin-6 were missing in 3068 patients (62.3%)

^hData for C-reactive protein were missing in 620 patients (12.6%)

ⁱData for albumin were missing in 264 patients (5.4%)

^jData for ferritin were missing in 692 patients (14.1%)

^kData for procalcitonin were missing in 1803 patients (36.6%)

FIGURES

Figure 1: Association between BMI and Mortality. BMI, body mass index. N=4801 patients included in the analysis.

Figure 2: Association between BMI and ARDS, AKI-RRT, and Thrombotic Events. ARDS, adult respiratory distress syndrome; AKI-RRT, acute kidney injury treated with renal replacement therapy. N=3827 for ARDS, N=4693 for AKI-RRT, N=4799 for thrombotic events.

Figure 3: Relationship between BMI and circulating biomarkers of inflammation and thrombosis during the first 14 days of ICU admission after controlling for all other variables in the model. The error bars represent the 95% confidence interval around the marginal mean for each marker within each BMI category. Missing biomarker data (% of total cohort): Interleukin-6 3047 (62.5%), C-reactive protein 615 (12.6%), albumin 262 (5.4%), ferritin 687 (14.1%), procalcitonin 1798 (36.9%), fibrinogen (2378 (48.8%), D-dimer 780 (16%).

eMETHODS

Definitions

Renal, Liver, and Coagulation components of the Sequential Organ Failure Assessment (SOFA) score:

	Categories				
	0	1	2	3	4
SOFA Renal (Cr [mg/dl], UOP [ml/day], and acute RRT) Cr	Cr<1.2 and UOP≥500	Cr 1.2-1.9 and UOP≥500	Cr 2-3.4 and UOP≥500	Cr 3.5-4.9 and UOP≥500	Cr≥5 or UOP≤200 or acute RRT or ESRD
SOFA Liver (Bilirubin, mg/dl)	<1.2	1.2-1.9	≥2*	--	---
SOFA Coagulation (Platelets, K/mm ³)	≥150	100-149	≤99*	--	--

Abbreviations: Cr, creatinine (mg/dl); ESRD, end-stage kidney disease; RRT, renal replacement therapy; UOP, urine output. *The liver and coagulation components of the SOFA score were binned due to low frequency of events in categories “3” and “4”.

Multivariable Models for Clinical Outcomes

MORTALITY

1. Age
2. Gender
3. Race
4. Ethnicity
5. Hypertension
6. Diabetes
7. Coronary artery disease
8. Congestive heart failure
9. Cancer
10. Immunodeficiency state
11. Current smoking
12. Absolute lymphocyte count
13. Presence of shock
14. Corticosteroid use
15. Remdesivir use
16. PaO₂:FiO₂ ratio if mechanically ventilated
17. SOFA liver score
18. SOFA coagulation score
19. SOFA kidney score
20. Number of hospital ICU beds

ARDS

1. Age
2. Gender
3. Race

4. Ethnicity
5. Hypertension

Modelling BMI and Inflammatory/Thrombotic Biomarkers

We used population-averaged panel data models involving generalized estimating equations (GEE) with an assumption of exchangeable correlation structure of exchangeable correlation structure in which daily observations for markers within a subject are assumed to be equally correlated. The choice of the exchangeable correlation structure was empirically driven using the following criteria: Rotnitzky–Jewell (RJ), Rule out, and Quasi-likelihood under the independence model criterion (QIC). RJ criteria³¹ state that the working correlation structure should be close to the true structure with Huber-White (robust) Sandwich Estimation of the standard errors, which is considered robust to misspecification.^{32, 33} Rule out criteria considers that, in practice, failure of convergence for a GEE would be used to rule out the correlation structure under consideration.³⁴ Using GEE also allowed us to account for incomplete biomarker data (e.g. when not available at each follow-up time point during the subject’s ICU stay). If a particular subject was missing one or more out of 14 repeated measurements, the remaining available data was used in the analyses, instead of forcing the subject to drop out.

We performed several analyses of circulating biomarkers using BMI as a continuous or categorical variable. We also used Quasi-likelihood under the Independence model criterion (QIC) and Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC) to confirm the best fitting model when using BMI as a continuous or categorical variable. To interpret rate of change of the circulating biomarker for each unit increase in the BMI, we presented the findings for the continuous scaled BMI. For further sensitivity analyses we performed subgroup analyses limiting to those admitted to the ICU within 72 hours of hospitalization and/or those without diabetes.

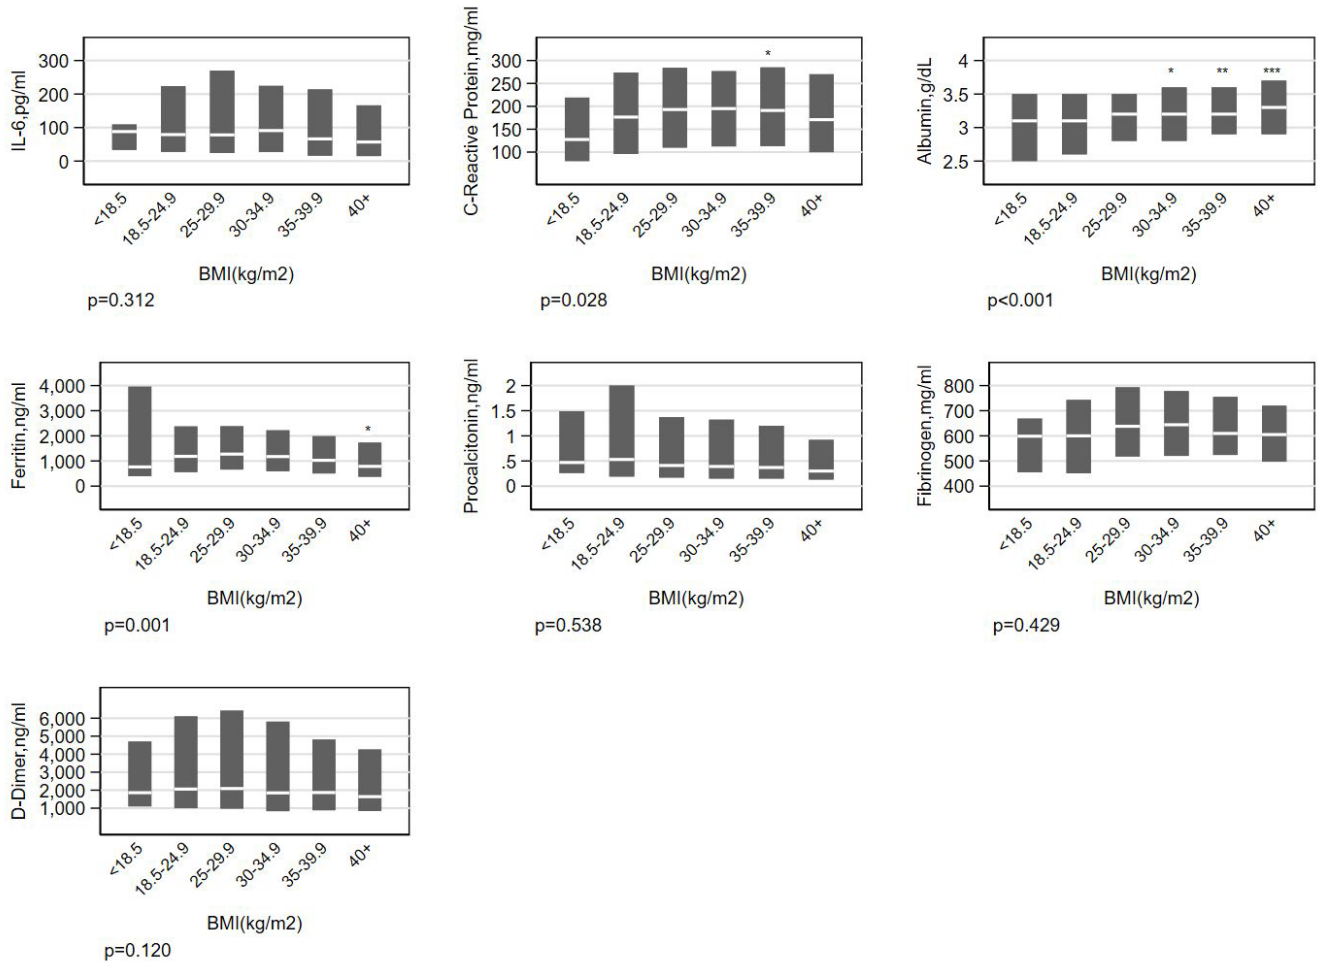

eFigure 1: Flow diagram describing exclusion criteria and number of patients available for analysis

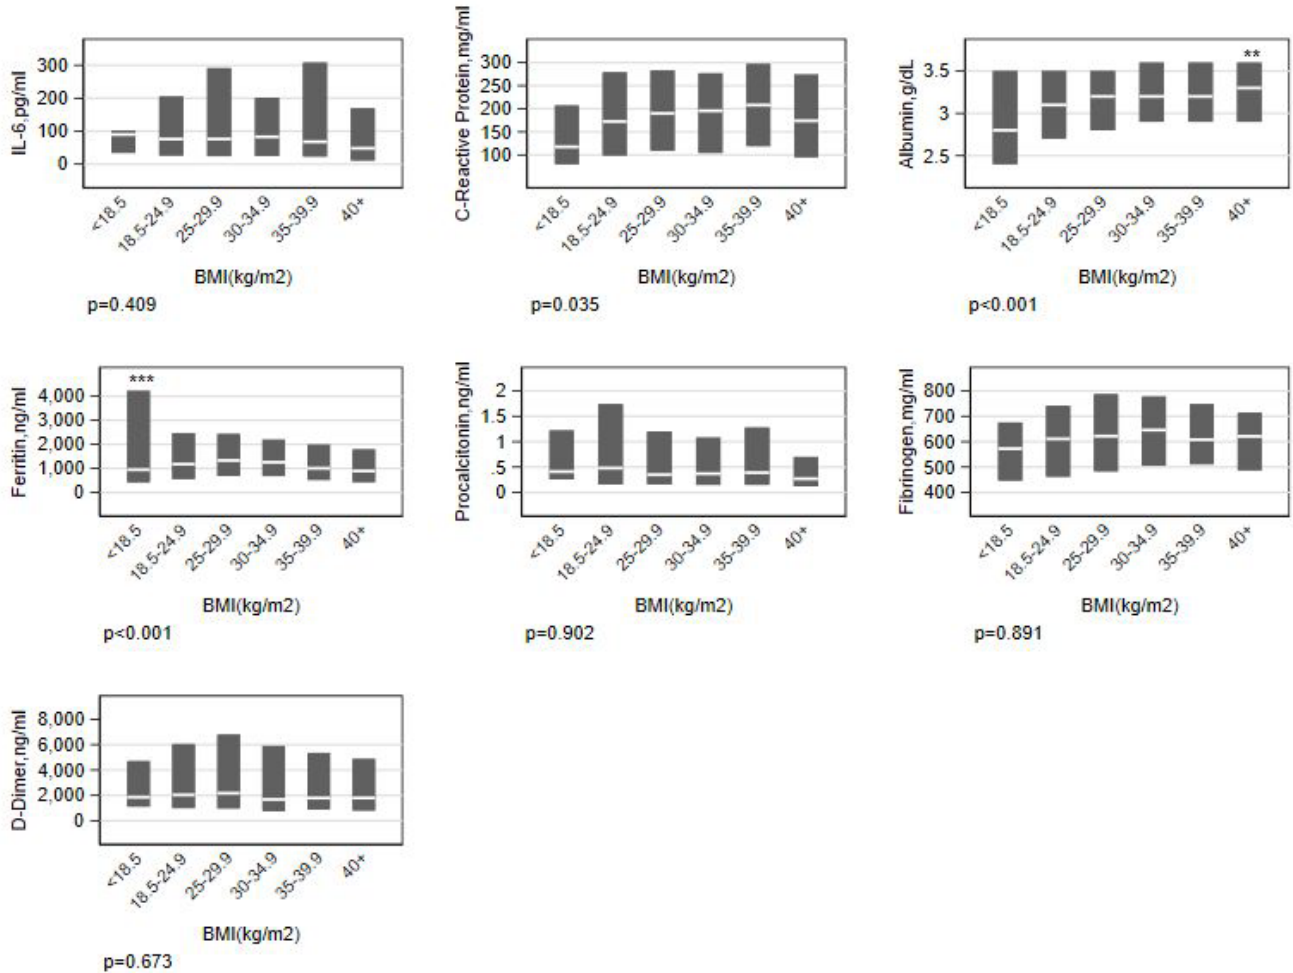

eFigure 2: Distribution of patients by BMI

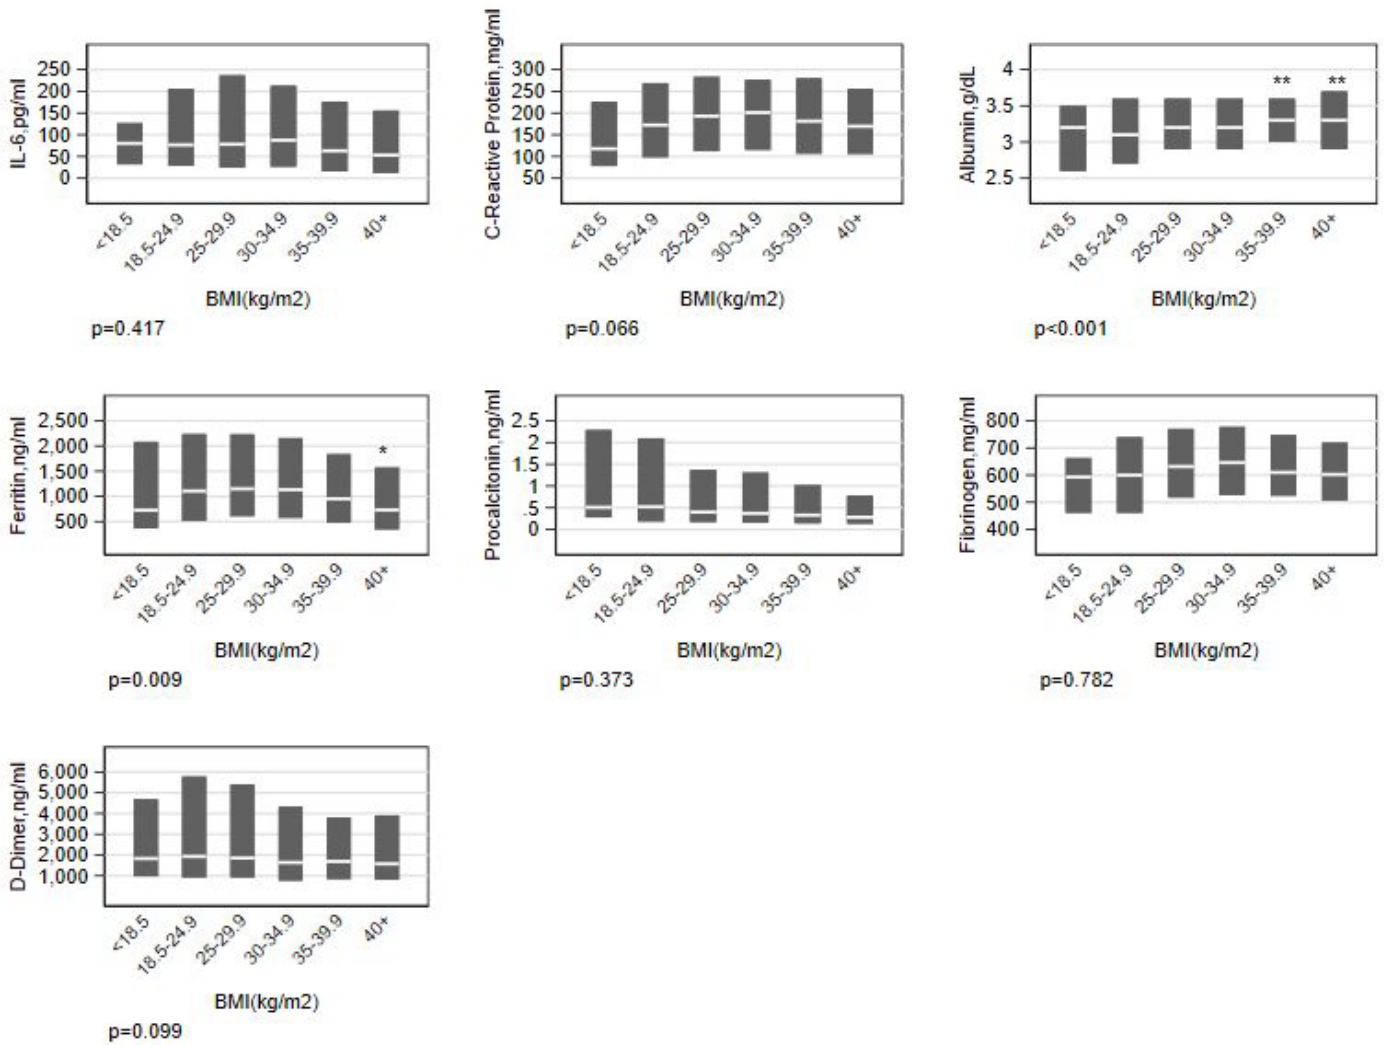

eFigure 3: Floating bar graph comparing BMI categories and levels of circulating biomarkers in the entire cohort but limited to the first 72 hours of ICU admission. The floating bar indicates the median (25-75th interquartile range). Only the highest daily values were used. P-values using Analysis of Variance (ANOVA). Tukey adjusted pairwise comparison with reference range (18.5-<25 kg/m²) for overall significance. *p<0.05; **p<0.01; ***p<0.001.

eFigure 4: Floating bar graph comparing BMI categories and levels of circulating biomarkers in patients without diabetes during the first 72 hours of ICU admission. Only the highest daily values were used. P-values using Analysis of Variance (ANOVA). Tukey adjusted pairwise comparison with reference range (18.5-<25 kg/m²) for overall significance. *p<0.05; **p<0.01; ***p<0.001.

eFigure 5: Floating bar graph comparing BMI categories and levels of circulating biomarkers in patients admitted to the ICU within 72 hours of hospitalization. Only the highest daily values were used. P-values using Analysis of Variance (ANOVA). Tukey adjusted pairwise comparison with reference range (18.5-<24.9 kg/m²) for overall significance. *p<0.05; **p<0.01; ***p<0.001.

Missing	1.33 (0.69, 2.54)
SOFA liver score	
1	1.17 (0.99, 1.38)
2	1.81 (1.46, 2.24)

Missing	1.16 (0.95, 1.42)
SOFA coagulation score	
1	1.15 (0.99, 1.34)
2	1.59 (1.33, 1.88)
Missing	1.13 (0.69, 1.84)
Treatment	
Corticosteroids	0.88 (0.72, 1.09)
Remdesivir	0.61 (0.39, 0.95)
Time Varying Covariates*	
Mechanically ventilated (versus no ventilation)	
PaO ₂ /FiO ₂ ≥ 200	0.98 (0.97, 0.99)
PaO ₂ /FiO ₂ 100-199	0.99 (0.98, 1.00)
PaO ₂ /FiO ₂ <100	0.98 (0.97, 0.99)
SOFA kidney score	
1	0.99 (0.98, 1.00)
2	0.97 (0.96, 0.99)
3	0.95 (0.92, 0.99)
4	0.98 (0.97, 0.99)
Missing	0.98 (0.94, 1.01)
Treatment	
Corticosteroids	1.02 (1.01, 1.03)
Remdesivir	1.02 (1.01, 1.03)

* Only significant (p<0.05) time varying covariates were included in the model

eTable 4: Unadjusted and Multivariable Adjusted Relationship between BMI and ARDS in Patients (N= 4907)[†]

BMI Category	Unadjusted Analysis: Hazard Ratio (95% CI)	Multivariable Analysis*: Hazard Ratio (95% CI)
<18.5	0.90 (0.66, 1.22)	0.90 (0.66, 1.23)
18.5-24.9	1.00	1.00
25-29.9	1.20 (1.09, 1.32)	1.21 (1.11, 1.33)
30-34.9	1.37 (1.22, 1.53)	1.40 (1.24, 1.58)
35-39.9	1.33 (1.20, 1.46)	1.36 (1.24, 1.48)
40+	1.26 (1.08, 1.47)	1.34 (1.15, 1.56)

*model includes BMI, age, sex, race, Hispanic ethnicity, comorbidities (hypertension, diabetes mellitus, coronary artery disease, congestive heart failure, chronic obstructive pulmonary disease, cancer, immunodeficient state, HIV), current smoker, home immunosuppressive and anticoagulation medications, absolute lymphocyte count on ICU admission, altered mentation, SOFA kidney score, SOFA liver score, SOFA coagulation score, presence of shock, interventions (corticosteroids, remdesivir), and number of ICU beds in hospital

[†]Death was treated as competing risk

eTable 5: Complete Multivariable Competing Risk Regression Model for ARDS that Includes all Patients

Variable	Hazard Ratio (95% CI)
BMI (versus 18.5-24.9)	
<18.5	0.90 (0.66, 1.22)
25-29.9	1.21 (1.11, 1.33)
30-34.9	1.40 (1.24, 1.58)
35-39.9	1.36 (1.24, 1.48)
40+	1.34 (1.15, 1.56)
Age	1.00 (1.00, 1.00)
Female (versus male)	0.93 (0.86, 0.99)
Race (versus black)	
White	1.07 (0.94, 1.22)
Others	1.21 (1.01, 1.45)
Unknown	1.11 (0.95, 1.30)
Hispanic ethnicity	1.10 (1.00, 1.22)
Comorbidities	
Hypertension	0.99 (0.92, 1.08)
Diabetes mellitus	1.04 (0.97, 1.12)
CAD	0.87 (0.79, 0.97)
Congestive heart failure	0.96 (0.86, 1.09)
COPD	0.99 (0.87, 1.13)
Cancer	0.89 (0.77, 1.03)
Immunodeficiency	0.99 (0.87, 1.13)
HIV	0.90 (0.69, 1.16)
Current smoker	1.00 (1.00, 1.00)
Home immunosuppressive medications	0.95 (0.83, 1.09)
Home anticoagulant medications	0.94 (0.85, 1.04)
Absolute lymphocyte count	
≥ 1000	0.94 (0.87, 1.01)
Missing	0.87 (0.77, 0.99)
Shock on Day 1 of ICU admission	1.34 (1.19, 1.50)
Altered mentation	
Yes	1.02 (0.92, 1.14)
Missing	1.20 (1.03, 1.39)
ICU beds in hospital	
50-199	1.05 (0.81, 1.34)
≥ 200	1.14 (0.70, 1.84)
SOFA kidney score	
1	1.14 (1.05, 1.25)
2	1.08 (0.94, 1.23)
3	0.85 (0.66, 1.08)
4	1.11 (0.99, 1.24)
Missing	1.16 (0.71, 1.89)

SOFA liver score	
1	0.93 (0.82, 1.04)
2	0.89 (0.76, 1.04)
Missing	0.68 (0.60, 0.77)
SOFA coagulation score	
1	1.06 (0.97, 1.15)
2	0.81 (0.71, 0.94)
Missing	1.09 (0.77, 1.55)
Treatment	
Corticosteroids	1.14 (0.99, 1.32)
Remdesivir	0.94 (0.78, 1.12)

eTable 6: Unadjusted and Multivariable Adjusted Relationship between BMI and AKI-RRT (N=4739)[†]

BMI Category	Bivariate Analysis Hazard Ratio (95% CI)	Multivariable Analysis*: Hazard Ratio (95% CI)
<18.5	0.77 (0.28, 2.07)	0.91 (0.29, 2.80)
18.5-24.9	1.00	1.00
25-29.9	1.68 (1.28, 2.20)	1.46 (1.10, 1.94)
30-34.9	2.17 (1.69, 2.80)	1.83 (1.37, 2.43)
35-39.9	2.27 (1.65, 3.13)	2.01 (1.44, 2.79)
40+	2.69 (2.04, 3.55)	2.27 (1.56, 3.31)

*model includes BMI, age, sex, race, Hispanic ethnicity, comorbidities (hypertension, diabetes mellitus, coronary artery disease, congestive heart failure, chronic kidney disease, cancer), current smoker, PaO₂/FiO₂ ratio in invasively mechanically ventilated patients, presence of shock, admission labs (lymphocyte count, d-dimer), SOFA liver score, SOFA coagulation score, number of ICU beds in hospital, interventions (corticosteroids, remdesivir)

[†]Death was treated as competing risk

eTable 7: Complete Multivariable Competing Risk Regression Model for AKI-RRT

Variable	Hazard Ratio (95% CI)
BMI (versus 18.5-24.9)	
<18.5	0.91 (0.29, 2.80)
25-29.9	1.46 (1.10, 1.94)
30-34.9	1.83 (1.37, 2.43)
35-39.9	2.01 (1.44, 2.79)
40+	2.27 (1.56, 3.31)
Age	0.99 (0.99, 1.00)
Female (versus male)	0.55 (0.47, 0.65)
Race (versus black)	
White	0.51 (0.40, 0.65)
Others	0.58 (0.41, 0.84)
Unknown	0.63 (0.50, 0.81)
Hispanic ethnicity	0.96 (0.71, 1.29)
Comorbidities	
Hypertension	1.46 (1.18, 1.81)
Diabetes mellitus	1.45 (1.19, 1.77)
CAD	0.90 (0.73, 1.11)
Congestive heart failure	1.05 (0.80, 1.37)
Cancer	0.94 (0.64, 1.37)
Current smoker	1.00 (1.00, 1.00)
Baseline CKD (versus no CKD)	
Stage 3	1.69 (1.28, 2.24)
Stage 4-5	4.23 (2.93, 6.11)
Missing	1.30 (1.06, 1.59)
Absolute lymphocyte count ≥ 1000 per mm³	0.96 (0.82, 1.13)
PaO₂/FiO₂ ratio (versus not receiving mechanical ventilation)	
Mechanically ventilated, PaO ₂ /FiO ₂ ≥ 200	1.62 (1.30, 2.04)
Mechanically ventilated, PaO ₂ /FiO ₂ 100-199	2.10 (1.61, 2.75)
Mechanically ventilated, PaO ₂ /FiO ₂ <100	2.73 (2.16, 3.45)
Shock on Day 1 of ICU admission	1.25 (0.95, 1.62)
D-dimer	
1000-2500	1.10 (0.92, 1.33)
>2500	1.60 (1.30, 1.97)
Missing	1.46 (1.15, 1.86)
ICU beds in hospital	
50-199	1.07 (0.79, 1.45)
≥ 200	1.05 (0.76, 1.46)
SOFA liver score	
1	0.88 (0.62, 1.24)
2	1.16 (0.79, 1.70)
Missing	0.97 (0.67, 1.41)

SOFA coagulation score	
1	1.17 (0.93, 1.46)
2	1.24 (0.86, 1.79)
Missing	NE
Treatment	
Corticosteroids	1.21 (1.01, 1.45)
Remdesivir	0.73 (0.51, 1.03)

NE, not estimable due to small sample

eTable 8: Unadjusted and Multivariable Relationship between BMI and Thrombotic Events (N=4907)[†]

BMI Category	Bivariate Analysis Hazard Ratio (95% CI)	Multivariable Analysis*: Hazard Ratio (95% CI)
<18.5	0.77 (0.30, 1.98)	0.39 (0.05, 3.17)
18.5-24.9	1.00	1.00
25-29.9	1.04 (0.87, 1.48)	1.18 (0.85, 1.65)
30-34.9	1.26 (0.94, 1.70)	1.16 (0.82, 1.63)
35-39.9	1.03 (0.73, 1.45)	0.93 (0.56, 1.53)
40+	1.21 (0.89, 1.64)	1.35 (0.86, 2.12)

*model includes BMI, age, sex, race, Hispanic ethnicity, comorbidities (hypertension, diabetes mellitus, coronary artery disease, congestive heart failure, chronic obstructive pulmonary disease, chronic liver disease, alcoholism, cancer, immunodeficient state), current smoker, home medications (immunosuppressives, anticoagulants), ICU admission labs (lymphocyte count, WBC, platelets, d-dimer, fibrinogen), PaO₂/FiO₂ ratio in invasively mechanically ventilated patients, presence of shock, SOFA kidney score, SOFA liver score, treatment interventions (corticosteroids, remdesivir);

[†]Death was treated as competing risk in this model

eTable 9: Complete Multivariable Competing Risk Regression for Thrombotic Events

Variable	Hazard Ratio (95% CI)
BMI (versus 18.5-24.9)	
<18.5	0.39 (0.05, 3.17)
25-29.9	1.18 (0.85, 1.65)
30-34.9	1.16 (0.82, 1.63)
