Abstract

Understanding and communicating the risk of pregnancy complications post-living kidney donation is imperative as the majority of living kidney donors (LKD) are women of childbearing age. We aimed to identify all original research articles examining complications in post-donation pregnancies and compared the quality and consistency of related guidelines. We searched Embase, MEDLINE, PubMed, society webpages, and guideline registries for English-language publications published up until December 18, 2020. Ninety-three articles were screened from which 16 studies were identified, with a total of 1399 post-donation pregnancies. The outcome of interest, post-donation pregnancy complications, was not calculable, and only a narrative synthesis of the evidence was possible. The absolute risk of pre-eclampsia increased from ~1%–3% pre-donation (lower than the general population) to ~4%–10% post-donation (comparable to the general population). The risks of adverse fetal and neonatal outcomes were no different between post-donation and pre-donation pregnancies. Guidelines and consensus statements were consistent in stating the need to inform LKDs of their post-donation pregnancy risk, however, the depth and scope of this guidance were variable. While the absolute risk of pregnancy complications remains low post-donation, a concerted effort is required to better identify and individualize risk in these women, such that consent to donation is truly informed.

KEYWORDS

donor nephrectomy, donor outcomes, kidney transplantation, living donor, pre-eclampsia

1 | INTRODUCTION

Living kidney donor (LKD) transplants are a valuable resource. They have a greater survival advantage compared to deceased donor transplantation or remaining on dialysis,¹ they are

cost-efficient,² and help combat the deficit in available organs. It was long believed that kidney donation did not infer a risk to the health of the LKD. Recently, some studies have called this into question,^{3,4} though this is not a universal finding^{5,6} and the absolute risk to LKDs remains low.

Abbreviations: BMI, body mass index; CI, confidence interval; CKD, chronic kidney disease; EMG, ethnic minority groups; ESKD, end-stage kidney disease; GFR, glomerular filtration rate; LKD, living kidney donors; MeSH, medical subject headings; OR, odds ratio.

Maria Pippias and Laura Skinner are joint first authors.

Kidney donation results in a degree of kidney function loss; by 10 years post-donation 12% of LKDs will have an estimated glomerular filtration rate (GFR) of <60 ml/min.⁷ Piccoli et al., demonstrated that even early stages of chronic kidney disease (CKD) can lead to an increased risk of adverse events in pregnancy.⁸ As the majority of LKD are women of childbearing age,⁹ it is vital that a clear picture of the risks associated with pregnancy post-kidney donation is obtained and that the available guidance is comprehensive.

We performed a systematic review to answer the question “Are LKD at an increased risk of pregnancy-induced complications following a donor nephrectomy, compared to the risks of pregnancy-induced complications in healthy women who have not undergone a donor nephrectomy?” Second, we identify guidelines, consensus statements, and expert opinions which include the issue of pregnancy in LKD. Third, we identify areas which could be addressed in guidelines focusing on pregnancy in LKD.

2 | METHODS

2.1 | Systematic review of pregnancy outcomes in LKD

On December 18, 2020, a PubMed, EMBASE, and Cochrane library search was performed for the medical subject headings (MeSH) terms and text words for kidney transplantation, living kidney donor combined with the MeSH terms for pregnancy; maternal, fetal, pregnan*, nephrect*, kidney, rena*, nephro*, postdona*, and donation (Figure S1).

All study designs which included LKD with a post-donation pregnancy with any maternal or fetal complication were included. Publications were limited to human-based, English-language studies, without time limits for the length of follow-up or publication date. Nephrectomies for non-donation causes were excluded. Initial screening of study titles and abstracts was independently performed by three authors (MP, LS, and KJJ) using Rayyan software.¹⁰ Disagreements were resolved by consensus or discussion with a third reviewer. Eligibility assessment of the full article and data extraction was performed independently by two authors (MP and MN, LS, or KJJ). A pre-specified list of maternal, fetal, and neonatal outcomes was extracted as proportions and/or odds ratios without limitations on outcome domains, that is, all time points were included (Table S1, Appendix S1). The reference lists of relevant publications were hand-searched. Study authors were directly contacted when clarification was required, that is, uncertainty over study duplication¹¹ or missing data.¹²

MP and LS independently assessed the risk of bias pertaining to a study's participant selection, ascertainment of exposure, and assessment of outcomes using the Risk Of Bias In Non-randomized Studies of Interventions (ROBINS-I) tool.¹³ Consensus was reached using dialogue. The plots for visualizing the risk-of-bias assessments were created using the robvis web app.¹⁴ Certainty in the study was assessed using the GRADE approach to rating certainty.¹⁵

Populations were grouped as pre-donation, post-donation, and general population. Bar charts were used to graphically represent

the percentage of hypertensive disorders in pregnancy and fetal complications by population group as reported in studies deemed moderate/low risk of bias. A lack of consistent outcome definitions and the heterogeneity of the controls inhibited a pre-specified meta-analysis. Heterogeneity was informally investigated by structuring figures and tables by study design.¹⁶ See the PRISMA 2020 checklist (Appendix S2).

2.2 | Guidelines, consensus statements, and expert opinions

A PubMed search was performed for the MeSH terms and text words for guidelines (practice guideline(s), clinical practice guideline(s), standards, consensus statement, and consensus) combined with the MeSH terms for kidney transplantation and living kidney donor. Furthermore, national renal bodies' websites were examined along with a Google search and a hand-search of the relevant guidelines' reference lists. Based on the available studies of pregnancy outcomes in LKD, which from 2009 were far superior in terms of study design to prior studies, we limited the inclusion of guidelines to those published from 2010 onwards. Where two guidelines from the same group had been published since 2010, we included the most recent.

3 | RESULTS

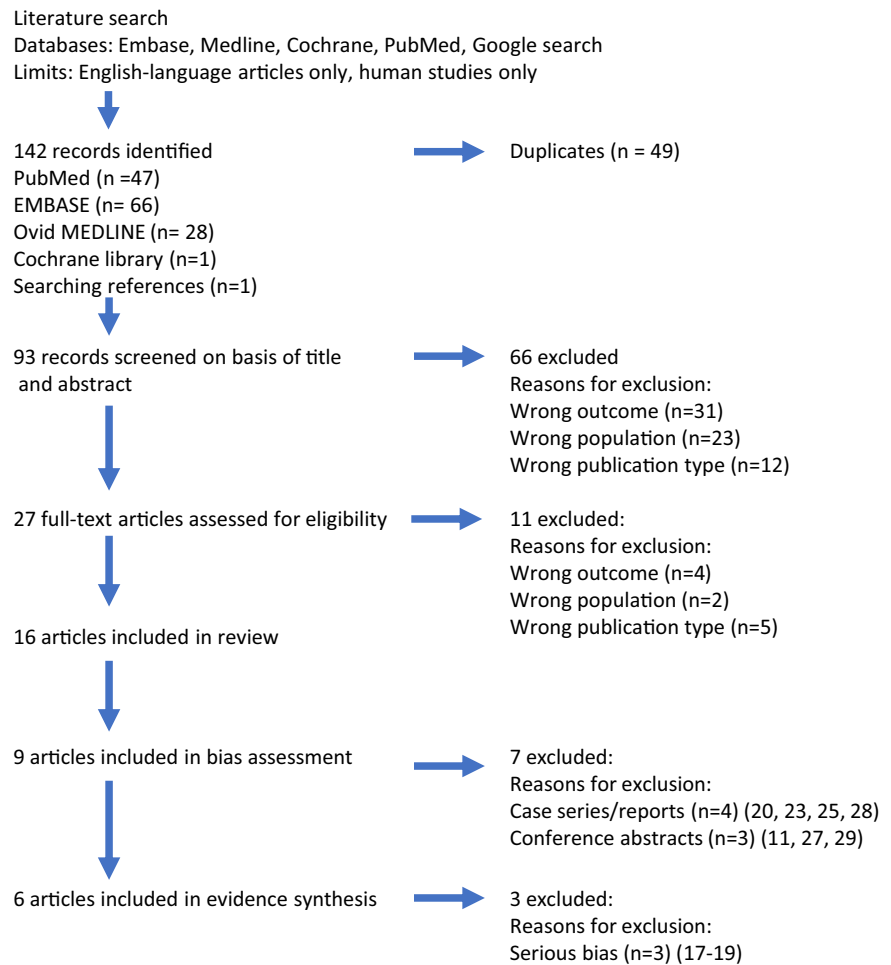

3.1 | Systematic review of pregnancy outcomes in LKD

Of the 93 articles identified, 66 were excluded based on the initial title/abstract screening, leaving 27 for full screening; 16 articles were included in the systematic review (Figure 1).^{11,12,17-30} These were published over 35 years (1985–2020), from eight countries (Table 1). Four case studies/series were identified but not discussed further.^{20,23,25,28} Risk-of-bias, varied from low^{21,24,26} to moderate^{12,22,30} to serious¹⁷⁻¹⁹ (Figure 2). Studies with a low risk of bias were broadly consistent in the direction of their findings. The certainty in the evidence was deemed low for the outcomes gestational hypertension and pre-eclampsia (Table 2) and very low for gestation (<37 weeks) and birthweight (<2500g, Table 2). The percentage of hypertensive disorders in pregnancy and fetal complications in the pre-donation, post-donation, and general population are summarized in Figures 3 and 4, respectively. Although all pregnancy complications were included, the predominant complications identified were hypertensive disorders of pregnancy, proteinuria, and gestational diabetes.

3.2 | Maternal outcomes

The initial three studies by Buszta et al.,¹⁷ Jones et al.,¹⁸ and Wrenshall et al.,¹⁹ published over 25 years ago, were all US-based single-center retrospective studies, with a study design that was either a review of the medical notes, a telephone- or postal-survey, respectively. The

FIGURE 1 Selection of studies and reasons for exclusion at each stage of the systematic review.

LKD pregnancy outcomes in these studies were compared to general population outcomes and not to well-matched control groups. In 39 post-donation pregnancies in 23 LKD studied by Buszta, all women were normotensive during pregnancy.¹⁷ Similarly, none of the 25 pregnancies in 14 post-donation women in the Jones cohort were complicated by gestational hypertension.¹⁸ Wrenshall reported pre-eclampsia in 4.4% of post-donation pregnancies as compared to the general population incidence of 6%–8%.¹⁹ Based on the poor quality of these studies (i.e., high risk of recall-, survival- and response-bias, small sample sizes, and incomplete data reporting), they were excluded from Figures 3 and 4.

We identified seven retrospective cohort studies with control groups.^{11,21,22,24,26,27,30} Of these, three had a before-after design,^{21,22,30} whereby pregnancy outcomes were assessed in women both before and after LKD and three studies compared the pregnancy outcomes of LKD with ("healthy") controls.^{21,22,30} Reiser et al., via the Norwegian Renal Registry identified 408 LKD of childbearing age (≤ 45 years old) between 1967 and 2002.²¹ Using the Norwegian Medical Birth Registry, they identified 326 LKD with pregnancies before and/or after kidney donation. They compared 106 post-donation pregnancies in 69 LKD to 620 pre-donation pregnancies, and a random sample of 21 511 general population pregnancies. The incidence of gestational hypertension was similar in all groups (2.8% post-donation, 1.8% pre-donation, and 1.5% in the

general population, $p = .26$). In the adjusted analysis, pre-eclampsia occurred at double the rate in post-donation (5.7% vs. 2.6%, $p = .026$) pregnancies. The mean post-donation pregnancy age was 31.9 years, versus 25 years in the pre-donation pregnancy group. The higher rate of pre-eclampsia remained even after adjustments for maternal age, pregnancy number, and birth year.

Ibrahim et al., presented a before-and-after study by means of a postal survey to all 2102 LKD who donated between 1963 and 2007 in Minnesota, US; 75% responded. When comparing post-donation to pre-donation outcomes, there was a higher percentage of gestational diabetes (2.7% vs. 0.7%, $p = .0001$), gestational hypertension (5.7% vs. 0.6%, $p < .0001$), pre-eclampsia (5.5% vs. 0.8%, $p < .0001$), and proteinuria (4.3% vs. 1.1%, $p < .0001$). Overall, post-donation outcomes were worse than pre-donation, but similar to general population outcomes. Expanding on the same cohort, the group presented the long-term consequences of post-donation pre-eclampsia in the LKDs (followed up for 21 ± 12 years from the index pregnancy) in a 2017 abstract.¹¹ They reported an increased likelihood of proteinuria, hypertension, and eGFR decline in post-donation pregnancies complicated by pre-eclampsia, though these risks were comparable to the risks experienced by the general population with pre-eclampsia.¹¹

In a Korean study of 225 LKD, Yoo et al. (2018) compared 56 post-donation pregnancies in 39 LKD with 370 pre-donation pregnancies in

TABLE 1 Overview of the 12 studies identified, excluding case reports/series, which reported on the pregnancy outcomes in living kidney donors (LKD)

Number of LKD	Number of post-donation pregnancies	Number of control pregnancies	Donation period	Time from donation to pregnancy	Setting	Study design	Results	Conclusion	Limitations/ comments
Retrospective cohort and matched cohort studies									
1. Reisaeter et al., 2009 ²¹									
326	106 pregnancies in 69 LKD	620 in LKD pre-donation & 21000 in non-LKD	1967–2002	5 years (3.4) (mean, SD)	University Hospital, Norway	Medical Birth Registry. Controls: pre-donation pregnancies and random sample of women from the Medical Birth Registry. Before-and-after-design.	<p>The occurrence of pre-eclampsia was more common after donation than before (in adjusted analysis only).</p> <p>Pre-donation: 2.6%, post-donation: 5.7%; general population: 3.1%. Complications pre- versus post-donation: chronic HTN: 0.2 versus 0.9%; gestational HTN: 1.8 versus 2.8%; pre-eclampsia: 2.6 vs. 5.7%; birth weight < 500 g: 0.5 versus 0.9%; gestational age < 22 weeks: 0.3 versus 1.0%; stillbirth: 1.1 versus 2.8%; neonatal death (< 28 days since birth): 0.5 versus 0.0%.</p>	<p>"No differences observed in the occurrence of adverse pregnancy outcomes in donors. The finding of more frequent preeclampsia post pregnancy should be interpreted with caution given the low numbers. Supports idea that pregnancy after donation is safe, women of fertile age should not be discouraged, careful monitoring is warranted. Potential donors should be informed of the increased risk of preeclampsia with reference to the possible effect on the infant"</p>	<p>98% participants reported as white. Outcomes defined. % missing data not reported.</p>
2. Ibrahim et al. 2009 ²²									
1589	3213 pregnancies in 1085 LKD	204 pre-donation pregnancies in 98 LKD who also had 173 post-donation pregnancies and 2519 pre-donation pregnancies in 846 LKD	1963–2007	Not stated	Nephrology Clinic, Minnesota, US	Retrospective postal questionnaire with telephone follow-up of non-responders. Controls: Pre-donation pregnancies. Before-and-after-design.	<p>Post-donation pregnancies had worse outcomes compared to pre-donation pregnancies. Complications pre- versus post-donation: gestational HTN: 0.5 versus 3.5%; pre-eclampsia: 0.5 vs. 3.5%; gestational diabetes: 0.5 versus 0.6%; proteinuria: 1.5 versus 4.6% premature delivery: 7.4 versus 8.7% (OR: 1.06; 95% CI: 0.61; 1.87) fetal loss: 21.1 versus 24.3%; (OR: 1.35; 95% CI: 0.58; 3.18).</p>	<p>Post-donation pregnancy is associated with a higher likelihood of adverse outcomes whether a LKD had a pre-donation pregnancy or not. The frequency of adverse outcomes is similar and in some domains better than those reported in the general population. Importantly, there is a 7-fold increase in the adjusted risk of preeclampsia in post-donation pregnancies.</p>	<p>75% response rate. Self-reported outcomes. Subject to selection bias and recall bias, survival bias, response bias. 24–39% loss to follow-up rate. 97% of responders reported as white. Outcomes defined.</p>

Conference abstracts									
10. Ibrahim et al., 2017 ¹¹									
2360	311	0	1963–2013	Not stated. Follow-up 25 ± 12 years from donation, 21 ± 12 years from pregnancy.	Nephrology Clinic, Minnesota, US	Retrospective questionnaire	Outcomes in LKDs with pre-eclampsia (N = 38) versus LKD without pre-eclampsia (N = 273): LKDs with pre-eclampsia were younger at time of donation (23 ± 4 vs. 27 ± 6, <i>p</i> < .001) and a lower proportion had a pregnancy prior to donation (24% vs 54%, <i>p</i> < .001). ESKD: 1 versus 0; Hypertension: 55% versus 27%; Diabetes mellitus: 18% versus 7%; Proteinuria: 18% versus 6%. LKDs with pre-eclampsia were more likely to develop hypertension and proteinuria.	"LKDs with preeclampsia after donation are more likely to become proteinuric, hypertensive and their eGFR may decline at a faster rate. These outcomes are, however, comparable to what is seen in women with a history of PE and two kidneys and also male donors."	Abstract. Note this includes the 173 post-donation pregnancies previously reported in. ²² Ethnicity not reported.
11. Lee et al., 2019 ²⁷									
248	248	5 665 539	2005–2014	Not stated	Multi-center, California, Florida, and New York, US	Retrospective cohort. Controls: all other pregnancies 2005–14 listed on the Healthcare Cost and Utilization Project State Inpatient Databases.	No difference in risk for hypertensive disorders of pregnancy. Donors had increased risk of membrane-related disorders (OR 1.48, 1.01–2.11, <i>p</i> = .045) and a decreased risk of gestational diabetes (OR 0.53; 0.30–0.96, <i>p</i> = .037).	"Future research should assess risk against matched controls to elucidate the impact of kidney donation on women of child-bearing age."	Abstract. 10.9% of participants reported as Black.
12. Kara-Hadjj Safi et al., 2019 ²⁹									
66	5 pregnancies	0	2007–2017	Not stated	Single-center, Tlemcen, Algeria	Descriptive study of 100 (male and female) LKDs at least 1-year post-donation.	No maternal or fetal complications seen.		Abstract. Unable to contact corresponding author to clarify numbers.

FIGURE 2 Traffic light plot of the domain level, risk of bias judgments for each individual retrospective cohort, and matched-controlled studies and retrospective descriptive studies without a control group. *Additional information on missing data obtained by direct contact with author.

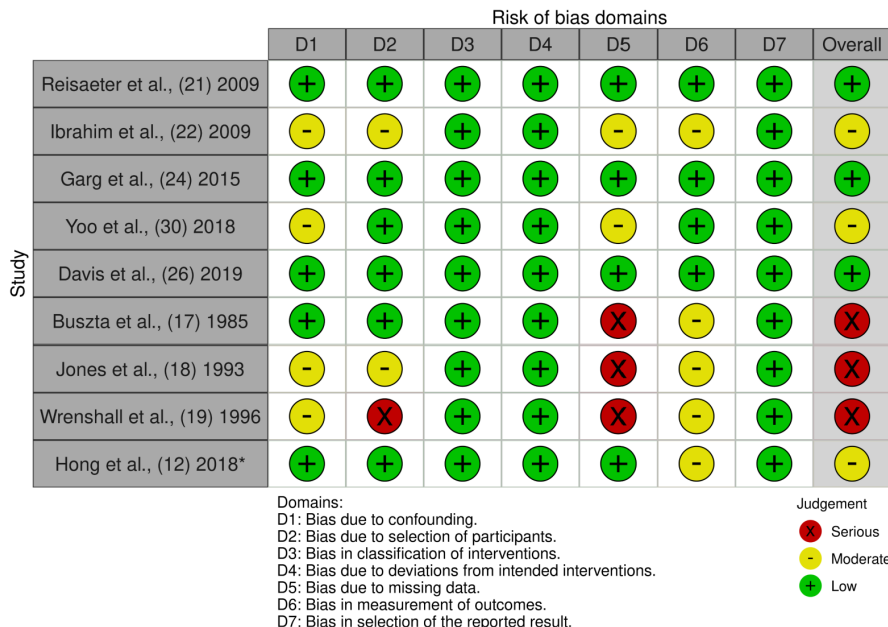

TABLE 2 Outcomes and certainty of evidence

Maternal outcomes	Effect	Number of pregnancies/events overall/events in donors	Number of studies	Certainty in the evidence
Pre-eclampsia	The occurrence of pre-eclampsia was more common in LKD after donation, compared to before donation or in the general population.	27904/812/56	5	Low ⊕⊕○○○
Gestational hypertension	The occurrence of gestational hypertension was more common in LKD after donation, compared to before donation or in the general population.	27904/464/55	5	Low ⊕⊕○○○
Fetal outcomes	Effect	Number of pregnancies/events overall/events in donor pregnancies	Number of studies	Certainty in the evidence
Gestation <37 weeks	The occurrence of delivery <37/40 weeks gestation appears to be more common in LKD after donation, compared to before donation or in the general population.	27904/1728/90	5	Very low ⊕○○○ due to imprecision and inconsistency
Birthweight <2500g	The occurrence of a birthweight <2500g appears to be more common in LKD after donation, compared to before donation or in the general population.	27904/1221/22	3	Very low ⊕○○○ due to imprecision and inconsistency

Note: Certainty in evidence assessed by methodological limitations of the studies, indirectness, imprecision, inconsistency, and likelihood of publication bias.

186 pre-LKDs and with 437 propensity-matched non-donor pregnancies. There were no significant differences between the incidence of gestational hypertension (5.4% post-donation vs. 2.7% pre-donation, $p = .282$; and 4.1% in non-donors, $p = .889$) or pre-eclampsia (3.6% post-donation vs. 2.4% pre-donation, $p = .616$; and 2.7% in non-donors, $p = .704$). Post-donation women were older with a higher body mass index (BMI) and were more likely to undergo cesarean section.³⁰

Three studies compared outcomes to the general population. Garg et al. (2015)²⁴ compared 131 post-donation pregnancy outcomes in 85 LKD who donated during 1992–2010 in Ontario, Canada

to a healthy general population cohort of 510 women with 788 pregnancies. The risk of gestational hypertension or pre-eclampsia was higher in LKDs (11% vs. 5%, odds ratio [OR]:2.4, 95% confidence interval [CI]:1.2–5.0, $p = .01$). Older LKD mothers (>32 years) had a significantly higher likelihood of these outcomes (OR:9.4, 95% CI:3.2–27.5). In pregnancies occurring >2 years from donation/cohort entry the odds of gestational hypertension or pre-eclampsia was 3.6 (95% CI:1.6–8.3) times higher in LKD.

Lee et al. (2019, conference abstract) retrospectively reviewed 5 665 787 pregnancies, from US centers, recorded in the Healthcare Cost

FIGURE 3 Hypertensive complications in pregnancy in the pre-donation, post-donation, and general population presented by study for pre-eclampsia (upper panel) and gestational hypertension (lower panel).

and Utilization Project State Inpatient Databases.²⁷ The same proportion of hypertensive complications were noted in the 248 LKD post-donation pregnancies compared to the 5 665 539 non-donor pregnancies. LKD had an increased risk of premature rupture of membranes and oligohydramnios (OR: 1.48, 95% CI: 1.01–2.11, $p = .045$) but a decreased risk of gestational diabetes (OR: 0.53, 95% CI: 0.30–0.96, $p = .037$).

Davis et al. (2019) using the Intermountain Healthcare Enterprise Data Warehouse, compared pregnancy outcomes in 59 LKD (≥ 2 years after donation) with 236 age- and race-matched controls.²⁶ The risk of pre-eclampsia/eclampsia was not statistically different between the groups (OR: 2.96, 95% CI: 0.98–8.94, $p = .06$). LKD ≤ 30 years, had a four-fold increased risk of pre-eclampsia/eclampsia (OR: 4.09, 95% CI: 1.07–15.59, $p = .04$). Although the number of women in this sub-group was not stated and the observed differences may be confounded by the absence of co-morbidity-matched controls.

3.3 | Fetal and neonatal outcomes

In most studies, there were no differences in adverse fetal and neonatal outcomes between post-donation, pre-donation, and

non-donor pregnancies (Figure 4). Reisaeter and Garg found similar rates of low birthweight (< 2500 g) or premature (delivery < 37 weeks) neonates.^{21,24} In the study by Yoo, no neonates from post-donation pregnancies were of a low birthweight, although it should be mentioned that this was defined as < 2800 g, as compared to the more widely adopted threshold of < 2500 g.³⁰

There were no fetal or neonatal deaths in the post-donation cohort studied by Garg and similar death rates between groups in the studies by Reisaeter and Yoo (2018).^{21,24,30} In contrast, Ibrahim reported an increase in fetal loss (OR: 1.83, 95% CI: 1.37–2.46) and premature deliveries (< 36 weeks) (OR: 1.90, 95% CI: 1.03–3.48).¹¹ However, fetal loss was reported as a composite of fetal death, miscarriage, and abortion. No statistical analysis is offered to compare fetal death specifically, though rates were lower in post-donation pregnancies (2.1% vs. 4.9%).

3.4 | The available guidance: what is recommend?

Table 3 lists the eight clinical practice guidelines,³¹⁻³⁸ three consensus statements,³⁹⁻⁴¹ and four expert-opinion papers,⁴²⁻⁴⁵ all published between 2010 and 2020.

FIGURE 4 Fetal complications in pregnancy in the pre-donation, post-donation, and general population presented by study. From top to bottom: gestation <37 weeks, birthweight <2500g, infant death <28 days/transfer to NCCU, and fetal death.

Four guidelines and two consensus statements recommended enquiring into previous pregnancy complications during the assessment of a potential LKD.^{31,32,35,40,41} Six guidelines recommended informing the potential LKD of the increased risk of post-donation pregnancy complications.^{31,33-37} One consensus statement suggested that alternative donors should be sought for women who had not completed their family and had a history of pre-eclampsia.⁴⁰ The 2017 KDIGO guidelines advised against excluding women solely on their desire to conceive post-donation and suggested that women with a history of pre-eclampsia may be suitable donor candidates.³⁵ Three guidelines^{31,35,37} and two consensus statements^{40,41} suggested increased or close follow-up of pregnant LKD. The UK Renal Association guideline suggested all LKD were offered low dose aspirin to reduce the risk of pre-eclampsia.³⁸

Some guidelines gave conflicting information, for example, one guideline stated that “no additional risks have been described during the pregnancy of patients having donated a kidney”. However, they then specified that the consent form should state: ‘If you want to become pregnant after donation, you must inform your gynecologist as you are more likely to suffer from high blood pressure or diabetes during pregnancy.’³¹

The consensus from the expert opinions was that women should be counseled on the increased likelihood of gestational hypertension or pre-eclampsia (Table 2).^{39,41-46}

Mandelbrot et al. recommended quantifying this increased risk, advising clinicians state that “overall the rates of gestational hypertension or pre-eclampsia increase from ~5% to 11%.”⁴¹ However, they continued by recommending that pregnancy care is tailored according to a woman’s individualized risk of complications, taking into consideration the impact of race, BMI, and age on their risk of pre-eclampsia.⁴¹ Lentine and Segev point out that potential LKD must also be informed that most women had uncomplicated pregnancies after kidney donation.⁴⁵

4 | DISCUSSION

We performed a systematic review to answer the question “Are LKD at an increased risk of pregnancy-induced complications following a donor nephrectomy, compared to the risks of pregnancy-induced complications in healthy women who have not undergone a donor nephrectomy?” We found nine relevant studies, the consensus from which was that the maternal risks associated with pregnancy in LKD

2016			1–3,6–8				<p>"Female donors should be reassured."</p>
Lentine and Segev; Understanding and communicating medical risks for living kidney donors: A matter of perspective ⁴⁵							
2016	US		1–3,6–8				<p>"For women of childbearing potential considering donation, we agree with recommendations of a recent AST LDCOP consensus statement that counseling should include the possibility of increased risk of gestational hypertension and preeclampsia after donation compared with experience in otherwise similar healthy women. A balanced presentation, however, should also note that in available studies, most women had uncomplicated pregnancies after kidney donation."</p>

increased from the pre-donation risk. In relative terms, donation took LKDs from a risk level below that of the general population prior to kidney-donation, to a risk level comparable to that of the general population post-kidney donation. Risk of adverse fetal and neonatal outcomes was not different between post-donation and pre-donation pregnancies.

The main limitations of these studies were a low number of post-donation pregnancies and event rates, the choice of relevant outcome measures, limited generalizability of the study groups, and the lack of suitable comparators. In the largest study using a before-and-after design, there were six cases of pre-eclampsia and six of gestational hypertension in 173 post-donation pregnancies.²² The largest matched-cohort study by Garg reported on 131 post-donation pregnancies, of which 15 were complicated by pre-eclampsia and hypertension and eight babies were born before 37 weeks gestation.²⁴

Wiles et al., demonstrated that hypertension (rather than eGFR) is the strongest predictor of pre-term (<34 weeks) delivery (OR: 16.5, 2.74–∞) in women with CKD.⁴⁷ Furthermore, they reported an increased likelihood of low birthweight infants born to women with proteinuric CKD.⁴⁷ These pre-pregnancy parameters were not reported in any of the studies. While, in the absence of proteinuria, LKDs are not considered to have CKD, screening for proteinuria and/or hypertension should form part of the pre-pregnancy work up to better inform women of their risk of adverse fetal outcomes. This would also aid in identifying women who are likely to require increased surveillance in pregnancy for the development of superimposed pre-eclampsia, given the challenge in diagnosing this condition in women with pre-existing hypertension, proteinuria, and a single kidney. Overall, however, the equally low rates of fetal complications in post-donation and pre-donation or general population pregnancies can be used to provide relative reassurance to women undergoing LKD that their likelihood of placental disease affecting the fetus is unchanged by donation.

The generalizability of the results of these studies is limited to white women, as up to 98% were of this ethnicity (Table 1). Information on post-donation risk of hypertensive complications of pregnancy in ethnic minority groups (EMG) cannot be inferred from the studies to date. Women from EMG are known to have a higher risk of pre-eclampsia.⁴⁸ Moreover, a recent review suggests that African American women with pre-eclampsia experience more severe hypertension and increased mortality as compared to women of other ethnicities.⁴⁹ As such, more studies documenting the pregnancy outcomes of non-white LKDs are required to better inform post-donation risk in this group.

The lack of a suitable comparator has been a particular problem when analyzing long-term post-donation risk. Until 2009, the studies by Buszta, Jones, and Wrenshall were the body of evidence with which guidelines on pregnancy risk in LKD were issued.^{50,51} These studies compared the pregnancy outcomes of LKD to known outcomes in the unscreened general population. LKD are not a random subset of the population, rather an extensively screened group who

are deemed to be at low risk of end-stage kidney disease (ESKD). Given the overlap between risk factors for hypertensive complications of pregnancy, and those for ESKD (e.g., BMI >35 kg/m², CKD, diabetes mellitus), comparison of LKDs to the general population is unlikely to yield accurate attributable risk.^{35, 52-54}

To solve the conundrum of the adequate control group three studies included the pregnancy outcomes of the LKD both pre- and post-donation. Although the before-and-after design is useful for assessing short-term impacts, "threat to internal validity" may occur when assessing long-term impacts. Over a longer period, one is more likely to develop a confounding condition which may obscure the effects of an intervention, for example, an increased BMI post-donation. While the before/after design may appropriate risk more accurately than comparison to the general population, a more accurate comparator would be potential LKDs considered suitable for donation who did not proceed to donate. Accurate coding of these individuals in healthcare databases would allow for this group to be identified and their outcomes investigated.

The final limitation of all the studies reviewed was the absence of information on the LKD who did not have a post-donation pregnancy and the reasons why. Therefore, potential medical or psychosocial consequences of donation that may have precluded pregnancy in LKDs remain unknown.

As a result of the small sample sizes and inconsistent comparator groups, we were unable to perform a meta-analysis to provide a single estimate of effect. Our search for studies was comprehensive, albeit limited to English language studies. Furthermore, we do not strongly suspect publication bias as both negative and positive studies have been published.

Our second aim was to identify guidelines, consensus statements, and expert opinions which included the issue of pregnancy in LKD. While the guidelines offered albeit limited guidance on the acceptance of women of childbearing age as potential LKD, they were broadly consistent in stating that overall pregnancy after kidney-donation was of a risk similar to that of the general population and that women should be informed of this risk. They varied in their guidance regarding enquiring into prior pregnancy-induced complications, such as gestational diabetes and post-donation pregnancy care.³⁴ The 2017 KDIGO guidelines state that, "*women should not be excluded from donation solely on...a desire to have children after donation.*"³⁵

More recent guidelines tended to be more comprehensive in their guidance, increasingly recognizing the importance of individualizing care. For example, as opposed to the blanket exclusion of women who have yet to complete their families, KDIGO and Canadian expert commentaries suggest that history of previous hypertensive disorders of pregnancy should be used to inform the prediction of individual post-donation pregnancy risk and as such guide decisions as to potential LKD acceptability.^{35,40} Similarly, expert consensus from the US published in 2020 suggests that care in post-donation pregnancies should be tailored to individual risk.⁴¹ This is particularly important given the increasing rates of obesity

and older-age pregnancy, both factors recognized to increase risk of pregnancy complications.⁴²

4.1 | Communicating risks

Lentine and Segev propose that informed consent must be based on informing potential LKD of their baseline (pre-donation) risk, the risk attributable to donation and their subsequent absolute (post-donation) risk of adverse pregnancy outcomes.⁴⁵

Baseline risk comprises demographic (e.g., age, ethnicity) and clinical (e.g., BMI, smoking status) characteristics, which in combination with the risk attributable to donation, can be used to calculate an absolute risk score for hypertensive complications of pregnancy. Established perinatal registries could be used to calculate the baseline risk of hypertensive disorders of pregnancy. To be able to combine both the baseline risk and the risk attributable to donation to create the absolute risk score, linkage of perinatal registry data to a

BOX 1 How can the guidance and consent procedure on pregnancy outcomes in LKD be improved?

1. Post LKD pregnancy risk needs to be personalized in light of the changing profile of the LKD who is increasingly older and more often overweight at the time of donation.
2. The additional post-donation risk of pregnancy complications in LKD should always be seen in light of the national or regional baseline risk of adverse pregnancy outcomes.
3. The absolute risk of hypertensive-pregnancy complications in LKD should be available in a risk-stratified manner, for example, by age, BMI, and ethnicity, however, further studies powered to detect differences between these population sub-sets are required to provide this information.
4. Informing potential LKD of their overall level of risk, taking into consideration the risks outlined in 1–3, should form part of the LKD consent process.
5. There should be uniformity in enquiring about previous pregnancy-associated complications, that is gestational diabetes and hypertension, and neonatal complications while consenting for LKD.
6. Clearer guidance on LKD pregnancy follow-up is needed. LKD should be secured follow-up according to general international guidelines for pregnancies. Furthermore, they should be risk evaluated and referred to specialist obstetric care if deemed to be at increased risk.
7. It would be best to utilize more recent guidelines as those published prior to 2015 require revision.

BOX 2 Future research priorities and recommendations

1. Living kidney donor registries should collect the baseline characteristics required to calculate attributable risk of living kidney donation to hypertensive disorders of pregnancy, that is ethnicity, previous hypertensive disorders of pregnancy, and body mass index.
2. The baseline risk of hypertensive disorders of pregnancy should be determined using data held in perinatal registries.
3. Risk prediction models for hypertensive complications of pregnancy in LKD should be developed by linking LKD and perinatal registry data. One should accept that these registries, in the short term, may lack some variables required to individualize risk, that is, ethnicity.
4. LKD registries should prospectively collect data on suitable LKDs that did not proceed to donation. This will improve the quality of control groups required to understand long-term LKD outcomes.
5. Qualitative research to understand prospective LKDs' concerns surrounding post-donation pregnancy is needed.
6. The long-term health consequences of hypertensive pregnancies in women post-kidney donation should be established.

robust large dataset, such as a prospective LKD registry is required. In an ideal scenario, the absolute risk of hypertensive pregnancy complications for the potential LKD would be derived by inputting baseline characteristics into a predicted risk calculator, such as www.transplantmodels.com.

Additionally, potential LKDs should be informed of the long-term maternal consequences of pregnancy-induced hypertensive complications. In the general population, pre-eclampsia is associated with a greater than two-fold risk of death from cardiovascular disease, a 5- to 9-fold increased risk of ESKD and an increased risk of diabetes.⁵⁵⁻⁵⁸ A recent study found that women with a pre-donation pregnancy complicated by gestational hypertension had an increased risk of developing post-donation hypertension, as compared to LKDs without pre-donation gestational hypertension.⁵⁹ Population-based prospective LKD registries could be used to examine the association between post-donation hypertensive disorders of pregnancy and risk of long-term maternal cardiovascular and kidney disease to better inform potential donors.

Given the uncertainties surrounding post-donation hypertensive complications in pregnancy, the communication of risk to potential LKDs remains challenging. In a recent survey of 392 transplant professionals from 30 countries, there was marked variability in the frequency with which adverse pregnancy outcomes were discussed. Fifty-six percent of respondents always discussed pre-eclampsia,

BOX 3 A summary for practitioners counseling women on pregnancy post-living kidney donation

To date, 16 studies, published over a 35-year period with follow-up of 1399 post-donation pregnancies have been performed. As all these studies are slightly different, we cannot say with precision what the average risk or risk to the individual woman and their baby is.

The pregnancy-associated complications that have been most studied are hypertension in pregnancy and pre-eclampsia. On average, the occurrence of hypertension in pregnancy changed from 1%–9% pre-donation or in non-donors to 4%–12% post-donation. Pre-eclampsia changed from 1%–3% pre-donation or in non-donors to 4%–10% post-donation.

The risks to babies that have been reported are mainly limited to premature delivery, low birth weight, and transfer to the intensive care unit or death. Overall, there was no difference in the risk to babies born to kidney donors compared to the general population. Screening for pre-pregnancy hypertension and/or proteinuria in post-LKD women planning pregnancy can be used to individualize risk of adverse fetal outcomes.

12% often did, 12% rarely did and 6% never discussed it. Only 20% of respondents were able to accurately answer questions on absolute versus relative risk for rare outcomes.⁶⁰ While this survey may be subject to the inherent biases of self-reports, it suggests there is a need to improve and standardize the communication of risk to potential LKDs. [Box 1](#) lists our guidance on this topic, [Box 2](#) lists our recommendations for future studies, and [Box 3](#), provides a guide for practitioners counseling potential LKDs.

5 | CONCLUSION

The increased risk of hypertensive disorders in pregnancy post-donation is evident in four retrospective studies, although all were limited to some extent by sample size and the lack of well-matched controls. Though the relative risk of pregnancy-related complications in LKD increases relative to the risk in the non-donor, the absolute risk remains very low. The risk of long-term complications from hypertensive disorders in pregnancy is minimal.^{57,61} Perhaps, the combination of these two factors is the reason why LKD guidelines vary in the degree of attention paid to this issue. The LKD of the future is likely to differ from the LKD of yesterday. As such more focus should be placed on better identifying and individualizing risk for LKD in the face of both older age and higher BMI at kidney-donation and subsequent pregnancy, and in non-white LKD. Only by doing so will consent to donation be truly informed.

For now, one should keep in mind that a potential LKD's personalized risk remains unknown, however, the consensus is that a LKD could be reassured that the absolute risk of post-donation pregnancy complications to mother and baby remains low.

DISCLOSURE

The authors of this manuscript have conflicts of interest to disclose as described by the *American Journal of Transplantation*.
