## Abstract

Currently, there is no evidence whether ganciclovir, or its oral prodrug valganciclovir, penetrates into the cerebrospinal fluid of human infants treated for congenital cytomegalovirus infection. Here, we report a case study providing evidence that ganciclovir, administered as valganciclovir, reaches the infant's cerebrospinal fluid when used at the currently recommended dose for congenital cytomegalovirus infection.

**Keywords:** Valganciclovir, Ganciclovir, Cytomegalovirus, Cerebrospinal fluid, Congenital infection

## Background

Ganciclovir (GCV) is the drug of choice for the treatment of congenital cytomegalovirus (CMV) infection. In fact, 6 weeks intravenous GCV therapy, compared with no treatment, has been demonstrated to significantly prevent hearing deterioration [1] and developmental delays [2] in infants with congenital CMV infection involving the central nervous system. Valganciclovir (V-GCV), an oral pro-drug of GCV, nowadays represents a valuable alternative to GCV and, compared to GCV, does not require prolonged hospitalization and catheterization, thus avoiding considerable costs for the Health Care System, and infectious risks for the infants [3]. For both these drugs, cerebrospinal fluid (CSF) penetration has never been demonstrated in congenitally CMV infected infants undergoing antiviral therapy at the currently recommended dosages.

## Case report

A 30-year-old woman had a primary CMV infection in the first trimester of pregnancy (gestation week 9), defined by the presence of immunoglobulin (Ig) M and low avidity IgG. At gestation week 20, CMV DNA was

evidenced in the amniotic fluid sample at concentrations of  $3.8 \times 10^5$  genomic copies (GC)/mL. Intrauterine growth retardation was detected starting gestation week 30. A foetal brain magnetic resonance imaging (MRI), performed two weeks later, was normal. A small for gestational age (<10<sup>th</sup> centile for gestational age) female infant in good clinical conditions was delivered at 38 weeks gestational age. Congenital CMV infection was confirmed by means of quantitative Polymerase Chain Reaction (qPCR) performed on urine sampled on day of life (dol) 2.

On dol 11, the infant was referred to our centre to undergo a diagnostic workup for congenital CMV infection. Clinical examination, fundus oculi, abdominal and cerebral ultrasound, and auditory brainstem evoked responses were all negative; complete blood count and transaminase levels were in the normal range for the infant's age. Of note, a brain MRI performed at 1.5 Tesla (Magnetom Avanto, Siemens Medical Solution, Malvern, PA, USA) failed to find any brain lesions. CMV DNA search was performed on urine and blood samples by an automated system for nucleic acid extraction (Nuclisens EasyMag, Biomerieux) and a commercially available TaqMan Real Time Polymerase Chain Reaction kit (ELITech Group S.p.A.) for quantitative CMV DNA amplification. According to our screening procedure, and following informed consent by the parents, a lumbar puncture for cerebrospinal fluid (CSF) CMV DNA

search and CSF indices was carried out. CMV DNA was detected in all the samples tested (Table 1).

Since the CMV-DNA search in the CSF was positive, on dol 20 we decided to start antiviral treatment with a commercial oral solution of V-GCV (Valcyte®, Roche S. p.A., Segrate, Italy) at 16 mg/kg/dose twice a day. On dol 21, after the uneventful administration of two doses of V-GCV, the baby was discharged home. The drug dosage was adjusted weekly according to the weight increase. During V-GCV therapy, complete blood count, transaminase, and creatinine levels were monitored three times (on dol 27, 45, and 55 respectively) for possible drug toxicity: the first two blood tests were within the normal range for the patient's age whereas, on dol 55, a remarkable transaminase increase was detected (Alanine aminotransferase: 328 U/L, Aspartate Aminotransferase: 400 U/L). Due to the onset of liver toxicity presumably related to antiviral therapy, V-GCV was withdrawn on dol 55 (after 35 days of therapy) and never resumed. Fifteen days later, transaminase levels were in the normal range.

CMV DNA qPCR on plasma, urine and CSF samples were again performed on dol 45 (Table 1). At the same time, plasma trough and peak values (one hour before and two hours after V-GCV administration, respectively) and CSF GCV concentration (performed concomitantly with GCV plasma trough sample) were evaluated by means of High-Performance Liquid Chromatography assay with fluorescence detection (Table 1). Ongoing clinical, ophthalmological, audiological and neurological follow-up (by means of the Bayley Scales of Infant Development-III) is normal at twelve months of age.

**Table 1 Summary of the laboratory findings obtained on cerebrospinal fluid, blood, and urine samples before (dol 11) and after 25 days of Valganciclovir therapy (dol 45)**

Findings	Dol 11	Dol 45
Cerebrospinal Fluid		
Proteins	67,9 mg/dL	59,0 mg/dL
White Cells	12 cells/ $\mu$ L	9 cells/ $\mu$ L
Red Cells	141 cells/ $\mu$ L	373 cells/ $\mu$ L
CMV-DNA	2.835.371 GC/ml	Negative
GCV	-	0,52 $\mu$ g/ml
Blood		
CMV-DNA	115.068 GC/ml	821 GC/ml
GCV (trough)	-	0,53 $\mu$ g/ml
GCV (peak)	-	5,54 $\mu$ g/ml
Urine		
CMV-DNA	>25.000.000 GC/ml	619.137 GC/ml

See text for the abbreviations.

## Discussion

A randomized, controlled trial, demonstrated that ganciclovir, administered at 6 mg/kg/dose twice a day for 6 weeks intravenously, is able to prevent hearing deterioration [1] and developmental delays [2] in infants with congenital CMV infection involving the central nervous system. V-GCV, an oral pro-drug of ganciclovir that is rapidly converted into ganciclovir after intestinal absorption, reached plasma concentrations comparable to those achieved with administration of intravenous ganciclovir when used at 16 mg/kg/dose twice a day [4]. V-GCV has demonstrated to be well tolerated and is increasingly used because, compared to GCV, it does not require hospitalization and catheterization, thus avoiding considerable costs for the Health Care System and infectious risks for the infants. Moreover, V-GCV seems to be suitable for prolonged home therapy [3].

The evaluation of CSF levels is used to predict brain interstitial fluid concentrations of a drug [5]. Although GCV penetration into the CSF has been demonstrated in some reports dealing with CMV infected adults and children in different clinical situation (an adult suffering renal failure [6], a child with acute lymphoblastic leukemia who exhibited a reduced creatinine clearance [7], and two bone marrow transplanted patients on different ganciclovir regimen therapy [8]), our report provides evidence, for the first time, that GCV, administered as V-GCV, reaches the infant's CSF when used at the currently recommended dosages for congenital CMV infection [4]. Our GCV plasma trough and peak concentrations (Table 1), detected by means of a validated technique [9], were consistent with those reported in the medical literature [3]; GCV plasma (trough value) and CSF levels (trough value) were overlapping in this case (Table 1), although additional results are needed to establish any significant pharmacokinetic correlation between plasma and CSF GCV concentrations in neonates.

CMV DNA qPCR performed on CSF before and during V-GCV therapy (Table 1) showed a reduced viral load in the CSF, suggestive of effective therapy on brain infection. Although the CSF GCV concentration of 0,52  $\mu$ g/ml we reported was below the inhibitory concentration (IC) 50 for most CMV clinical isolates [10], it must be taken into account that the CSF sample was drawn concomitantly with the plasma trough sample, thus allowing a GCV CSF peak level over the requested IC 50. Besides, the CSF CMV DNA negativisation cannot be fully explained since the persistence of CMV DNA into the CSF of untreated infants is unknown.

According to published guidelines [11], and in order to prevent possible ongoing brain damage resulting from CMV replication in the infant's brain, we decided (following the parents' informed consent) to start V-GCV therapy in this patient given the positive CSF CMV

DNA and despite normal CSF indices (Table 1) and neuro-imaging. Nonetheless, in our opinion, further studies are necessary to evaluate the need for therapy, if any, in infants with positive CSF CMV DNA and undetectable brain damage.

### Consent

Written informed consent was obtained from the patient's parents to publish this Case report. A copy of the written consent can be submitted to the Editor-in-Chief of this journal.

### Abbreviations

GCV: Ganciclovir; CMV: Cytomegalovirus; V-GCV: Valganciclovir; CSF: Cerebrospinal fluid; Ig: Immunoglobulin; GC: Genomic copies; MRI: Magnetic Resonance Imaging; qPCR: quantitative Polymerase Chain Reaction; DOL: Day of life; IC: inhibitory concentration.

### Competing interests

The authors declare that they have no competing interests.

### Authors' contributions

FN and BB conceived the study, reviewed the literature, and drafted the manuscript; VC collected the data and critically revised the manuscript; AG and GL performed the CMV DNA research on the biological samples of the mother and infant; PV performed the drug dosages on plasma and CSF samples; MdC made substantial contributions to conception and design of this report and critically revised the manuscript. All authors read and approved the final manuscript.
