Abstract

A Ni/Al_2O_3 catalyst has been modified incorporating CeO_2 and MgO promoters in order to improve its performance in the steam reforming of biomass pyrolysis volatiles. Ni/Al_2O_3, Ni/CeO_2-Al_2O_3 and Ni/MgO-Al_2O_3 catalysts have been prepared and fresh and deactivated catalysts have been characterized by N_2 adsorption/ desorption, X-ray Fluorescence (XRF), X-ray powder diffraction (XRD), Temperature Programmed Oxidation (TPO), Transmission Electron Microscopy (TEM) and a technique based on Fourier Transform Infrared Spectroscopy-Temperature Programmed Oxidation (FTIR-TPO). The results obtained revealed a similar initial activity for the three catalysts tested (conversion higher than 98 %), whereas stability has been greatly improved by incorporating CeO_2 as promoter, as it enhances the gasification of coke precursors. However, Ni/MgO-Al_2O_3 catalyst is slightly less stable than Ni/Al_2O_3, presumably as a result of its lower reducibility due to the formation of $MgAl_2O_4$ spinel phase. Catalysts deactivation has been associated with coke deposition, although sintering phenomenon became also evident when the Ni/CeO_2-Al_2O_3 catalyst was tested. The coke deposited on the catalysts does not present any specific morphology, which is evidence of its amorphous structure in the three catalysts studied.

1.   Introduction

The depletion of fossil fuels and the environmental issues caused by their excessive use make necessary to explore alternative renewable and clean energy sources. In light of this situation, the thermochemical routes of biomass valorisation have attracted increasing attention [1-4]. Thus, pyrolysis [5-8] and gasification [9-11] of biomass have been extensively studied in literature in order to obtain high value added products, such as bio-oil, syngas and hydrogen.

Fossil fuel based processes are nowadays mostly used for producing hydrogen, whose demand is growing annually, with ammonia production and oil refining being the principal applications [12]. Besides, hydrogen is a clean fuel with greater energy density than other fuels [13] and surely will play an essential role as energy carrier in the future. The most studied routes for hydrogen production from biomass are steam gasification [9, 14-16] and steam reforming of the bio-oil obtained in biomass fast pyrolysis [17-20]. However, increasing attention has been recently paid to a strategy based on biomass pyrolysis and in-line steam reforming [21-23] due to several advantages compared to gasification and bio-oil steam reforming process. On the one hand, the use of two steps allows optimizing operating conditions in each step separately [24]. Besides, the temperature used in the reforming step is lower than that used in gasification, which attenuates catalyst deactivation by Ni sintering. Moreover, the main drawback of gasification lies in the formation of tar compounds together with the syngas [25, 26], which is avoided in the pyrolysis-reforming process, i.e., an almost tar free gas product is obtained [21]. On the other hand, the steam reforming of bio-oil requires the prior condensation of the volatile stream leaving the pyrolysis reactor, its storage and the subsequent volatilization steps, which involve operational problems and are energy demanding. Furthermore, the two-step process reforms all the oxygenate compounds

55　produced in the pyrolysis of biomass and avoids the re-polymerization of phenolic

56　compounds occurring in the volatilization of the bio-oil.

57　Ni based commercial steam reforming catalysts have been widely used in the

58　petrochemical industry for methane and naphtha reforming and they have also been

59　proven to perform well as secondary catalysts in biomass gasification [27], bio-oil

60　steam reforming [28], as well as in the in-line reforming of the volatiles formed in

61　biomass pyrolysis [21]. Apart from Ni, other base metals (Co, Fe) and noble metals (Pt,

62　Ir, Rh…) have been used as active phase in the reforming processes [29, 30]. The

63　activity order of these metals is not clearly established in literature, with Ni being

64　identified as the most appropriated one [13, 18, 28, 31] because of its activity for

65　breaking C-C and O-H bonds and its moderate cost compare to noble metals. However,

66　Ni is very active for the undesired methanation and coke formation reactions, and has

67　low activity for the desired Water-Gas Shift reaction [18]. The most commonly used

68　support for the Ni active phase has been Al_2O_3 [31] due to its high mechanical strength,

69　tuneable textural properties and availability [18, 32]. However, the moderate acidity of

70　Al_2O_3 support enhances the polymerization reactions leading to coke formation [33, 34].

71　Thus, the high coke formation rate on Ni/Al_2O_3 catalysts is the main challenge in bio-oil

72　steam reforming process [18, 28, 35].

73　Modification of Ni/Al_2O_3 catalysts by incorporating metal oxide promoters (CeO_2,

74　La_2O_3, MgO, CaO, ZrO_2…) has been widely studied in literature in order to increase

75　their activity, reducibility, stability and regenerability in the reforming of oxygenate

76　compounds [36-38]. Amongst the different metal oxides, CeO_2 has shown excellent

77　properties to improve the thermal stability of the alumina by promoting the dispersion

78　of Ni on the support, thereby favouring stronger metal-support interactions [39, 40].

79　Furthermore, CeO_2 enhances Water-Gas Shift reaction and favours coke gasification

80 because of its redox properties and high oxygen storage capacity [41, 42]. Furthermore,

81 Chen et al. [43] studied methane dry reforming and observed that the formation of

82 $CeAlO_3$ phase can inhibit the growth of graphitic carbon on the Ni surface. Alkali

83 metals (MgO and CaO) have been incorporated into Ni/Al_2O_3 catalysts in order to

84 reduce the acidity of Al_2O_3 support and decrease the coke formation rate. Besides, MgO

85 favours H_2O adsorption and OH mobility on the surface, enhancing coke gasification

86 [32, 44]. Sánchez-Sánchez et al. [45] reported that Mg addition leads to $MgAl_2O_4$ spinel

87 phase formation, which modifies the interaction extent of Ni with Al_2O_3.

88 This study deals with hydrogen production from biomass based on a two-step in-line

89 process. In the first step, biomass (pine sawdust) is pyrolyzed in a conical spouted bed

90 reactor (CSBR) operating in continuous mode by feeding biomass and using steam as

91 fluidizing agent. The volatile stream formed in the pyrolysis step is fed in-line into the

92 second step, which is a catalytic fluidized bed reactor (CFBR). The good performance

93 of the this CSBR-CFBR two-step process has already been proven when a commercial

94 and synthesized Ni catalyst are used in the reforming step, as it allows attaining full

95 conversion of the volatiles in the reforming step and high hydrogen yields at zero time

96 on stream [21, 46]. However, catalyst deactivation is considerable, and therefore

97 improvements in catalyst stability are required for increasing process viability. In order

98 to improve Ni/Al_2O_3 catalyst stability, a study has been carried out on the effect CeO_2

99 and MgO promoters have on the evolution of conversion and product yields with time

100 on stream, and they have been related to the catalyst deactivation by coke deposition

101 and Ni sintering based on several catalyst characterization techniques.

102 **2.   Experimental**

103 **2.1. Materials**

104　The biomass used is forest pine wood, whose main properties are summarized in

105　Table1. The biomass has been crushed, ground and sieved to a particle size in the 1-2

106　mm range in order to ease continuous feeding operation. The ultimate analysis has been

107　determined in LECO CHN-932 and VTF-900 elemental analyzers. The ultra-

108　microbalance SARTORIOUS M2P is on-line with a computer for the processing of the

109　data provided by the analyzer. The proximate analysis (volatile matter, fixed carbon and

110　ashes) has been determined in a thermogravimetric analyzer (TA Instrument TGA

111　Q5000IR). The higher heating value (HHV) has been measured in a Parr 1356

112　isoperibolic bomb calorimeter. As observed in Table 1, the empirical formula of the

113　biomass is $CH_{1.47}O_{0.67}$.

114　**Table 1**. Pine wood sawdust characterization.

Ultimate analysis (wt.%)	
Carbon	49.33
Hydrogen	6.06
Nitrogen	0.04

115

2.2. Catalyst preparation and characterization

117　Ni/Al_2O_3, $Ni/CeO_2-Al_2O_3$ and $Ni/MgO-Al_2O_3$ catalysts were prepared with 10 wt.%

118　nominal content of Ni. Prior to their synthesis, the $\gamma-Al_2O_3$ was pretreated by calcination

119　under air environment at 1000 ºC for 5 h to thermally stabilize the support thus avoiding

120   any possible phase change during the process, as well as improving the mechanical

121   strength of the catalyst. The support was ground and sieved to a particle size in the 0.4-

122   0.8 mm range. Ni/Al_2O_3 was prepared by wet impregnation of the support with an

123   aqueous solution of $Ni(NO_3)_2.6H_2O$ (VWR Chemicals, 99 %). It was then dried at 120

124   ºC for 24 h, followed by calcination at 700 ºC for 3 h.

125   Modified supports were prepared by successive wet impregnation method. Prior to

126   loading the Ni, calcined Al_2O_3 was modified with the promoter oxides (CeO_2, MgO) by

127   impregnation in aqueous solutions of $Ce(NO_3)_3 \cdot 6H_2O$ and $Mg(NO_3)_2 \cdot 6H_2O$,

128   respectively. The concentration of metal-promoter oxides onto the Al_2O_3 was fixed at

129   10 wt.%. The modified supports were dried overnight and calcined at 900 ºC for 3 h.

130   Subsequently, Ni was impregnated with an aqueous solution of $Ni(NO_3)_2 \cdot 6H_2O$ (VWR

131   Chemicals, 99 %) followed by drying at 120 ºC for 24 h and calcination at 700 ºC for 3

132   h.

133   The physical properties of the catalysts (BET surface area, pore volume and average

134   pore diameter) were measured by N_2 adsorption-desorption (Micromeritics ASAP

135   2010). Prior to analysis, the samples were degassed under vacuum at 150 ºC for 8 h.

136   X-ray Fluorescence (XRF) spectrometry was used to measure the metal content of the

137   catalysts. The chemical analysis of the samples was carried out under vacuum using a

138   sequential wavelength dispersion X-ray fluorescence spectrometer (WDXRF),

139   PANalytical AXIOS, equipped with Rh tube and three detectors. The samples were

140   prepared mixing flux Spectromelt A12 from Merck (ref. No. 11802) with powder

141   catalyst in a ratio of approximately 20:1. The samples were melted in an induction

142   micro-furnace prior to chemical analysis.

Temperature Programmed Reduction (TPR) measurements were carried out in an AutoChem II 2920 Micromeritics for determining the reduction temperature of the different metal phases in the catalysts. In order to remove water or any other impurity, the catalysts were thermally treated under helium stream at 200ºC. TPR analyses were carried out from room temperature to 900ºC (heating rate of 5 ºC min^{-1}) in a H_2 stream diluted in Ar (10 vol.%).

Crystalline structures of reduced and deactivated catalysts were analyzed by X-ray powder diffraction (XRD) using Bruker D8 Advance diffractrometer with a $CuK_{\alpha1}$ radiation. Scanning was conducted over 2θ = 10-80º range using 0.04º steps, with measuring times being 12 s per step. Scherrer equation was used for calculating the average Ni crystallite particle size, which allows determining metal dispersion according to the method described by Miyazawa et al. [47].

Temperature Programmed Oxidation (TPO) was conducted for deactivated catalysts in order to measure the amount of coke deposited and identify its possible nature and location. A thermobalance (TGA Q5000TA Thermo Scientific) connected in-line to a Blazer Instruments mass Spectrometer (Thermostar) was used, following a heating rate of 5 ºC min^{-1} from 100 to 800 ºC in a stream of O_2 diluted in He. Prior to combustion, the sample was stabilized with He stream at 100 ºC for 30 minutes and a final temperature of 800 ºC was maintained for 30 minutes in order to ensure full coke combustion.

TPO was also carried out following the coke combustion by FTIR spectrospopy in a Nicolet 6700 spectrophotometer (Thermo) to determine the nature of the coke burned at different temperatures. The deactivated catalysts were pelletized with KBr and introduced into the catalytic chamber under vacuum at 100 ºC for 1 h in order to desorb

167   impurities. Combustion is carried out under air flow from 100 to 550 ºC at a rate of 5 ºC

168   min^{-1}, and the final temperature was maintained for 1 h. Simultaneously, CO_2 signal was

169   recorded in a mass spectrometer (OmniStar ThermoStar).

170   Additionally, the nature of the coke deposited on the catalyst was studied by TEM

171   (transmission electron microscopy) images and SEM (scanning electron microscopy)

172   images, obtained by means of Phillips CM20 and JEOL JSM-6400, respectively.

173   **2.3. Experimental equipment, conditions and reaction indices**

174   A scheme of the bench scale reaction equipment used for the biomass pyrolysis-steam

175   reforming process is shown in Figure 1. The reaction system consists of two steps

176   connected in line: i) biomass pyrolysis in a conical spouted bed reactor; ii) in-line steam

177   reforming of the volatiles leaving the pyrolysis step in a fluidized bed reactor. The good

178   performance of the CSBR for biomass [48-51], tyre [52-54] and plastic [55-57]

179   pyrolysis has already been proven in previous studies.
180

181   Figure 1. Scheme of the laboratory scale catalytic steam reforming plant.

182 Biomass was continuously fed (0.75 g min^{-1}) into the conical spouted bed reactor where

183 pyrolysis is carried out at 500 ºC for maximizing the volatile stream (gas and bio-oil)

184 yield [58].The bed was made up of 30 g of silica sand in the 0.3-0.35 mm range. Steam

185 has been used as fluidizing agent, with water flow rate being 3 mL min^{-1} to ensure

186 stable hydrodynamic performance. Thus, a steam/biomass ratio of 4 was used in all the

187 runs. A high precision Gilson 307 pump was used for measuring the water flow rate.

188 Prior to entering the reactor, it was vaporized and heated to the pyrolysis temperature by

189 means of a preheater. Both the preheater and the CSBR were placed inside a radiant

190 oven of 1250 W.

191 Biomass pyrolysis products were identified and quantified elsewhere [21, 58]. The inert

192 behaviour of steam in the biomass pyrolysis was previously verified, i.e., product

193 distribution is almost the same as when N_2 is used as fluidizing agent. Besides, the good

194 features of the conical spouted bed reactor, namely, short residence time, high heat and

195 mass transfer rates and rapid char removal, lead to high gas and bio-oil yields (overall

196 yield of 82 %). Thus, the main compounds in the volatile stream obtained in the first

197 step are CO (3.4 wt.%), CO_2 (3.3 wt.%), phenols (16.5 wt.%), ketones (6.4 wt.%),

198 saccharides (4.5 wt.%), furans (3.3 wt.%), acids (2.7 wt.%), alcohols (2.0 wt.%) and

199 aldehydes (1.9 wt.%). It should be noted that a water yield of 25 wt.% is obtained in

200 biomass pyrolysis, which also acts as reforming agent in the second step.

201 This volatile stream formed in the biomass pyrolysis reactor was fed into the fluidized

202 bed reactor placed in line, thus ensuring bed isothermicity and avoiding operational

203 problems encountered when operating in fixed bed reactors [59]. Before entering the

204 reactor, the volatile stream circulates throughout a filter and a cyclone in order to

205 eliminate possible char and sand particles entrained from the pyrolysis reactor. The total

206 mass in the fluidized bed reactor was 25 g, with catalyst particle size being 0.4-0.8 mm

207　and silica sand particle size 0.3-0.355 mm. The space-time used was 20 g_{cat} min $g_{volatiles}^{-1}$

208　for all the catalysts studied. The catalysts were reduced prior to the reforming process

209　by an in situ reduction process at 710 ºC for 4 h under H_2 stream (10 vol.%) diluted with

210　N_2. The reforming reaction was carried out at 600 ºC, as previous studies on this

211　commercial catalyst showed no significant improvement when temperature was

212　increased in the 600-700 ºC range [21]. The fluidized bed reactor was placed inside a

213　radiant oven of 550 W.

214　Both reactors and its respective radiant ovens are located inside a convection oven kept

215　at 270 ºC (Figure 1) in order to avoid the condensation of both the volatile stream

216　formed in the pyrolysis reactor and the products formed in the fluidized bed reactor, as

217　the latter should be avoided prior to analysis.

218　The product condensation system consists of a condenser cooled with tap water and a

219　coalescence filter, which ensures non-condensable gases are clean for analysis. The

220　product stream is analyzed in-line by: i) a Varian 3900 GC provided with HP-Pona

221　column and flame ionization detector (FID); ii) a Varian 4900 microGC outfitted with

222　four modules (Molecular sieve 5, Porapack, CPSil and Plot Alumina) and a thermal

223　conductivity detector (TCD). The first sample of the product stream is taken at the

224　fluidized bed reactor outlet, i.e., before condensing the products. The second one

225　consisting of permanent gases is taken downstream the condensation system, which

226　allows determining the compositions of the products not monitored by GC analysis.

227　Thus, this system allows quantifying in line all the reforming products.

228　Reaction indices (conversion, carbon containing gaseous product yield and hydrogen

229　yield) have been defined in order to quantify the performance of the different catalysts

230　prepared. It should be noted that these indices are related to the reforming reactor, and

231   therefore the char formed in the pyrolysis reactor, which has been continuously

232   withdrawn, has not been considered.

233   Thus, conversion in the reforming reactor is defined as the ratio between the C moles in

234   the gaseous product (C_{gas}) stream and the C moles in the volatile stream at the fluidized

235   bed reactor inlet ($C_{volatiles}$):

236    $$X = \frac{C_{gas}}{C_{volatiles}} 100 \qquad (1)$$

237   Likewise, the yield of any carbon containing gaseous product is defined as the ratio

238   between the molar flow rate of compound i (F_i) and the molar flow rate of the volatile

239   stream at the fluidized bed reactor inlet ($F_{volatiles}$):

240    $$Y_i = \frac{F_i}{F_{volatiles}} 100 \qquad (2)$$

241   Regarding hydrogen yield, it is defined as follows:

242    $$Y_{H_2} = \frac{F_{H_2}}{F_{H_2}^0} 100 \qquad (3)$$

243   where F_{H2} is the actual H_2 molar flow rate and F_{H2}^0 is the maximum H_2 molar flow rate

244   allowable by stoichiometry. The following stoichiometry is considered for the steam

245   reforming of biomass pyrolysis volatiles:

246    $$C_n H_m O_k + (2n - k)H_2O \longrightarrow nCO_2 + (2n + m/2 - k)H_2 \qquad (4)$$
247   **3.   Results**

248   **3.1. Effect of CeO$_2$ and MgO promoters on Ni/Al$_2$O$_3$ catalyst**

249 The surface properties of the fresh catalysts (BET surface area (S_{BET}), pore volume

250 (V_{pore}) and average pore diameter (d_{pore})) and their Ni content and metal dispersion

251 (D_{XRD}) are set out in Table 2. As observed, the BET specific surface area decreases

252 when CeO_2 or MgO is incorporated into Al_2O_3 support, from 76.2 to 65.7 and 63.9 m^2

253 g^{-1}, respectively. Likewise, pore volume also decreases, with this decrease being more

254 significant for Ni/MgO-Al_2O_3 (from 0.39 to 0.27 cm^3 g^{-1}). It is well established that low

255 metal oxide loadings in the support lead to atomic dispersion of Ce and Mg ions on the

256 alumina, which does not have a significant effect on the textural properties [45].

257 However, an excess of Ce and Mg (up to 6 wt.% for CeO_2 [60] and 1 wt.% for MgO

258 [61]) blocks the porous structure of the Al_2O_3 support, decreasing the surface area, as

259 well as the pore volume of the catalysts. Furthermore, the formation of $MgAl_2O_4$ phase

260 (detected by XRD analysis) enhances the decrease in pore volume observed for

261 Ni/MgO-Al_2O_3 catalyst [62].

262

263 **Table 2**. Textural properties, nickel content and dispersion of the fresh catalysts.

Catalyst	Ni content wt.%	S_{BET} m^2 g^{-1}	V_{pore} cm^3 g^{-1}	d_{pore} Å	D_{XRD}[a] %
Ni/Al_2O_3	9.8	76.2	0.39	182.4	9.7
Ni/CeO_2-Al_2O_3	8.2	65.7	0.36	181.2	5.4
Ni/MgO-Al_2O_3	9.8	63.9	0.27	167.6	6.5

264 [a] Dispersion calculated by XRD based on Ni crystallite size [63].

265

266 The Ni content calculated by XRF analysis shows that the values obtained are close to

267 nominal loading (10 wt.%), which is evident that the wet impregnation method used for

268 catalyst preparation is adequate. Ni dispersion is calculated based on both the (97.1

269 nm)/(Ni particle size (nm) ratio [63] and Ni crystallite size by applying Scherrer

270 equation to the diffraction peak at $2\theta = 52°$ in the XRD analysis (associated with the Ni

271 phase). As observed, active phase dispersion values are quite low and they are even

272 lower when CeO_2 and MgO are added as promoters. The low Ni dispersion obtained is

273 presumably a consequence of the high Ni content and low surface area of the supports

274 [64]. In fact, a lower metal dispersion is expected for $Ni/CeO_2-Al_2O_3$ and $Ni/MgO-$

275 Al_2O_3 than for Ni/Al_2O_3 catalyst due to the lower BET surface area available for Ni

276 deposition.

277 Figure 2 shows the XRD patterns of the three reduced catalysts. Diffraction lines at $2\theta =$

278 44º, 52º and 76º attributed to crystalline Ni phases are observed in all of them, which

279 correspond to (1 1 1), (2 0 0) and (2 2 0) planes, respectively [65], whereas NiO is not

280 detected, and therefore this specie is fully reduced. Regarding Ni/Al_2O_3 catalyst, typical

281 diffraction peaks corresponding to Al_2O_3 support are detected, apart from those for Ni

282 phase. However, $NiAl_2O_4$ spinel phase is not detected by this technique because its

283 phase diffraction lines ($2\theta = 29º$, 45º and 60º [66]) overlap those of Al_2O_3 phase [32,

284 67]. Likewise, $NiAl_2O_4$ spinel is not detected by XRD analysis to the reduced Ni/CeO_2-

285 Al_2O_3 catalyst. However, $CeAlO_3$ spinel phase diffraction lines are identified at $2\theta =$

286 23º, 44º, 47º and 60º, as well as those of CeO_2 phase at $2\theta = 28º$, 33º, 47º and 56º.

287 Osorio-Vargas et al. [60] related these CeO_2 peaks to fluorite structure, identified by

288 planes (1 1 1), (2 0 0), (2 2 0) and (3 1 1), and they attributed the good segregation of

289 CeO_2 on the Al_2O_3 support to this phase. Furthermore, the presence of $CeAlO_3$ is a

290 consequence of solid-state reaction between Ce_2O_3 and Al_2O_3 above 600 ºC, with Ce_2O_3

291 being previously formed from CeO_2 in the presence of H_2 above 800 ºC [68]. Therefore,

292 the presence of both phases is evidence that CeO_2 is partially reduced to Ce_2O_3 to form

293 $CeAlO_3$ spinel phase when the catalyst has been reduced. Concerning $Ni/MgO-Al_2O_3$

294 catalyst, both $NiAl_2O_4$ spinel and $MgAl_2O_4$ spinel have been identified. However, both

295 spinel phases have the same diffraction angles, and so their intensity cannot be

296   determined separately [69, 70]. Qiu et al. [71] also detected both spinel phases and they

297   concluded that $NiAl_2O_4$ spinel formation is inhibited and $MgAl_2O_4$ spinel formation

298   enhanced when the MgO content is below 7 wt.%.
300   Figure 2. XRD patterns of the reduced catalysts. Crystalline phases: (●) Ni (◆) Al_2O_3

301   (✥) $CeAlO_3$ (◆) CeO_2 (✥) $MgAl_2O_4$ (✥) $NiAl_2O_4$.

303   Figure 3 shows the TPR profiles of Ni/Al_2O_3, $Ni/CeO_2-Al_2O_3$ and $Ni/MgO-Al_2O_3$

304   catalysts. Regarding Ni/Al_2O_3 catalyst, two main reduction peaks are observed at 620 ºC

305   and 780 ºC. Besides, a small peak is observed at lower temperatures, which presumably

306   corresponds to the reduction of NiO with little or no interaction with Al_2O_3 [32].

307   Moreover, the peak at 620 ºC can be associated with NiO strongly interacting with

308   Al_2O_3 support, which at higher temperature corresponds to Ni integrated in the $NiAl_2O_4$

309   spinel phase [72]. Concerning $Ni/CeO_2-Al_2O_3$ catalyst, it can be seen that these

310   reduction peaks shift to lower temperatures (550 ºC and 710 ºC) when CeO_2 is used as

311   promoter, indicating that the presence of CeO_2 weakens the interation of NiO with

312   Al_2O_3 [60]. It is to note that another small reduction peak is observed at higher

313   temperature (> 800 ºC) associated with the reduction of bulk ceria crystallites related to

314      $CeAlO_3$ formation [73]. Concerning $Ni/MgO-Al_2O_3$ catalyst, the low capacity for

315   reduction of the catalyst prepared is noteworthy, as evidenced by a small peak at 550 ºC

316   related to NiO interacting with Al_2O_3 support. Besides, another peak at high

317   temperature (> 800 ºC) is observed related to the Ni incorporated into $MgAl_2O_4$ spinel,

318   which is difficult to reduce [32, 62].
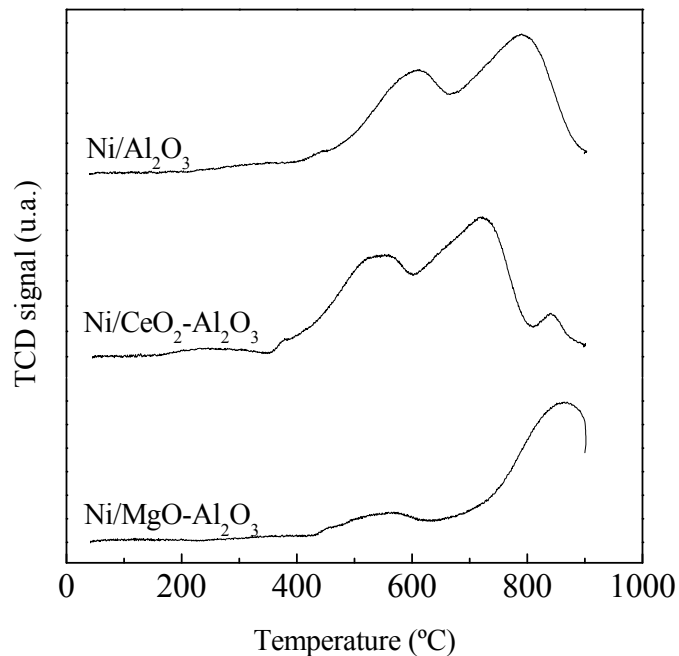

320   Figure 3. TPR profiles of Ni/Al_2O_3, $Ni/CeO_2-Al_2O_3$ and $Ni/MgO-Al_2O_3$ catalysts.

321   **3.2. Comparison of the catalysts performance**

322   Figure 4 displays the evolution of conversion (Eq. (1)) with time on stream for the three

323   catalysts tested. It is to note that the times on stream for a conversion to be lowered to

324   80 % depend on the catalyst used (98, 155 and 91 min for Ni/Al_2O_3, $Ni/CeO_2-Al_2O_3$ and

325      $Ni/MgO-Al_2O_3$, respectively), i.e., the $Ni/CeO_2-Al_2O_3$ catalyst allows operating for

326   longer periods with high conversion values. Furthermore, almost full conversion is

327   obtained at zero time on stream, with reforming conversion of biomass pyrolysis

328   volatiles being above 98 % for the three catalysts prepared. As observed, Ni/MgO-

329   Al_2O_3 is the less stable one, with conversion decreasing from 99.1 % at zero time on

330   stream to 56.6 % for 106 min on stream. This low stability of the Ni/MgO-Al_2O_3

331   catalyst is related to the low catalyst reducibility observed by TPR analysis, since less

332   Ni active phase on the catalyst leads to faster catalyst deactivation. Likewise, Garcia et

333   al. [69] tested different Ni/Al_2O_3 catalysts promoted with MgO and observed lower

334   stability for the catalyst in which the spinel phase was formed and reducibility was

335   limited. Furthermore, although Ni/Al_2O_3 catalyst shows an initial stable period (40

336   min), its deactivation rate is similar to that observed for Ni/MgO-Al_2O_3, with

337   conversion decreasing from 97.8 % at 40 min on stream to 73.9 % at 103 min.

338   However, it is clearly observed that incorporating CeO_2 as promoter the catalyst

339   deactivation rate is attenuated considerably, with conversion decreasing from 99.5 % at

340   zero time on stream to 94 % for 104 min, and conversion being still 60 % at 200 min.

341   The good stability of Ni/CeO_2-Al_2O_3 catalyst for oxygenate compound reforming has

342   been reported in the literature, and is related to CeO_2 redox properties and its high

343   oxygen storage capacity, as well as to the enhancement of water adsorption by

344   inhibiting coke formation and evolution on the catalyst surface [42, 45].
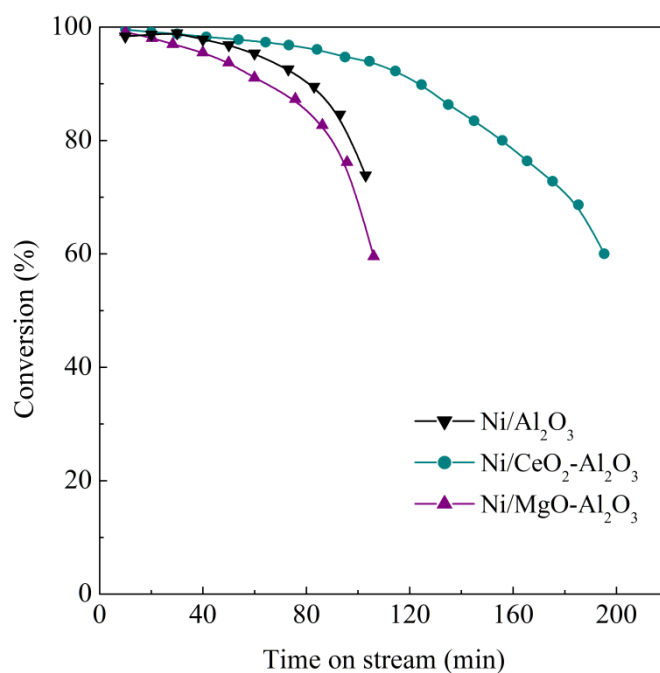

345

346   Figure 4. Evolution of conversion with time on stream for the different catalysts.

347   Figure 5 shows the evolution of H_2 yield (calculated based on the maximum allowable

348   by stoichiometry, Eq. (3)) and other gaseous compound yields (Eq. (2)) with time on

349   stream for Ni/Al$_2$O$_3$ (Figure 5a), Ni/CeO$_2$-Al$_2$O$_3$ (Figure 5b) and Ni/MgO-Al$_2$O$_3$ (Figure

350   5c) catalysts. As observed, as time on stream is increased H_2 and CO_2 yields decrease

351   for the three catalysts, which is evidence of a lower extension of reforming and water-

352   gas shift reactions when the catalyst is deactivated. Besides, this decrease is more

353   pronounced for Ni/MgO-Al$_2$O$_3$ catalyst (Figure 5c). Thus, H_2 yield decreases from 93.7

354   to 44.3 % and the one of CO_2 from 91.2 to 48.4% for 106 min. It is to note that an initial

355   period has been observed for Ni/Al$_2$O$_3$ catalyst (Figure 5a), with H_2 yield (93.8 %) and

356   CO_2 yield (91.6 %) being almost constant for 40 min. However, after this period the

357   decrease in H_2 and CO_2 yields is more pronounced than for Ni/CeO$_2$-Al$_2$O$_3$ catalyst

358   (Figure 5b). Catalyst deactivation rate increases with time on stream for the three

359   catalysts studied; that is, there is an autocatalytic effect suggesting that non-converted

360 oxygenates are the main coke precursor because the deactivation is faster as their

361 concentration in the reaction medium is higher.

362 Regarding CO yield, it is almost constant for Ni/Al$_2$O$_3$ catalyst, but increases slightly

363 with time on stream for Ni/MgO-Al$_2$O$_3$ and in a more pronounced way for Ni/CeO$_2$-

364 Al$_2$O$_3$, which is due to a balance between the lower extension of reforming and water-

365 gas shift reactions and its formation by cracking (especially decarbonylation) reactions.

366 Comparing the CO yields obtained with the three catalysts, on one hand, the lower

367 value of CO yield obtained when Ni/Al$_2$O$_3$ catalyst is used is evidence of the lower

368 extension of the water-gas shift reaction when the support is modified. On the other

369 hand, the higher value of CO yield obtained when Ni/CeO$_2$-Al$_2$O$_3$ is used is related to

370 the redox capacity of this catalyst, i.e., its reduction to CeO$_{2-x}$ by unreacted

371 hydrocarbons (C$_x$H$_{1-x}$) and reoxidation back to CeO$_2$ by CO$_2$ leads to the formation of

372 CO in both steps [73].

373

374

375
Figure 5. Evolution of H_2 and other gaseous compound yields with time on stream for

Ni/Al_2O_3 (a), Ni/CeO_2-Al_2O_3 (b) and Ni/MgO-Al_2O_3 (c) catalysts.

378   Concerning CH_4 and light hydrocarbons yields, they increase slightly as deactivation

379   proceeds, but their yields are below 2 % for the three catalysts. Therefore, oxygenate

380   cracking reactions hardly occur under reaction conditions, even when the catalysts are

381   deactivated and reforming reactions are attenuated.

382   Several studies dealing with the dry reforming of hydrocarbons relate the good stability

383   of Ni/CeO_2-Al_2O_3 catalysts to the formation of $CeAlO_3$ spinel, which plays a key role in

384   the removal of coke precursors by the following reaction mechanisms [43, 73]: i)

385      $CeAlO_3$ spinel may react with CO_2 to form CO and CeO_2; and ii) CeO_2 oxidizes the

386   coke precursors located at the Ni-support boundary and restores $CeAlO_3$ sites. Besides,

387   this mechanism for the removal of coke precursors may also explain the higher CO

388   yields obtained using Ni/CeO_2-Al_2O_3 catalyst.

389   **3.3. Catalyst deactivation**

390   One of the main concerns of bio-oil steam reforming process is the fast catalyst

391   deactivation, generally caused by coke deposition or Ni sintering [18, 74]. In order to

392   overcome or minimize this deactivation, it is of uttermost importance to understand the

393   mechanism leading to catalyst deactivation. Accordingly, this section deals with the

394   decline in the catalyst textural properties, modifications on different crystal phases and

395   the nature and location of the coke deposited.

396   Table 3 shows the textural properties of deactivated Ni/Al_2O_3, Ni/CeO_2-Al_2O_3 and

397   Ni/MgO-Al_2O_3 catalysts. A comparison of these properties with those shown in Table 2

398   for the fresh catalysts reveals that the BET surface area is almost the same for the

399   Ni/Al_2O_3 catalyst (76.2 and 74.7 m^2 g^{-1} for the fresh and deactivated catalysts,

400   respectively), whereas it decreases slightly for Ni/CeO_2-Al_2O_3 (from 65.7 to 58.6 m^2 g^{-1}

401   ) and Ni/MgO-Al_2O_3 (from 63.9 to 57.5 m^2 g^{-1}). Furthermore, pore volume and pore

402 diameter decrease for the three catalysts due to the coke deposited, which is evidence

403 that the coke may block the biggest pores either fully or partially, with the latter causing

404 a decrease in the diameter to access the pore.

405 **Table 3**. Textural properties of the deactivated catalysts and Ni crystallite size (d_{Ni}).

| Catalyst | S_{BET} | V_{pore} | d_{pore} | d_{Ni} (fresh) | d_{Ni} (deact.) |
	$m^2\ g^{-1}$	$cm^3\ g^{-1}$	Å	nm	nm
Ni/Al_2O_3	74.7	0.29	153.3	10	13
$Ni/CeO_2-Al_2O_3$	58.6	0.23	165.2	18	31
$Ni/MgO-Al_2O_3$	57.5	0.20	140.0	15	19

406

407 Figure 6 shows XRD patterns of the three deactivated catalysts. It is to note that no

408 significant differences are observed when they are compared with the XRD profiles of

409 the fresh catalysts (Figure 2). Besides, diffraction lines attributed to Ni crystalline

410 phases are observed for the three catalysts studied, but those of NiO are not identified,

411 which reveals that catalyst deactivation is not caused by the active phase oxidation. The

412 deactivated $Ni/CeO_2-Al_2O_3$ catalyst records another diffraction line representative of

413 $CeAlO_3$ spinel phase at $2\theta = 34°$, which does not appear in fresh catalyst, indicating the

414 formation of this spinel phase under reaction conditions. In order to determine catalyst

415 irreversible deactivation by Ni sintering, Ni crystallite size has been calculated for fresh

416 and deactivated catalysts (Table 3), applying the Scherrer equation for the diffraction

417 peak at $2\theta = 52°$. As observed in Table 3, the Ni crystallite size for Ni/Al_2O_3 and

418 $Ni/MgO-Al_2O_3$ catalysts does not increase considerably, and therefore the fast

419 deactivation observed for these catalysts is not due to Ni sintering. In the case of

420 $Ni/CeO_2-Al_2O_3$ catalyst, the Ni crystallite size increases from 18 to 31 nm, which

421 suggests that certain sintering occurs under the reaction conditions. Navarro et al. [62]

422 showed also a higher Ni particle size under reaction conditions when they used CeO_2 as

promoter for Ni/Al$_2$O$_3$, and they relate it to the poor Ce particle dispersion in the catalyst, which cannot avoid Ni sintering and stabilize the catalyst.
Figure 6. XRD patterns of the deactivated catalysts. Crystalline phases: (●) Ni (♦) Al$_2$O$_3$ (✥) CeAlO$_3$ (♦) CeO$_2$ (✥) MgAl$_2$O$_4$ (✥) NiAl$_2$O$_4$.

Therefore, as Ni particle sintering is not significant for Ni/Al$_2$O$_3$ and Ni/MgO-Al$_2$O$_3$ catalysts, the main cause of catalyst deactivation with time on stream is the coke deposited on these catalysts. In the case of Ni/CeO$_2$-Al$_2$O$_3$, although sintering may affect catalyst stability, the influence of the coke deposited on this catalyst will be also analysed. Thus, temperature programmed oxidation (TPO) of the coke deposited has been carried out in order to analyze the amount and the nature and location of the coke deposited. The amount of the coke deposited on the three catalysts has been summarized in Table 4 and their TPO profiles have been plotted in Figure 7. As aforementioned, the time on stream of each catalyst was not the same (103, 200 and 106 min for Ni/Al$_2$O$_3$, Ni/CeO$_2$-Al$_2$O$_3$ and Ni/MgO-Al$_2$O$_3$, respectively). Therefore, in order to compare the

439   amount of coke deposited on the different catalysts, the average coke deposition rate has

440   been defined as follows:

441     $$\bar{r}_{coke} = \frac{W_{coke}/t}{W_{catalyst}\, m_{biomass}}$$ (5)

442   with $W_{catalyst}$ and W_{coke} being the catalyst and coke masses, respectively, $m_{biomass}$ the

443   biomass mass flow rate in the feed and t the reaction time in each run.

444   Table 4 shows a lower average coke deposition rate for $Ni/CeO_2-Al_2O_3$ catalyst (0.31

445     $mg_{coke}\, g_{cat}^{-1}\, g_{biomass}^{-1}$), which is consistent with the lower deactivation observed when the

446   evolution of conversion and product yields with time on stream has been monitored

447   (Figures 4 and 5, respectively). This is an especially relevant result, since the Ni/CeO_2-

448   Al_2O_3 catalyst has been exposed to higher partial pressures of non-converted oxygenate

449   compounds for longer reaction times, and the extension of coke formation is therefore

450   higher. Similarly, the fast decrease in conversion and H_2 and CO_2 yields with time on

451   stream observed for $Ni/MgO-Al_2O_3$ is related to the higher average coke deposition rate

452   (0.77 $mg_{coke}\, g_{cat}^{-1}\, g_{biomass}^{-1}$) when this catalyst is used. Furthermore, significant

453   differences on the coke nature and location are observed depending on the promoter

454   used (Figure 7). The nature and location of the coke deposited is ascertained in the

455   literature based on the combustion temperature of the different coke fractions observed

456   in the TPO profiles [32, 75, 76], as follows: i) the coke that burns below 500 ºC is

457   related to the amorphous coke or the one deposited on Ni particles catalyzing its

458   oxidation. This coke fraction encapsulates Ni particles, hindering the access of reactants

459   to the active sites, and is therefore the main responsible for catalyst deactivation; ii)

460   higher combustion temperatures are associated with the combustion of structured or

461   filamentous coke, with less influence on catalyst deactivation. Regarding the Ni/Al_2O_3

462   catalyst (Figure 7), two clearly defined peaks are observed, the first one at 480 ºC

463 associated with amorphous coke and the second one at 600 ºC related to a more

464 structured coke. Similarly, both peaks are observed in the case of Ni/MgO-Al$_2$O$_3$, with

465 the one at low temperature being more pronounced. Therefore, it seems that the

466 incorporation of MgO as promoter inhibits the evolution of the coke towards a more

467 structured material, as has also been observed by other authors [62]. As concerns the

468 Ni/CeO$_2$-Al$_2$O$_3$ catalyst, the coke deposited on this catalyst burns at a lower temperature

469 (the main peak below 400 ºC), which is related to CeO$_2$ enhancing coke gasification

470 during the steam reforming of biomass pyrolysis volatiles and coke oxidation during its

471 combustion. It is widely reported in the literature [18, 43, 45] that CeO$_2$ incorporation as

472 promoter enhances water adsorption and provides redox properties to the support, which

473 increase the oxygen available on the surface, thus favouring coke gasification and

474 inhibiting its growth and evolution towards a more structured coke.

475 **Table 4**. Coke content and average coke deposition rate for the three catalysts.

| Catalyst	C_c wt.%	r_{coke} $mg_{coke} \, g_{cat}^{-1} \, g_{biomass}^{-1}$
Ni/Al$_2$O$_3$	2.84	0.37
Ni/CeO$_2$-Al$_2$O$_3$	4.52	0.31
Ni/MgO-Al$_2$O$_3$	6.15	0.77

476

Figure 7. TPO profiles of the coke deposited on the different catalysts.

Figures 8 and 9 show SEM and TEM images, respectively, for Ni/Al_2O_3 (a), Ni/CeO_2-Al_2O_3 (b) and Ni/MgO-Al_2O_3 (c) deactivated catalyst. As observed, none of the catalysts contains filamentous coke; that is, although the coke undergoes graphitization, filaments are not formed, and therefore it is mainly amorphous. Furthermore, the higher Ni particles observed for Ni/CeO_2-Al_2O_3 catalyst by TEM technique are evidence of a slight sintering of this catalyst.
485

486   Figure 8. SEM images of deactivated Ni/Al_2O_3 (a), $Ni/CeO_2-Al_2O_3$ (b) and Ni/MgO-

487   Al_2O_3 (c) catalysts.

488

489
Figure 9. TEM images of deactivated Ni/Al$_2$O$_3$ (a), Ni/CeO$_2$-Al$_2$O$_3$ (b) and Ni/MgO-

Al$_2$O$_3$ (c) catalysts.

TPO-FTIR technique has been used in order to acquire a deeper knowledge about the

effect the promoter has on the nature of the coke deposited on each catalyst. Figure 10

shows the evolution of FTIR bands of the different functional groups throughout

combustion. According to the literature, the assignment of the FTIR bands in the coke

analysis to the functional groups is as follows [77-79]: 880 cm^{-1} to -COOH δ

deformation vibration; 1050 cm^{-1} and 1110 cm^{-1} to the stretching vibration of C-O

bonds or oxides on the support; 1260 cm^{-1} to the stretching vibration of C-O bonds in

alcohols, ethers or related compounds, and/or the stretching asymmetric vibrational

500   mode of C-O-C bonds; 1385 cm^{-1} to C-H in aliphatics; 1450 cm^{-1} to bending vibrations

501   in $-CH_2$ and $-CH_3$ aliphatic groups and/or symmetric stretching vibrations of O=C-O

502   bonds in acetate groups; 1505 cm^{-1} to symmetric stretching vibrations of O=C-O bonds

503   in carbonate groups and/or C=C bonds in slightly condensed aromatics; 1580 cm^{-1} to

504   C=C in polycondensed aromatics or asymmetric stretching vibrations of O=C-O bonds

505   in acetate groups; 1650 cm^{-1} to C=C stretching vibrations in cyclic alkenes and/or C=O

506   stretching vibrations in aldehydes and ketones; 2850, 2925 and 2960 cm^{-1} to the

507   stretching vibration of C-H in -CHn aliphatic groups; 3450 cm^{-1} to the stretching

508   vibration of O-H bonds, which correspond to the adsorbed water. The assignment of IR

509   bands to particular species is not straightforward due to the high diversity of functional

510   groups in the coke.

511

512

513
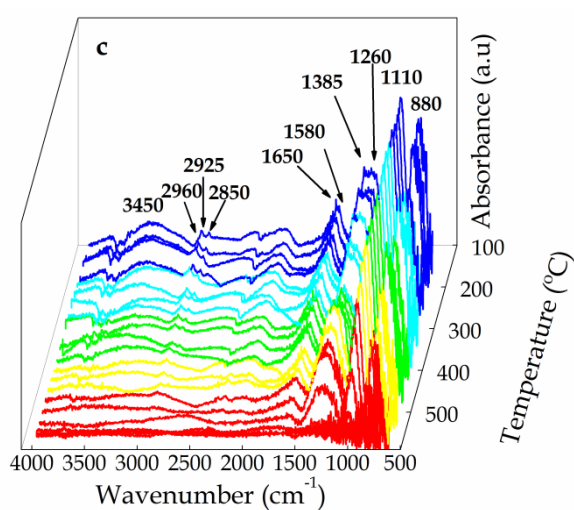

Figure 10. Evolution of FTIR bands corresponding to different functional groups with combustion temperature (TPO-FTIR analysis) for the coke deposited on Ni/Al_2O_3 (a), $Ni/CeO_2-Al_2O_3$ (b) and $Ni/MgO-Al_2O_3$ (c).

As observed, the same FT-IR bands appear in the profiles of the three deactivated catalysts, suggesting that the nature of the coke deposited on the three catalysts is very similar, which corresponds to an oxygenated nature, but their TPO profiles differ depending on the promoter used, with coke combustion temperature being lower for $Ni/CeO_2-Al_2O_3$ catalyst (Figure 7). In addition, significant features are observed for $Ni/CeO_2-Al_2O_3$ in the FTIR spectrum, and are summarized as follows: i) 1050 cm^{-1} and 1110 cm^{-1} bands associated with the oxides of the support decrease initially, but greatly

524 increase at high temperatures, presumably due to the different oxidation states of this

525 promoter; ii) 3450 cm^{-1} band intensity is very high compared to the other catalysts,

526 which is evidence of a large amount of water adsorbed on this catalyst. Both

527 characteristics of $Ni/CeO_2-Al_2O_3$ catalyst (its redox properties and the higher capacity

528 for water adsorption) lead to a higher stability, since they minimize coke deposition and

529 enhance precursor gasification [45, 64].

4.   Conclusions

531 Biomass fast pyrolysis in a conical spouted bed reactor and in-line steam reforming of

532 the volatiles formed in a fluidized bed reactor is a highly suitable strategy for H_2

533 production. However, the type of promoter used significantly affects catalyst stability.

534 Thus, $Ni/MgO-Al_2O_3$ is slightly less stable than Ni/Al_2O_3 catalyst, presumably due to

535 the formation of $MgAl_2O_4$ spinel and the difficulties for reducing the Ni interacting with

536 this spinel. Nevertheless, CeO_2 addition as promoter improves considerably Ni/Al_2O_3

537 catalyst stability, maintaining 60 % conversion once 200 min operation has elapsed,

538 which is related to CeO_2 redox properties, as they increase oxygen availability on the

539 surface, as well as water adsorption capacity, which enhance coke precursor gasification

540 and attenuate catalyst deactivation. Besides, the presence of $CeAlO_3$ spinel also favours

541 coke precursor gasification, and therefore improves catalyst stability.

542 Moreover, although sintering effect is observed for $Ni/CeO_2-Al_2O_3$ catalyst, which may

543 contribute to catalyst decay, deactivation is mainly associated with the coke deposited

544 on the catalyst, which decreases the BET surface area, pore volume and pore diameter,

545 and therefore partially blocks the support pores. Besides, the coke deposited is not

546 evolved coke and its combustion is catalysed by the metals on the catalyst, and therefore

547 occurs at low temperatures (below 400 ºC). The slower evolution of the coke deposited

548 towards more graphitic coke is attributed to the capability of CeO_2 for coke gasification.

549   Whenever MgO is added to Al_2O_3 support, although the evolution of coke to more

550   graphitic structures is attenuated, higher coke deposition rates are attained, which lead

551   to faster catalyst deactivation.
