*These authors contributed equally to this work

Purpose: This study aimed to compare clinically relevant outcomes following transarterial chemoembolization (TACE) and transarterial radioembolization (TARE) in patients with unresectable hepatocellular carcinoma (HCC) using only prospective randomized clinical trials as a source of information.

Materials and methods: A meta-analysis was performed to compare the efficacy of TARE and TACE in treating patients with unresectable HCC. Only prospective randomized trials were included in the quantitative analysis. Overall and progression-free survival, disease control rate, and transplantation rate were the variables under analysis.

Results: Overall survival at 1 year was similar between the two treatment groups (OR =1.31, 95% CI: 0.56–3.04, $P=0.53$). Progression-free survival at 1 year was also not statistically different between the two treatments (OR =0.23, 95% CI: 0.02–2.45, $P=0.22$). Although a higher proportion of patients underwent transplantation in the TARE group (30% vs 20.8%), this difference was not statistically significant (OR =0.68, 95% CI: 0.23–2.01; $P=0.49$).

Conclusion: TARE and TACE provide similar outcomes in unresectable HCC. The role of TARE should be explored in selected patient subpopulations in future clinical trials.

Keywords: selective internal radiation, SIRT, TARE, TACE, outcome, transplantation rates

Introduction

Transarterial chemoembolization (TACE) is the most widely used primary treatment for hepatocellular carcinoma (HCC).¹ According to Western guidelines and clinical practice,^{2,3} as well as based on positive results from two randomized trials and three subsequent meta-analyses, it is the recommended first-line therapy for those patients who are in the intermediate stage and for those who are in the early stage but cannot be treated by resection, transplantation, or percutaneous ablation.⁴ Conventional TACE consists of the intra-arterial infusion of a cytotoxic agent usually mixed with the oily contrast medium Lipiodol, followed by embolization of the tumor blood vessels with gelfoam or calibrated particles, while in TACE based on drug-eluting beads (DEBs), ie, DEB-TACE, DEBs loaded with doxorubicin are used.⁵ Both procedures rely on the combined cytotoxic and ischemic effect to induce tumor cell killing.

In contrast, transarterial radioembolization (TARE, also called selective internal radiation therapy or SIRT) consists of the intra-arterial infusion of much smaller beads that are loaded with a radioactive isotope (yttrium-90), and it relies on the beta radiation emitted by the isotope to induce tumor necrosis.⁵ In noncontrolled prospective and retrospective series, TARE resulted in high rates of objective tumor responses,

prolonged time to progression, and overall survival similar to those with TACE.⁵ Over the past few years, three prospective randomized clinical trials have compared both intra-arterial procedures with main end points other than overall survival.^{6,7} However, survival outcomes have also been reported in these three trials. We have performed a meta-analysis to compare the efficacy of SIRT and TACE in treating patients with unresectable HCC considering only randomized studies that may provide the highest possible level of evidence.

Materials and methods

Study design and inclusion criteria

Clinical trials comparing TACE and SIRT were searched in PubMed. Only randomized controlled trials that included patients with HCC were considered eligible and included in the quantitative analysis. A primary analysis was planned to compare overall survival between TACE and SIRT, while progression-free survival, disease control rate, progression rate, and rate of liver transplantation were secondary aims.

Search strategy

Figure 1 reports the search strategy followed in this meta-analysis. A bibliographic research was conducted of the PubMed, Cochrane Library, and Embase databases. Keywords used included chemoembolization/TACE AND radioembolization/TARE/SIRT/yttrium-90 AND hepatocellular carcinoma. Articles published in English until April 2017 were retrieved. Relevant reviews and meta-analyses of locoregional treatments in unresectable HCC were also examined for potential suitable studies and data. The proceedings of the annual meetings of the American Society of Clinical Oncology (ASCO

and the ASCO gastrointestinal [ASCO GI] Cancers Symposium), European Society of Clinical Oncology (ESMO and ESMO GI), European Association for the Study of the Liver (EASL), American Association for the Study of Liver Diseases (AASLD), and International Liver Cancer Association (ILCA) in the years 2010 through 2017 were systematically reviewed to detect unpublished data if pertinent.

Data extraction and management

Two authors (ACG and GLF) independently screened the titles and abstracts of all the selected studies. All the abstracts of potentially eligible trials were independently read by the same authors who decided whether the study was selected. The full text of all selected papers was then analyzed by the same authors to select all the trials finally included in the pooled analysis. When there are discrepancies in trial search or selection, they discussed with a third researcher (BS) to reach a final consensus. The internal validity of the trial was assessed by evaluating the method used for randomization, blindness, report of missing data, allocation sequence, and allocation concealment. All selected trials published as full-text articles in a peer-reviewed journal were analyzed and classified using the Jadad score when possible. Qualitative and quantitative analyses of the selected articles were independently performed by the same two authors (ACG and GLF); when there are discrepancies, they discussed with a third researcher (BS) to reach a final consensus. Overall and progression-free survival, disease control rate, and transplantation rate were the variables under analysis.

Statistical analysis

Meta-analysis was performed in accordance with the PRISMA statement recommendations.⁹ Data were entered in a computer database for transfer and statistical analysis in Review Manager 5.2. Heterogeneity among the trials was assessed with descriptive aim using the I^2 test. I^2 values above 50% were deemed to suggest large among-trial heterogeneity, values of 25%–50% were deemed to show modest heterogeneity, and values below 25% were deemed to represent low heterogeneity. A level <5% was assumed to be statistically significant. Differences between categorical outcome parameters were quantified using the OR and corresponding 95% CI. Summary statistics for dichotomous outcome data were assessed using the Mantel–Haenszel method. Summary statistics for generic inverse variance data were calculated using the inverse variance method. Pooled analysis of the OR was performed using a random-effect model, assuming an error of 5% as an index of statistical significance.

Figure 1 Process of selection of studies for the meta-analysis.

Results

Study selection and characteristics

The combined search yielded 67 potentially relevant articles, 64 of which were excluded because they were not randomized controlled trials. Three studies published from 2014 to 2016 were analyzed. They included 49 HCC patients treated with TARE and 48 who underwent TACE.^{6–8} One trial had time to progression as the primary end point and the preplanned sample size of 45 patients was not met due to slow recruitment.⁶ A second trial had health-related quality of life (HRQoL) as the primary end point and recruited the planned sample of 25 patients.⁷ The third trial was considered a pilot trial with no specific end point or sample size calculation and recruited 28 patients.⁸ The first two studies were judged to be of high quality and the last one was considered of moderate quality. Table 1 presents the characteristics of the patients in the three randomized clinical trials. Figure S1 shows a funnel plot.

Outcomes

A significant heterogeneity between the trials was detected for progression-free survival (I^2 test: 76%), while no heterogeneity was detected for overall survival, disease control rate, or transplantation rate. As illustrated in Figure 2A, there were no differences in overall survival at 1 year between the two treatment groups (OR =1.31, 95%

CI: 0.56–3.04, $P=0.53$). Progression-free survival at 1 year was also not statistically different between the two treatments (OR =0.23, 95% CI: 0.02–2.45, $P=0.22$), as shown in Figure 2B. Figure 3 shows how progression rates and disease control rates were also not significantly different between groups, with OR values of 0.61 (95% CI: 0.14–2.70, $P=0.51$) for progression rates and 1.80 (95% CI: 0.51–6.30, $P=0.36$) for disease control rates. Finally, although a higher proportion of patients underwent transplantation in the TARE group (30% vs 20.8%), such difference was not statistically significant (OR =0.68 95% CI: 0.23–2.01, $P=0.49$), as shown in Figure 4.

Discussion

TACE is recommended for patients with intermediate-stage HCC according to the Barcelona Clinic Liver Cancer (BCLC) classification,¹⁰ as well as for those with early-stage tumors that cannot be treated with percutaneous ablation, resection, or transplantation.^{1,2} This recommendation is based on strong scientific evidence coming from two randomized clinical trials in which carefully selected patients with low tumor burden were recruited.^{11,12} Without further scientific support, its use has nevertheless been expanded to treat almost any patient with liver-only or liver-predominant disease even in the presence of vascular invasion.^{13,14} In consequence, TACE is the most frequently used primary therapy for HCC worldwide.¹⁵

Abbreviations: TACE, transarterial chemoembolization; TARE, transarterial radioembolization.

TARE was initially used to treat those patients who were considered suboptimal candidates for TACE due to the large tumor burden or vascular invasion.^{16,17} Contrary to TACE and due to the much smaller size of the beads,

TARE can be safely used in patients with portal vein occlusion or hepatofugal portal vein blood flow.¹⁸ For the same reason, it may also avoid the enhanced release of angiogenic factors, such as vascular endothelial growth factor (VEGF)

Figure 4 Forest plots of transplantation rates.

Abbreviations: TACE, transarterial chemoembolization; TARE, transarterial radioembolization.

and others, caused by the hypoxic microenvironment induced by TACE. This increase in serum VEGF levels after TACE may indeed predict a worse overall survival in TACE-treated patients.¹⁹ Finally, permanent occlusion of the feeding vessels precludes subsequent TACE procedures and contraindicates the technique when the tumors cannot be targeted in a highly selective fashion.

Other indications of TARE have been integrated in experienced centers, including radiation lobectomy to rescue patients for resection and radiation segmentectomy to achieve complete tumor necrosis when percutaneous ablation is not feasible due to tumor location.²⁰ The indications of TACE and TARE have thus progressively overlapped and TARE may in fact compete with TACE in some treatment characteristics. For instance, while the access of cytotoxic drugs to tumor cells is hampered by tumor volume constraints in TACE, leakage from Lipiodol, and physical distance of drug-eluting particles from target tumor cells, the delivery of radiation to tumor cells in TARE is secured provided the particles reach the tumors as confirmed in the pretreatment workup.

Retrospective studies comparing single-center experience and different meta-analyses have shown no differences in outcomes.²¹ However, a strong patient selection bias is inherent to such studies and, therefore, the quality of the information derived from these meta-analyses is low. This is the first meta-analysis comparing TACE and TARE that analyzes a significant number of patients derived only from prospective randomized clinical trials. The analysis indicates that overall and progression-free survival at 1 year, liver transplantation rate, and disease control rate were all not statistically different between the two therapeutic groups.

The PREMIERE trial⁶ demonstrated a benefit of TARE compared to TACE both in terms of time to progression (HR =0.122; 95% CI: 0.0227–0.557) and transplantation rate (54% vs 30%), which was not observed in the other two trials,^{7,8} where time to progression was similar and transplantation in patients was done anecdotally. Indeed, median

time to progression was not reached in the PREMIERE trial (progression rate at 1 year >90%) and it was 12.3 months in the Mainz trial, and progression-free survival was 3.6 months in the SIRTACE trial. These differences are probably due to the different patient characteristics. In the PREMIERE trial,⁶ most patients (75%) were in the early stage and had unilobar involvement, while in the Mainz trial, most patients were in the intermediate stage and had bilobar tumor involvement; in the SIRTACE trial, a relevant 20% of patients were in the advanced stage due to altered performance status, which is usually associated with higher tumor burden and worse outcomes. The findings are therefore not surprising. TARE does not target micrometastases. It has already been reported that the more tumors at baseline, the higher is the chance of having early tumor progression;²² so time to progression is expected to be longer among patients at earlier stages and the impact of a highly active treatment on tumor progression is likely higher in this stage. What is less expected is that median time to new hepatic lesions was 7.3 months for TACE vs not reached for TARE in the PREMIERE trial.⁶ A potential explanation is that identification of progression in the targeted liver volume could be more difficult in TARE-treated livers due to the heterogeneous contrast enhancement produced by radiation in the nontumoral liver.

In terms of absolute cost, TARE is more expensive than TACE. However, no cost-effectiveness analysis has been reported so far. Such analysis should take into account the differences in procedural cost, number of procedures (in TACE, 80% of subjects receive multiple treatments,²³ compared to 93% of SIRT patients receiving single treatment),²⁴ post-procedural follow-up (less intensive for TARE), and benefit in terms of survival and HRQoL. The benefit in terms of HRQoL initially shown in a nonrandomized study¹⁰ was not confirmed in the randomized SIRTACE trial,⁸ reflecting the limitations of QoL evaluation. Additionally, in the various retrospective and prospective studies, as well as in meta-analyses, there was no difference in the occurrence of

adverse events between the two procedures, with a tendency to a lower toxicity of TARE.

The main limitations of this meta-analysis are that none of the randomized controlled trials had overall survival as the main end point and, consequently, the samples are small; this is reflected in the high heterogeneity of the studies. Moreover, the target populations were not homogeneous across trials, as previously mentioned. In addition, we must also consider that in both groups, the modalities and regimens are different.

Our meta-analysis reveals that TARE and TACE have similar effects in unresectable HCC patients in terms of overall survival, disease control rate, transplantation rate, and progression rate. It is very unlikely that further trials will be conducted in unrestricted HCC populations, and our results suggest that comparative trials could better focus on specific indications, including lobar portal vein invasion, downstaging, or reduction of the dropout rate from transplant waiting lists.
