Abstract.

This study illustrates the strong potential of combining paleoenvironmental reconstructions and paleoclimate modeling to refine the paleoenvironmental and chronological context of archaeological and paleontological sites. We focus on the El Harhoura 2 cave (EH2), an archeological site located on the North-Atlantic coast of Morocco that covers a period from the Late Pleistocene to the mid-Holocene. On several stratigraphic layers, inconsistencies are observed between species- and isotope-based inferences used to reconstruct paleoenvironmental conditions. The stratigraphy of EH2 also shows chronological inconsistencies on older layers between age estimated by Optical Stimulated Luminescence (OSL) and Combination of Uranium Series and Electron Spin Resonance methods (combined US-ESR). We performed paleoclimate simulations to infer the global paleoclimate variations over the EH2 sequence in the area, and we conducted a consistency approach between paleoclimate reconstruction estimated from simulations and available from EH2 paleoenvironmental inferences. Our main conclusion show that the climate sequence based on combined US-ESR ages is more consistent with paleoenvironmental inferences than the climate sequence based on OSL ages. We also evidence that isotope-based inferences are more congruent with the paleoclimate sequence than species-based inferences. These results highlight the difference in scale between the information provided by each of these paleoenvironmental proxies. Our approach is transferable to other sites due to the increase number of available paleoclimate simulations.

Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions

1 Introduction

The reconstruction of paleoenvironments has long been a subject of great interest, particularly to study the past biodiversity. Archeological sites provide unique opportunities to infer paleoenvironements from faunal and/or vegetal remains (e.g., Avery, 2007; Denys et al., 2018; Stoetzel et al., 2011; Comay and Dayan, 2018; Matthews, 2000; Marquer et al., 2022) or stable light isotope composition of sediments or biological remains (e.g. Tieszen, 1991; Royer et al., 2013). These approaches allow one to characterize the past landscapes and biotic environments on the localities of the sites. However, inconsistencies between isotope compositions, the different types of remains and available stratigraphy are often to be faced and prevent to properly assess the possible relationships between biodiversity and paleoenvironmental changes. This is the case for the El Harhoura 2 (EH2) cave, an archeological site located on the North-Atlantic coast of Morocco, that we use here as a case study.

At EH2, paleoenvironments have mainly been inferred based on two different kinds of proxies: species presence and stable light isotope composition. Because of species habitat preferences, the presence and/or abundance of particular taxa is a strong indicator of certain types of environment, such as amphibians for more humid contexts, or gerbils and jerboas for more arid contexts (e.g., Fernandez-Jalvo *et al.*, 1998; Stoetzel *et al.*, 2011). Stable light isotope composition of small mammals teeth provide varied indications about diet and paleoenvironments (Longinelli and Selmo, 2003; Navarro et al., 2004; Royer et al., 2013), and thus about aridity, seasonal variations and vegetal cover. At EH2, inconsistencies are observed between species- and isotope-based inferences (Jeffrey, 2016; Stoetzel et al., 2019). On two stratigraphic layers, while species presence suggests drier conditions than usual, isotopic composition of Meriones teeth suggest a more humid and temperate climate. Such discrepancies are not fundamentally surprising, because species presence and isotopic composition do not deliver the exact same information: species presence carries a signal at the scale of faunal communities, while isotopic composition reflects the diet preferences of a limited number of individuals of a single species. But these mixed messages make it difficult to extrapolate the global environmental conditions of the site.

Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions

The stratigraphy of EH2 also shows some chronological inconsistencies. Radiocarbon dating (AMS-^{14}C) is the most reliable dating method, however it cannot date remains older than 50 ka. Beyond this reach, other dating methods must be applied, such as Optical Stimulated Luminescence (OSL) and Combination of Uranium Series and Electron Spin Resonance methods (combined US-ESR). It has been shown that OSL and combined US-ESR methods display important differences in the estimated age of the same stratigraphic layers (Ben Arous et al., 2020b). These differences are related to the fact that these dating methods do not date the same objects. OSL estimates the last time quartz sediment was exposed to light, while combined US-ESR estimates the age of fossil teeth. To date, the respective reliability of these methods is difficult to establish.

These kind of paleoenvironmental and chronological discrepancies are widespread in archeology and paleontology. Model simulations may inform us about the broader climate influences over the region, and therefore might enrich our understanding of the large-scale climate changes. Climate models allow to simulate paleoclimates using the physical laws that describe the dynamics and thermodynamics of the Earth system, and model data comparisons have shown that the large scale patterns are consistent with paleoclimate reconstructions, even though regional feature are underestimated or affected by model biases (Kutzbach and Otto-Bliesner, 1982; Braconnot et al., 2012; Duplessy and Ramstein, 2013; Schmidt et al., 2014; Harrison et al., 2015). They thus offer a consistent framework to test the consistency between climate drivers and environmental changes recorded at EH2 depending for the different stratigraphy options.

In this paper, we make use of simulations run over le last 10 years with the IPSL model to derive a set of atmosphere alone simulations with the latest version of the model (Boucher et al., 2020; Hourdin et al., 2020). This version is chosen because it of its skill in reproducing the climate in the region. However, because of the differences in scale and resolution between the archaeological record and the paleoclimate simulations, several caveats must be considered beforehand. Firstly, archaeological and paleoclimate data present different temporal resolution. Paleoclimate simulations present snapshots of the hypothetic climate states at precise ages. Conversely, an archeological layer is a stratigraphic/sedimentary unit that can cover shorter or longer periods and undergoes microclimatic

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions
Open Access
EGU

variations that cannot be disentangled. Nevertheless, because EH2 is dated from the Late Pleistocene to the mid-Holocene period (Marine Isotopic Stages (MIS) 5 to 1), which in the area is marked by important global climatic fluctuations over time (i.e. the last glacial-interglacial transition; e.g., Hooghiemstra *et al.*, 1992; deMenocal, 1995, 2004; Le Houérou, 1997; Carto *et al.*, 2009; Trauth *et al.*, 2009; Drake *et al.*, 2011, 2013; Blome *et al.*, 2012; Kageyama *et al.*, 2013; Couvreur *et al.*, 2020), we do not expect these differences to prevent a global consistency approach. Secondly, archaeological and paleoclimate data present different spatial resolution. The spatial resolution of the atmospheric grid use here is ~150 km (Boucher et al., 2020). Conversely, EH2 represents a precise locality, and most species whose presence was recorded have a lifetime dispersal range largely inferior to 150 km (e.g., the jird *Meriones shawii* has a home range estimated between 200-1000 m^2 (Ghawar et al., 2015)). Then, the climate described by the global simulations cannot faithfully represent the magnitude of the differences between the different paleoclimate periods, nor microclimate variations at EH2. We make the hypothesis that the results of the global climate simulations are sufficient to capture the large climate changes we are interested in. Regional dynamical or statistical approaches would be derived from these simulations and would add additional unknowns due to the fact that the tuning of these methods has to be done using present day observations at the site. The cave is now imbedded in an urban area that experiences rapid climate and environmental changes over the last century and it is unclear that tuning over this recent period would be valid for the past conditions we are considering in this study.

In order to discuss and refine the paleoenvironmental and chronological context of EH2, we conduct a consistency approach between paleoclimate reconstruction from simulations and paleoenvironmental inferences based on EH2 content from the literature. To overcome the issue of the differences between dates estimated with different dating methods, we considered two separate chronological sequences based on different dating method. Finally, for each of the chronological sequences, we test the consistency between paleoclimate variables extracted from simulations, and species presence and stable light isotope composition. We expect this consistency approach to discriminate paleoenvironmental inconsistencies between species- and isotope-based proxies, and also eventually to distinguish between the two chronological sequences, and therefore between the two dating methods.

Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions

The remainder of the manuscript is organized as follow. We present the EH2 cave and the different choices made to run the climate set of paleoclimates in section 2. In section 3 we present the consistency analyses and the results. The discussion in section 4 highlights the major results and the proof of concept of the proposed approach, before the general conclusion (section 5).

2 Material and methods

2.1 El Harhoura 2 cave

2.1.1 Presentation of the site

The archeological site EH2 is located on the Moroccan Atlantic coast in the Rabat-Témara region (33°57'08.9" N / 6°55'32.5" W). The climate of the area is marked by a strong seasonal variability (**Fig 1**) with a relatively warm and dry summer during which precipitations are almost absent and evaporation is particularly high, and a relatively cool and short winter, which is also the rainy season (Sobrino and Raissouni, 2000; Lionello et al., 2006). Inferences based on species presence and abundances suggest that, in the past, the site underwent important climatic fluctuations, which resulted in a succession of relatively humid/arid and open/closed environments at EH2 (Stoetzel, 2009; Stoetzel et al., 2011, 2012a, b). As a result, paleolandscapes of the Late Pleistocene are described as open steppe or savanna-like lands with patches of shrubs, woodlands and water bodies, the latter expanding during wet periods, especially during the mid-Holocene (Stoetzel, 2009; Stoetzel et al., 2012a, 2014).

Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions

2.1.2 Chronostratigraphy and dating hypotheses

EH2 displays a high resolution stratigraphy and its layers have revealed an impressive taxonomic richness and delivered an important amount of large and small vertebrate remains (Michel et al., 2009; Stoetzel et al., 2011, 2012b). Its stratigraphy is currently divided into 11 layers (**Fig2 A**) (each layer is abbreviated as "L" followed by the layer number), among which eight are well studied and considered in this study. All of these eight layers have been dated (Ben Arous et al., 2020b). Three different methods were used: AMS-^{14}C (Nespoulet and El Hajraoui, 2012; Marquer et al., 2022), OSL (Jacobs et al., 2012) and combined US-ESR (Janati-Idrissi et al., 2012; Ben Arous et al., 2020a). AMS-^{14}C is the most reliable dating method of the three and is used for recent layers (L1 and L2). However, for older layers beyond the reach of AMS-^{14}C (L3, L4a, L5, L6, L7 and L8), OSL and combined US-ESR method are used. However, when applied to a same layer, these two methods present discrepancies. For example, it is the case of L5 dated at ~60 ka by combined US-ESR and at ~100 ka by OSL (**Fig2 F**). In addition, when two consecutive layers are dated with these different methods, dates can be inconsistent with the relative position of the layers in the stratigraphy, as it is the case for the L8 dated at ~90 ka using combined US-ESR and L7 at ~110 ka using OSL (**Fig2 F**). To overcome this issue, we choose to set two separate dating hypothesis (DH) for the stratigraphic sequence: DH1 refers to the chronological sequence based on AMS-^{14}C and combined US-ESR dates, and DH2 on AMS-^{14}C and OSL dates. The DH are presented on **Fig2 F**.

2.1.3 Paleoenvironmental variables

Paleoenvironments at EH2 have been inferred based on two different kinds of proxies: species presence and stable light isotope composition. Regarding species presence, paleoenvironments are reconstructed using the Taxonomic habitat index (THI). The THI is a palaeoecological index which allows one to reconstruct the paleolandscape based on the species composition of the community (Stoetzel, 2009; Stoetzel et al., 2011, 2014). Each species is associated to its preferred habitat through an actualist approach. From that is deduced a qualitative composition of the paleolandscape, expressed as a

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions

percentage. Data are from Stoetzel et al. (2014) and are presented in **Fig2 B**. Note that the oasis habitat was not considered because its percentage of presence does not vary over the EH2 sequence.

Isotope-based inferences are from *Meriones* teeth. They provide information about the diet and the environment of studied individuals (Longinelli and Selmo, 2003; Navarro et al., 2004; Royer et al., 2013). Two isotopic fractions are considered: $\delta^{18}O$ and $\delta^{13}C$. Plants consumed by small mammals are sensitive to environmental conditions which shows up in their $\delta^{13}C$ and $\delta^{18}O$ values. Because of that, they are good indirect indicators of aridity, seasonal variation and vegetal cover (Longinelli and Selmo, 2003; Blumenthal et al., 2017; Blumenthal, 2019). We used $\delta^{18}O$ and $\delta^{13}C$ means, minimums and maximums, and reconstructed mean annual precipitations (MAP) computed from $\delta^{18}O$ from Jeffrey (2016). Data are presented in **Fig2 C, D** and **E**.

2.2 Paleoclimate reconstruction

2.2.1 Climate model

We ran a new set of paleoclimate simulations covering the Late Pleistocene to mid-Holocene period using the model LMDZOR6A (Hourdin et al., 2020). This model is the atmosphere-land surface component of the IPSL-CM6A-LR coupled model (Boucher et al., 2020) that has been used to run the CMIP6 ensemble of past, present and future climate simulations (Eyring et al., 2016), including the mid-Holocene (Braconnot et al., 2021), last interglacial (Sicard et al., 2022; Otto-Bliesner et al., 2021) and Pliocene (Haywood et al., 2016) periods. It has an atmospheric resolution of 144 points in longitude, 143 points in latitude and 79 vertical levels (144x143xL79). Compared to previous IPSL model version it has a finer spatial and vertical resolution and an improved representation of atmospheric and land surface processes. In addition, the simulated climatology of temperature and precipitation over the region is consistent with observations when the model is run for present day conditions with sea-surface temperature prescribed to the monthly climatology of the observed Atmospheric Model Intercomparison Project (AMIP) SST fields (Boucher et al., 2020, 2018) **(Fig 1** and **3)**. Comparison of the simulated annual mean cycle of surface air temperature and precipitation match quite well the observed one,

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions
Open Access
EGU

160 despite an overestimation of summer temperature and sligh 0-1 month shift in the seasonal cycle of precipitation (**Fig3**).

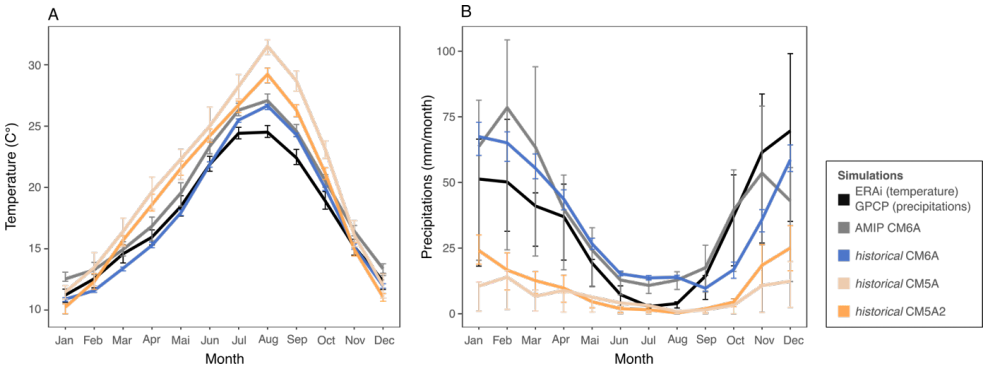

Fig. 3. Monthly variations in mean temperature (unit: C°) and precipitations (unit: mm/month) of the 165 ERAi and GPCP reanalyzed data, the AMIP CM6A simulations (atmosphere only) and *historical* coupled simulations of IPSL-CM5A-LR, IPSL-CM5A2-LR and IPSL-CM6-LR models on the four grid cells containing EH2 cave. Data were averaged on 30 seasonal cycles (1980-2009). Error bars are estimated from interannual variation over the averaged 30 years and is visualized by quartiles. As a reference for current climate we used monthly data from the global atmospheric reanalysis ERA-interim 170 for monthly mean temperature (Berrisford et al., 2011) and from the GPCP v2.3 (Global Precipitation Climatology Project) for monthly mean precipitations (Adler et al., 2018).

2.2.2 Paleoclimate simulations

We produced a total of six paleoclimate simulations with the LMDZOR6A model for the key periods 175 of the EH2 sequence: *midH* (for the mid-Holocene period), *earlyH* (for the early Holocene period), *midMIS3* (for the mid MIS3 period), *lateMIS4* (for the late MIS4 period), *midMIS4* (for the mid MIS4 period) and *MIS5d* (for the MIS5d period). The different simulations differ by prescribed Earth's orbital parameters, atmospheric trace gases composition, ice-sheet configuration and sea surface temperature (SST) in order to represent the climate conditions of the different periods (see **Table 2** for details). For

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

this we make use of preexisting paleoclimate and control simulations that have been run in the last 8 years with different versions of the IPSL model (Marti et al., 2010; Dufresne et al., 2013; Boucher et al., 2020) (details are available in **Table 1**).

Table. 1. Preexisting coupled simulations from the IPSL repository.

Model	IPSL-CM6A-LR	IPSL-CM5A-LR	IPSL-CM5A-LR	IPSL-CM5A-LR	IPSL-CM5A-LR	IPSL-CM5A2-LR
Date	~ 6 kyr BP	~ 9 kyr BP	~ 40 kyr BP	~ 60 kyr BP	~ 66 kyr BP	~ 115 kyr BP
References	Kageyama et al. (2017) Braconnot et al. (2021)	Le Mézo et al. (2017)	Le Mézo et al. (2017)	Le Mézo et al. (2017)	Le Mézo et al. (2017)	Sicard personal communication

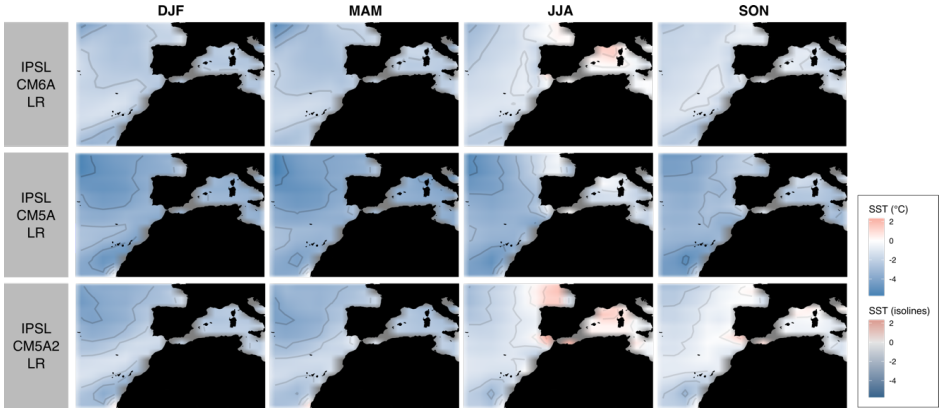
We also ran a control simulation *Ctrl* (see **Table 2** for details), representative of the present-day climate. The Sea Surface Temperature (SST) boundary conditions used in *Ctrl* correspond to the mean annual cycle of the SST estimated from current observations used for the AMIP (Boucher et al., 2018) and repeated in time. This *Ctrl* simulation will be considered as the reference for the current climate in our ensemble of new atmospheric simulations.

Unfortunately, simulated paleoclimate SST are not directly comparable because they were performed using different versions of the IPSL model (**Table 1**). This is due to the fact that the various versions of the model are characterized by different physical representations, resolutions and tuning. In particular, these different model versions show different present-day SST biases when compared to observations (**Fig 4**). They translate in different representation of the seasonal cycle of surface air temperature and precipitation at EH2 in simulations with LMDZOR6 when used as boundary condition instead of the AMIP SST field (**Fig 3**). The magnitude of the seasonal cycle is overestimated and precipitation are underestimated with almost no seasonality when IPSLCM5A or IPSLCM5A2 control SST are used as boundary condition. This differences that can be attributed exclusively to the differences in the SST biases are significant and may deteriorate the simulation of other variables of interest, thus complicating the intercomparison between our new LMDZOR6A simulations. Indeed, the differences between these simulations for the periods of interest at EH2 could then result from the difference in bias between the various versions of the model rather than representing significant climate differences between periods.

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions

205 In order to produce an homogeneous set of simulations we thus apply a correction to the SST fields to that the results better fit the observations for present day and the information of the SST changes for the different period is kept as part of the prescribed paleoclimate SST boundary conditions.



210 **Fig. 4.** SST biases of IPSL-CM5A-LR, IPSL-CM5A2-LR and IPSL-CM6A-LR relative to AMIP's SST (issued from current observations) (unit: °C). The seasons are DJF: December, January, February (winter); MAM: March, April, May (spring); JJA: June, July, August (summer); SON: September, October, November (autumn).

215 **2.2.3 Sea-surface boundary conditions**

We correct the simulated SST of each coupled simulation for the systematic bias of the model. This is done by removing the SST bias corresponding to the model version used. In other words, corrected SSTs were obtained according to the formula:

$$SSTcor = SSTsim + (SSTamip - SSTmod)$$

220 Where SSTsim are the SSTs from the coupled simulation, SSTamip are the AMIP SSTs, SSTmod the SSTs of the model version for current days and SSTcor the corrected SSTs, which will be used as boundary conditions in our new LMDZOR6A simulations. The underlying hypothesis in this correction scheme is that the mean annual SST bias cycle, e.g. SSTmod – SSTamip for each, is stationary in time.

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions

Note also that boundary conditions files of pre-existing (coupled) simulations were interpolated on a 143x144xL79 grid to be compatible with the grid of LMDZOR6A.

Configuration details for the new set of simulations are summarized in **Table 2**. The length of all these new simulations is 50 years, which is long enough given the fact that LMDZOR6A is an atmospheric model. In the following annual mean cycles are estimated from the last 30 years of each LMDZOR6A simulation.

Table. 2. Forcing and boundary conditions of the simulations produced in this study.

2.2.4 A subset of key paleoclimate variables

To characterize the large-scale climate over the area, we worked on the mean annual cycle of the four grid cells containing EH2. From simulations *Ctrl*, *midH, earlyH, midMIS3, lateMIS4, midMIS4* and *MIS5d* we extracted nine output variables. We choose to focus on variables that are likely to directly or

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions

indirectly influence the landscape and/or biotic environment. Based on a review of the ecological literature, we selected: *tsol* (temperature at surface, in C°) (Gillooly et al., 2001; Yom-Tov and Geffen, 2006; Ebrahimi-Khusfi et al., 2020), *precip* (precipitations, in mm.month^{-1}) (Yom-Tov and Geffen, 2006; Alhajeri and Steppan, 2016; Ebrahimi-Khusfi et al., 2020), *qsurf* (specific humidity, in kg.kg^{-1}) (Hovenden et al., 2012; Alhajeri and Steppan, 2016), *w10m* (wind speed at 10 meters, in in m.s^{-1}) (McNeil, 1991; Tanner et al., 1991; Chapman et al., 2011; Pellegrino et al., 2013), *sols* (solar radiation at surface, in W.m^{-2}) (Monteith, 1972; Fyllas et al., 2017), *drysoil_frac* (fraction of visibly dry soil, in %) (Paz et al., 2015) and *humtot* (total soil moisture, in kg.m^{-2}) (Paz et al., 2015). Two additional variables were computed. The diurnal temperature range *tsol_ampl_day* (in C°; Alhajeri and Steppan, 2016) computed from *tsol_max* (day maximum temperature) and *tsol_min* (day minimum temperature) as: *tsol_max – tsol_min*; and the hydric stress *hyd_stress* (in mm.day^{-1}; Martínez-Blancas and Martorell, 2020) computed from *evapot* (potential evaporation) and *evap* (evaporation) as: *evapot – evap*. We explore variations in monthly means (mean value of the variable) and monthly standard deviations (amplitude of seasonal variation). Correlation between these variables was tested and not found to be significant, suggesting that they all bring complementary information on environmental conditions over the regions

The association of paleoclimate simulations with the stratigraphic layers of EH2 is based on age proximity. This step is performed for both DH1 and DH2 (the DH presented in section 2.1.2). As a result, we obtain two hypothetic paleoclimate sequences corresponding to EH2 sequence.

2.3 Consistency analyses

To test the consistency between the paleoclimate simulations and paleoenvironmental inferences that have been made from the content of the EH2 site we use two kind of analyses: two-block Partial Least Squares (2B-pls) and pairwise correlation tests. For these analyses, the climate variables are the principal components provided by the principal component analysis described above. The different paleoenvironmental proxies considered are $\delta^{18}O$ and $\delta^{13}C$ means, minimums and maximums, and MAP, as well as percentages of represented habitats indicated by the THI.

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

The 2B-pls tests the global covariance between climate variables and paleoenvironmental variables. This multivariate method explores patterns of covariation between two sets of variables, i.e. two blocks (Sampson et al., 1989; Streissguth et al., 1993). Axes of maximum covariance between the two blocks are generated, thus reducing data dimensionality. A coefficient (r-PLS) is computed and represents the strength of covariation. The r-PLS is in the range of (0,1). The closer the r-PLS is to one, the stronger the covariation. P-values indicating the statistical significance of r-PLS were calculated based on 1000 permutations against the null hypothesis (absence of covariation between the two sets of variables). Then, to refine our results, we performed pairwise correlation tests.

In order to easily visualize the climate proximity/differences between EH2 layers we used a principal component analysis (Jolliffe and Cadima, 2016). This analysis allows one to find new uncorrelated variables that successively maximize variance (the principal components). They are computed from the eigenvectors and eigenvalues of the covariance/correlation matrix (correlation matrix in our case, as all the variables are standardized). Then, the data can be visualized along the leading principal components, which maximizes the amount of information displayed. It allows us to visualize EH2 layers into a climate-space, meaning that the proximity of stratigraphic layers in the plot simply represents the similarity between the climate of the layers. For each climate variable, we considered both the annual mean and seasonal variation, estimated by the annual standard deviation.

3 Results

3.1. Simulated climate changes

Changes in atmospheric circulation and pressure over the sequence are presented in **Fig 5**, and plots of monthly precipitations and temperatures for the region of EH2 are available in **Fig 6**. The similarity/dissimilarity between the climate of each period and the current climate is showed on similarity maps on **Fig 7**.

The dynamic over the region differ between winter and summer. Winter is marked by a vertical pressure gradient and dominated by a zonal circulation from west to east. In summer, the pressure gradient is

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

more horizontally-oriented, with the installation of a depression on the North African continent and the northward drift of high pressures on the Atlantic Ocean (**Fig 5**). All over the sequence, these processes shift slightly, especially between *lateMIS4, midMIS4, midMIS3* (period from ~66ka to ~40ka) and *Ctrl*, *midH, earlyH* (period from ~9ka until today) (**Fig 5** and **7**), at the exception of *MIS5d* (~115ka) which conditions are relatively close from current ones on **Fig 7**. There are also important changes in the magnitude of the seasonal temperature variation from June to October and of the seasonal precipitation variation from October to May between these two periods (**Fig 6**).

From ~115ka (*MIS5d*) until ~40ka (*midMIS3*), the climate was colder than today. From ~66ka (*midMIS4*) to ~40ka (*midMIS3*), there is also more precipitations in winter (**Fig 6**). These conditions share similarities with what can be found in slightly higher latitudes today (**Fig 7**), it is concomitant with the pressure along the North Africa (and Morrocan) coast (**Fig 5**). In ~115ka (*MIS5d*), conditions are also cold, but as dry as in the Holocene (**Fig 5**). They are not related to changes in the atmosphere dynamic (**Fig 5**) but rather to changes in insolation, with current analogs limited to North Africa (**Fig 7**). Starting from ~9ka (*earlyH*) the seasonal temperature variation is enhanced. Conditions in winter and spring are similar to the current climate (**Fig 7**), but with a warmer autumn and a much warmer summer (**Fig 6**). At ~6ka (*midH*), climate conditions are close from today (**Fig 7**), but with a slightly more important seasonal temperature variation (**Fig 6**).

Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions

Based on DH1, our results indicate four major climate transitions (**Fig 8**). The first occurs between L8 and L5. In L5 the climate is wetter and colder with more precipitation, more soil humidity, increased wind speed, less hydric stress and less portions of dry soil. Humidity, precipitations and wind speed also show an important seasonal variability. The second transition, less marked, is between L5 and L4a. Climate in L4a is rather similar to the climate in L5, but precipitations and humidity have increased. Seasonal variations are globally more pronounced. The third transition is between L3 and L2. The climate changes drastically between these two periods, with hotter and drier conditions in L2 corresponding to the end of the last deglaciation. Temperature, solar radiation, water stress and soil dryness all increase, coupled with a decrease in precipitation, soil moisture and wind speed. All these changes are consistent with aridification or desertification from L2. Surprisingly, however, specific humidity is enhanced, which is partly consistent with the decrease in precipitation and wind speed at this coastal location, and is concomitant with large changes of the atmospheric circulation patterns over this region from L2 (**Fig 5**). The last climatic transition is more subtle and occurs between L1 and Act. The environment in Act seems closer to the one in L8 with more seasonal variability in temperature, solar radiation and water stress (**Fig 8**).

Overall, there is an alternation of two main climate types. This partition is confirmed by the principal component analysis shown in **Fig 9**. The first principal component explains 65.85% of the observed variance (of the standardized variables) and splits the layers of EH2 into two climate regimes. The first regroups L3, L4a and L5 and is defined by humid and windy conditions with a high seasonal variability. The second includes Act, L1, L2 and L8 and is characterized by hot and dry conditions. The second axis, explaining 30.28% of the variability, divides the latter group into two subgroups: L1 and L2 with high seasonal variability, and Act and L8 with a lower seasonal variability.

Regarding DH2, we observe three important and abrupt climatic transitions (**Fig 8**). The first happened between L5 and L4a. In L4a, the climate is much windier and temperatures are colder with a substantial increase of diurnal temperature range. Precipitations and soil moisture increase importantly while hydric stress decreases. The climate also presents an overall higher seasonal variability. These tendencies persist in L3. The second transition is between L3 and L2. The soil is drier and the hydric stress increases

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

Climate of the Past Discussions

greatly as well as solar radiation and temperature. Precipitation and soil moisture are less important. Conditions in L1 are close from those in L2, a bit colder with a less marked water stress. The last climate transition, smoother than the previous ones, occurs between L1 and Act and is mainly marked by a global decrease of seasonal variations.

Results associated with DH2 suggest that three types of climate succeeded one another at EH2. The first group is composed of L8, L7, L6 and L5, the second by L3 and L4a and the third by L2, L1 and Act. As for DH1, this partition is supported by the principal component analysis results presented in **Fig 9**. The first principal component, which explains 52.10% of the observed variance, separates the group containing L8, L7, L6 and L5 with the one composed of L3 and L4a. The second principal component, explaining 42.35% of the observed variance, separates the group of L2, L1 and Act from others. L8, L7, L6 and L5 are characterized by a hot and dry climate and a low seasonal variation. L3 and L4a are defined by a wet and windy climate, with important precipitations and high seasonal variability. Finally, L2, L1 and Act present a hot environment associated with an important water stress.

3.2.2 Consistency analyses

Results of 2B-pls and pairwise correlations between climate and paleoenvironmental variables are presented in **Fig 10**. Regarding DH1, 2B-pls shows that there is a statistically significant covariation between THI values and all climate variables, and between isotope data and the second principal component (climate variables contributing to the second principal component are indicated in **Fig 9**). Specifically, this second principal component is positively correlated with $\delta^{18}O$ mean, maximum and minimum values and $\delta^{13}C$ maximum values. Conversely, DH2 presents no statistically significant result for 2B-pls nor correlations, meaning that for DH2 paleoclimate inferences and paleoenvironmental proxies are not consistent.

Climate of the Past Discussions

4 Discussion

Despite the differences in scale and resolution between climate and paleoenvironmental data, we find statistically significant and meaningful results. The climate changes considered seem to be large enough for a consistency to be detected between the climate and environmental data. First, we discuss the paleoclimate changes described by simulations over the period, and the underlying dynamical processes. Then, we address the contribution of climate simulations to the discussion of chronological and paleoenvironmental discrepancies of EH2.

4.1 Paleoclimate variation and underlying forcings

Paleoclimate simulations allow us to discuss several important climate changes at EH2 over the Late Pleistocene to mid-Holocene period. These paleoclimate variations may result from mixed influences from global and regional dynamical processes.

The variation of radiative-related variables (as sols, tsol or tsol_ampl_day) seems to depend more of global processes related to large-scale climate changes. They clearly separate interglacial climate (*Ctrl, midH, earlyH*) from glacial climate (*midMIS3, lateMIS4, midMIS4, MIS5d*). The warm/cold differences between these two periods is due to the size of the ice-sheet and variation in gaz concentration. For example, mean insolation and temperature significantly increase from early Holocene, along with higher gaz concentration and the retreat of the ice sheet. The amplitude of the seasonal variability of insolation and temperature also increases at this period, along with variations in obliquity and precession of the Earth orbit. Note that *MIS5d* is a peak of glacial sub-stage where conditions where quite mild, which explains the proximity of its climate with current ones.

The variation of the humidity-related variables (as precip, hydric_stress or drysoil-frac) seems to be mainly explained by a translation of the regional atmospheric dynamic processes over the sequence. For example, mean precipitations and soil moisture are higher from mid-MIS4 to mid-MIS3. At this time, the wet and cold westerly winds descend further south and blow across the area of EH2. This is explained by the position of the Açores High: the proximity of the high pressures creates a stronger pressure

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

gradient, thus favoring a stronger zonal circulation, which brings cooler and more humid air on the North African coast. Therefore, for this region, the dynamic effect and changes in moisture advection over the region have a significant impact on whether a warmer climate would lead to increased moisture content and precipitation.

4.2 Paleoclimate simulations and chronostratigraphy

The climate sequence varies significantly depending on the DH it is based on. Based on DH1, there is an alternation of semi-arid and temperate climates. The climate succession based on DH2 is quite different, with the presence of three main climate types and rapid transitions between them. The climate sequences based on DH1 and DH2 are not equally congruent with paleoenvironmental proxies from the literature. Indeed, several statistically significant correlations and covariation are found between the climate sequence based on DH1 and the paleoenvironmental inferences, while none are found for the one based on DH2. Thus, our results suggest that, with respect to EH2, combined US-ESR dating may be more reliable than OSL dating. As this dating process relies on quartz grains and that their chronology and origin is difficult to establish in the context of karstic coastal caves (as discussed in Ben Arous *et al.* (2020a)), OSL ages might have been overestimated (i.e. the age of the layers may be younger than estimed by OSL). Moreover, OSL dates can in some cases be internally inconsistent, meaning that they can have a number of reversals. For instance, it is known that water content influences the determinations. Considering the location of the cave on the coastline, inundations related to rising in sea level or very high tides may have occurred.

4.3 Paleoclimate simulations and paleoenvironmental inferences

Since the climate sequence based on DH1 is the only one displaying significant results, we focus on it in the following discussion. Isotope fractions are mainly correlated to seasonal variation in water stress (hyd_stress), insolation (sols) and temperature (tsol, tsol_ampl_day). This result is expected as $\delta^{18}O$ is an indicator of aridity (Longinelli and Selmo, 2003; Blumenthal et al., 2017; Blumenthal, 2019) and as

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

455 $\delta^{13}C$ is related to seasonal variation of temperature and water stress (O'Leary, 1988; Lin, 2013; Smiley et al., 2016). On the contrary to isotopes, the THI is only globally related to climate variations (only the 2B-pls performed on all climate variables is significant). It is not surprising either, as isotopes reveal fluctuations in particular variables that are temperature- and precipitation-related provided by a limited number of individuals of a single species, while THI is an estimate of the global type of the environment 460 provided by the whole microvertebrate communities. Thus, they do not deliver information at the same resolution.

Another explanation of the improved correlations between climate and isotope fractions may be that biologically-derived proxies (as the THI) are more complex functions of physical drivers than the isotope signal. Isotopes directly reflect to the magnitude of seasonal variation in insolation, water stress, 465 temperature and diurnal temperature range, because these variables condition the presence of essential elements for plants survival (e.g. sunlight, water in the soil). Thus, they are directly related to the type of vegetation. On the other hand, the THI relies on ecological preferences of species. Altogether, the variables of the THI give information about the proportion of biomes (e.g. forest, bush, steppe), and thus the spatial distribution and density of the vegetation. Consequently, its relationship to climate is more 470 indirect than for isotopes.

The large differences between the climate simulations and the fact that they provide a physical consistent view of the relationships between the different climatic variables allow us to discuss the inconsistencies existing between paleoenvironmental proxies at EH2. The two major ones concern L5 and L7. In both cases, isotope surveys and MAP from Jeffrey (2016) indicate more humid conditions with more 475 important precipitation than on other layers. On the contrary, the THI as well as the presence of the steppic species *Jaculus* cf. *orientalis* (often used as an indicator of particularly arid conditions) and the scarcity of aquatic species support a drier climate than on other layers (Stoetzel, 2009; Stoetzel et al., 2014). Large mammals would also support this last hypothesis, with an increase in the representation of gazelles and alcelaphines, and a decrease in the representation of bovines in both layers (Stoetzel et al., 480 2012a, 2014). Unfortunately, no combined US-ESR ages are available for L7 to date. Considering that climate conditions associate to L8 display less precipitation than currently, we could hypothesize a

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

similar climate for L7. In that case, this would support inferences from species presence. Nevertheless, we cannot exclude that a microclimatic event could have induced particular climatic conditions on L7. Concerning L5, the climate described by the sequence based on DH1 agrees with isotope surveys (Jeffrey, 2016). These conclusions are supported by the abundance of *Crocidura russula*, a shrew species associated with Mediterranean climates (Cornette et al., 2015). In addition, *Jaculus* cf. *orientalis* can also be considered as an indicator of more continental conditions, such as the distance from the coastline, rather than a marker of arid environments.

An important difference is noticed between the climate sequence and the THI on L1. Paleoclimate simulations indicate on a quite dry climate relatively to other layers, in contradiction with the composition of small and large mammal communities that suggest an expansion of forests and wetlands (Stoetzel *et al.*, 2014). This difference could be explained by the location of EH2: the cave is located at the interface of varied climate influences, as described previously. Because global climate models describe general climate characteristics, a local climate phenomenon could have generated a wetter environment in the surroundings of EH2.

5 Conclusions

Considering together paleoclimate simulations and paleoenvironmental inferences allows us to provide new insights into the chronostratigraphy and paleoenvironmental reconstruction of El Harhoura 2 cave. We find that the climate sequence based on combined US-ESR ages is more consistent with paleoenvironmental inferences than the climate sequence based on OSL ages. We also evidence that, overall, isotope-based paleoenvironmental inferences are more congruent with the paleoclimate sequence than species-based inferences. But, above all, we highlight the difference in scale between the information provided by each of these paleoenvironmental proxies. This study demonstrates that the combination of different sources of environmental data and climate simulations has a great potential for refining the paleoenvironmental and chronological context of archeological and paleontological sites. Even thought, its applicability on periods marked by less important climate changes remains to be tested. Although, our approach may concern a limited number of well-studied sites. However, with more

https://doi.org/10.5194/cp-2022-81
Preprint. Discussion started: 23 November 2022

powerful statistical tools, it could be extended to other sites whose context is less referenced, and perhaps even help establish it.
