Abstract

Background

Negative T-waves are associated with sudden cardiac death (SCD) risk in the general

population. Whether flat T-waves also predict SCD is not known. The aim of the study was to

examine the clinical characteristics and risk of SCD in general population subjects with flat T-

waves.

Methods

We examined the electrocardiograms of 6750 Finnish general population adults aged $\geq$30

years and classified the subjects into 3 groups: 1) negative T-waves with an amplitude $\geq$0.1

mV in $\geq$2 of the leads I, II, aVL, V4–V6, 2) negative or positive low amplitude T-waves with

an amplitude <0.1 mV and the ratio of T-wave and R-wave <10% in $\geq$2 of the leads I, II,

aVL, V4–V6, and 3) normal positive T-waves (not meeting the aforesaid criteria). The

association between T-wave classification and SCD was assessed during a 10-year follow-up.

Results

A total of 215 (3.2%) subjects had negative T-waves, 856 (12.7%) flat T-waves, and 5679

(84.1%) normal T-waves. Flat T-wave subjects were older and had more often cardiovascular

morbidities compared to normal T-wave subjects, while negative T-wave subjects were the

oldest and had most often cardiovascular morbidities. After adjusting for multiple factors,

both flat T-waves (hazard ratio [HR] 1.81; 95% confidence interval [CI] 1.13–2.91) and

negative T-waves (HR 3.27; 95% CI 1.85–5.78) associated with SCD.

Conclusions

Cardiovascular risk factors and disease are common among subjects with flat T-waves, but

these minor T-wave abnormalities are also independently associated with increased SCD risk.

3

Introduction

The T-wave in the electrocardiogram (ECG) coincides with the repolarization of the ventricles. Numerous physiological and pathological factors, e.g. age, sex, autonomic tone, drugs, and the presence of a cardiac disease, may affect the T-wave morphology, and T-wave abnormalities can be used as diagnostic tools in certain acute and chronic cardiac conditions [1]. There has been also growing interest on the long-term prognostic significance of T-wave changes, as there is an ongoing search for novel inexpensive and large-scale applicable prediction tools for sudden cardiac death (SCD). Several T-wave abnormalities, with varying complexity and applicability to clinical practice, have been associated with increased risk of SCD. Negative T-waves are easy to notice in clinical practice and are shown to predict SCD [2]. Other relatively simple T-wave abnormalities associated with SCD risk include wide frontal QRS-T angle and prolonged Tpeak-to-Tend interval [3–5]. On the other hand, more complex T-wave risk markers, including T-wave alternans, repolarization heterogeneity markers, and three-dimensional T-wave parameters usually require special computer analysis [5–8]. T-waves with low amplitude are easily assessed from the ECG, and they have been associated with cardiovascular mortality in the general population [9–11]. However, whether these flat T-waves are also linked to SCD risk in the general population is not known. Therefore, we investigated the characteristics of flat T-waves in a large Finnish general population cohort, and assessed the risk for SCD associated with these T-wave abnormalities.

4

Methods

Study population

The study population consisted of 7217 participants of the Social Insurance Institution's Mini-Finland Health Survey conducted in 1978–1980. Participants were aged ≥30 years and the survey population was a representative sample of the Finnish population. Participants were interviewed regarding their health status, medications, diseases, symptoms, and lifestyle. Furthermore, participants underwent health examinations including measurements of blood pressure, body mass index (BMI), and total serum cholesterol, in addition to the recording of an ECG. Moreover, plasma potassium levels were measured from a prespecified subset of participants. Participants' baseline diagnoses were assessed using structured criteria based on the interviews and the health examination findings (Supplemental Methods). The Mini-Finland Health Survey methods have been reported more extensively previously [12].

All participants of the Mini-Finland Health Survey were fully informed about the study, they participated in the study voluntarily, and the use of information for medical research was explained to them. Agreeing to participate in the baseline health examination was taken to indicate informed consent. The participants were free to unconditionally withdraw their consent at any time, in which case their data were deleted. The study was carried out following ethical guidelines and principals of the Declaration of Helsinki. The study protocol and the practice of the subjects' voluntary participation indicating informed consent were approved by the Institutional Review Board (IRB) of National Institute for Health and Welfare (IRB 00007085, Federalwide Assurance (FWA) 00014588).

Electrocardiographic measurement and analyses

A standard 12-lead ECG with a paper speed of 50 mm/s and calibration of 1 mV/10 mm was recorded from all study participants during the health examination in 1978–1980. After a few months, a second ECG was recorded from a subgroup of participants who had signs of cardiovascular disease in the health examinations, which were separately evaluated to assess the permanence of flat T-waves as an ECG finding over time. The recorded paper ECGs were digitized and digitally assessed in 2015–2016. Digital analysis was conducted by three examiners with a custom-made ECG analysis software. Using median beats, T-wave amplitude was assessed digitally with respect to the true baseline with 0.01 mV accuracy from each lead. The paper ECG digitizing and digital assessment method has been described in more detail previously [13]. After excluding subjects with missing health examination data, subjects with missing or unreadable ECGs, and subjects with atrial fibrillation, atrial flutter, left or right bundle branch block, second or third-degree atrioventricular block, pre-excitation pattern, pacemaker rhythm, or ECG findings not representing the general population, a total of 6750 subjects remained for the analyses.

Subjects were classified into 3 groups according to the T-wave polarities and amplitudes in leads I, II, aVL, V4–V6: 1) negative T-waves (negative T-wave with an amplitude of ≥0.1 mV in ≥2 of the leads), 2) flat T-waves (positive or negative T-wave with and amplitude <0.1 mV and the ratio of T-wave and R-wave <10% in ≥2 of the leads and not meeting the criterion for negative T-waves group), and 3) normal T-waves (not meeting the criteria for negative T-waves or flat T-waves groups).

QRS duration, QT interval and Tpeak-to-Tend interval were measured from lead V5. Bazett's formula was used for QT interval correction for heart rate. Frontal QRS axis and T axis were calculated automatically by the digital measurement software. QTc >450 ms in men and >460 ms in women, QRS-T angle >90 °, and Tpeak-to-Tend >90 ms were used as

6

130   cut-offs for abnormal values when the parameters were used as dichotomous categorical

131   variables. ST-segment depressions were defined as negative ST-segments of $\geq$0.1 mV at 60

132   ms from the J point in $\geq$2 of the leads I, II, III, aVL, aVF, and V1–V6.

133

134   *Follow-up*

135   Survey participants were followed from the baseline examination in 1978–1980 until the end

136   of 2011 using the nation wide Causes of Death Register maintained by Statistics Finland.

137   During the complete follow-up time of the Mini-Finland Health Survey, 1077 subjects (27%

138   of all deceased) of all the Mini-Finland participants were autopsied, of which 194 were SCD

139   cases (48% of SCD cases). SCD cases were determined by 2 cardiologists based on the death

140   certificates, hospital records, and autopsy records using the modified Cardiac Arrhythmia

141   Suppression Trial (CAST) criteria [14]. In cases of disagreement, a third cardiologist

142   reviewed the case and made the final classification. The primary endpoint was SCD, and the

143   secondary endpoints were cardiac death and death from any cause. Follow-up time was

144   limited to 10 years in the primary analyses, as the cardiovascular risk profile could change

145   during a longer follow-up. The complete follow-up time of the Mini-Finland Health Survey

146   was used in the secondary analyses.

147

148   *Statistical analysis*

149   Age and sex adjusted mean values ± standard deviation for continuous variables and the

150   prevalence of categorical variables were compared using the general linear model. Hazard

151   ratios (HRs) and 95% confidence intervals (CIs) were calculated using the Cox proportional

152   hazards model. The multivariate models were adjusted with age, sex, systolic blood pressure,

153   heart rate, total serum cholesterol, BMI, diabetes, active smoking, beta blocker medication,

7

154   left ventricular hypertrophy (LVH) on ECG based on the Sokolow-Lyon criterion, and

155   presence of cardiac disease. The survival of subjects in T-wave groups was compared using

156   Kaplan–Meier plots. The statistical significances of effect modification by baseline

157   characteristics were tested using the Wald test by entering an interaction term of T-wave class

158   and the respective baseline characteristic. All reported p-values are two-sided and $p<0.05$ was

159   considered statistically significant. All statistical analyses were performed using IBM SPSS

160   Statistics (version 25).

Results

A total of 215 (3.2%) subjects presented with negative T-waves, 856 (12.7%) with flat T-waves, and 5679 (84.1%) with normal upright T-waves. Examples of different T-wave morphologies are demonstrated in Figure 1. The distribution of T-wave morphologies in individual leads is presented in the Supplemental Figure.

The baseline characteristics of the subjects with different T-wave morphologies are displayed in Table 1. The age distributions of subjects with normal, flat, and negative T-waves are displayed in the Supplemental Table 1. Subjects with flat or negative T-waves were older, had higher blood pressure and heart rate, and had more often diabetes and cardiac morbidities ($p<0.05$ for all) than subjects with normal T-waves. However, subjects with negative T-waves had higher systolic blood pressure and had more often cardiac disease, coronary artery disease (CAD), diabetes, and beta blocker medication compared to subjects with flat T-waves ($p<0.05$ for all). Serum potassium was measured from a prespecified group of 2798 subjects (mean 4.5±0.4 mmol/l), with no significant differences between the T-wave groups.

The baseline ECG features are shown in Table 2. QRS and Tpeak-to-Tend intervals were longer in subjects with negative T-waves than subjects with either normal or flat T-waves ($p<0.05$ for both). LVH and ST-segment depressions were most common among negative T-wave subjects while being more common among flat T-wave subjects than normal T-wave subjects ($p<0.05$ for all). The frontal QRS-T angle was narrowest among normal T-wave subjects and widest in negative T-wave subjects ($p<0.05$). QTc was longest in subjects with flat T-waves and shortest in subjects with negative T-waves ($p<0.05$).

A second ECG was recorded few months after the baseline examinations from 247 subjects with flat T-waves (28.9% of the subjects with flat T-waves). Flat T-waves were

9

185 again observed in 149 (60.3%) of the subjects, while 24 subjects (9.7%) had negative T-

186 waves, and 3 (1.2%) subjects had LBBB in the repeat ECG.

187   During the 10-year follow up, 131 subjects (60.9%) with negative T-waves, 267

188 subjects (31.2%) with flat T-waves, and 547 subjects (9.6%) with normal T-waves died. Of

189 these, 25 (19.1%) in negative T-wave subjects, 32 (12.0 %) in flat T-wave subjects, and 60

190 (11.0%) in normal T-wave subjects were SCDs. The survival curves for SCD and all-cause

191 mortality according to the T-wave group are presented in Figure 2. Both flat T-waves and

192 negative T-waves associated with SCD, cardiac death, and all-cause mortality when compared

193 to subjects with normal T-waves. Subjects with negative T-waves had worse prognosis

194 compared to subjects with flat T-waves. After multiple adjustments, flat T-waves subjects had

195 HR 1.81 (95% CI 1.13–2.91) and negative T-wave subjects had HR 3.27 (95% CI 1.85–5.78)

196 for SCD, compared to subjects with normal T-waves. The prognoses associated with

197 individual T-wave abnormalities are displayed in Table 3.

198   No significant effect modification was found between T-wave class and sex, age

199 ≤ 50 or >50 years, BMI ≤ 25 or >25 kg/m^2, heart rate ≤ 70 or >70 bpm, presence of LVH,

200 presence of hypertension diagnosis, or presence of cardiac disease diagnosis for SCD risk.

201   When ECG repolarization parameters wide QRS-T angle, prolonged QTc, and

202 prolonged Tpeak-to-Tend interval were used as dichotomous categorical variables and entered

203 simultaneously with ST-segment depressions and T-wave class into an age and sex adjusted

204 model, only ST-segment depressions and T-wave class associated with increased SCD risk,

205 with both flat T-waves and negative T-waves associating with risk of SCD (Supplemental

206 Table 2). When further adjusted with multiple factors, only T-wave class associated with SCD

207 risk, with both flat T-waves and negative T-waves remaining associated with risk of SCD

208 ($p<0.05$).

10

209   In the secondary analyses using the complete follow-up of the Mini-Finland

210 Health Survey (mean 24.5±10.3 years), flat T-waves and negative T-waves similarly

211 associated with all endpoints, albeit not as strongly as in the primary analyses. During the

212 complete follow-up, flat T-waves had HR 1.40 (95% CI 1.05–1.85) for SCD when compared

213 to normal T-wave subjects after multivariate adjustments. The risks of endpoints associated

214 flat T-waves and negative T-waves during the complete follow-up are presented in the

215 Supplemental Table 3.

11

Discussion

In this large, prospective study, subjects with flat T-waves were more likely to have cardiovascular risk factors and cardiac disease compared to subjects with normal T-waves. Furthermore, flat T-waves independently associated with increased risk of SCD, in addition to cardiac death, and death from any cause. Still, cardiovascular morbidities were most common and the prognosis poorest among subjects with negative T-waves.

Normally, T-waves are upright in most of the ECG leads, and negative T-waves in leads I, II, V3–V6 are considered abnormal [1]. Multiple factors can have an effect on T-waves polarity and amplitude, for example age, sex, heart rate, autonomic nervous system, electrolyte disturbances, and drugs [1]. Furthermore, T-wave changes have been associated with cardiovascular conditions, e.g. hypertension, acute and chronic manifestations of CAD, left ventricular hypertrophy, and cardiomyopathies [1].

Since the T-wave corresponds to the vulnerable repolarization period of the cardiac cycle, multiple T-wave parameters have been studied and linked with increased risk for arrhythmic death. T-wave inversions, abnormal T-wave axis, and wide QRS-T angle have been associated with SCD in the general population [2,3,5]. Furthermore, prolonged Tpeak-to-Tend interval has been associated with SCD risk in the general population, although not all studies have had similar findings [4,5]. In addition, several complex T-wave parameters, including T-wave alternans, repolarization heterogeneity markers, and spatial T-wave parameters, have been shown to associate with increased SCD risk, but efficient analysis of these parameters requires special computer software [5–8].

Low amplitude or flat T-waves have been associated with sudden cardiac arrest in subjects with hypertrophic cardiomyopathy [15], and they are also more prevalent among subjects with early repolarization who will suffer ventricular fibrillation, compared to subjects with early repolarization with benign prognosis [16]. Low amplitude T-waves have been

12

241 linked also to ventricular tachycardia and ventricular fibrillation risk in some patients with

242 implantable cardioverter defibrillator [17]. Moreover, when flat T-waves were classified

243 together with negative T-waves in middle-aged men, this group of subjects was at increased

244 risk for SCD, compared to subjects with normal positive T-waves [18]. The present study is

245 the first to demonstrate that flat T-waves independently associate with increased SCD risk in

246 the general population.

247   After relevant exclusions, the prevalence of flat T-waves was 13% in the Mini-

248 Finland Health Survey cohort of the present study. The definition used in the present study

249 included both negative and positive T-waves with an amplitude <0.1 mV and the ratio of T-

250 wave and R-wave <10% as flat T-waves. The amplitude cut-off of ≥0.1 mV has been

251 commonly used for negative T-waves, as more minor negative T-waves can be difficult to be

252 definitely determined as negative in comparison to isoelectric or low amplitude biphasic or

253 positive T-wave [1,2]. Previous studies have commonly used the Minnesota Code definitions

254 to assess minor T-wave abnormalities, with prevalences ranging from 2% to 13% [9–11].

255 Although there are small differences between the definitions used in the present and the

256 previous studies, flat T-waves seem to be a relatively common finding in the general

257 population.

258   In the present study, abnormal T-waves were more prevalent among older

259 subjects. However, no significant effect modification was noted between the T-wave class and

260 age group, suggesting that age does not affect the prognosis associated with abnormal T-

261 waves. Subjects with flat T-waves also had more often cardiovascular morbidities than

262 subjects with normal T-waves. Nonetheless, flat T-waves predicted SCD, cardiac mortality

263 and all-cause mortality also independently from cardiovascular risk factors and diseases.

264 Furthermore, no significant effect modification between the T-wave class and presence of

13

265 diagnosed cardiac disease was observed. Finally, negative T-wave subjects had the highest

266 prevalence of cardiovascular morbidities and even worse prognosis.

267   T-wave morphology changes are caused by local or diffuse voltage gradient and

268 spatial changes in the ventricular repolarization [1]. T-wave changes after myocardial

269 infarction are assumed to be caused by nonradial potential gradients or decreased transmural

270 conduction velocity [19]. Other plausible mechanisms causing T-wave changes in heart

271 diseases include alterations in the autonomic nervous system and ventricular myocyte

272 hypertrophy [1]. Accordingly, it could be speculated that flat T-waves may in some cases act

273 as markers of underlying electrical or structural cardiac pathology, that may be less severe

274 than in subjects with negative T-waves. Moreover, myocardial fibrosis is also associated with

275 T-wave inversion and T-wave changes among SCD victims, especially in subjects with

276 ischemic heart disease [20]. Non-specific ST-T abnormalities have been also linked to

277 impaired left ventricular relaxation causing abnormal repolarization, with cardiac fibrosis

278 being a possible underlying mechanism [21]. Consequently, flat T-waves could also be a

279 direct sign of increased vulnerability for fatal ventricular arrhythmias.

280   We compared the T-wave classification to other easily assessable ECG

281 repolarization markers that have been associated with SCD. Some of the other analyzed

282 markers have independent clinical value, e.g. ST-segment depression may indicate an

283 underlying CAD. ST-segment depressions were most common in subjects with negative T-

284 waves, but were rarely observed in subjects with normal T-waves. This was in concordance

285 with the prevalence of CAD diagnosis in the health examinations, with the highest prevalence

286 of CAD observed in subjects with negative and lowest prevalence in subjects with normal T-

287 waves. Prolonged QTc, a known marker of increased risk of SCD, was notably longer among

288 subjects with flat T-waves. Flat T-waves are known to decrease the certainty of determining

289 the end of T-wave, which may explain the longer QT intervals [22]. Nonetheless, when the

14

290 repolarization markers were analyzed simultaneously in a multivariate model, the T-wave

291 classification was the only one that remained associated with SCD risk. This could indicate,

292 that the simple analysis of the polarities and amplitudes of the T-waves could relay major

293 information about the association between repolarization and SCD risk in clinical practice.

294

295 *Limitations*

296 Due to the inclusion criterion of age ≥30 years, these findings may not be directly applicable

297 to younger adult populations. As a further limitation, although the baseline examinations were

298 extensive, an echocardiographic study was not performed to survey participants, and,

299 consequently, no data was available on the cardiac structure or systolic function of the heart.

300 Moreover, although flat T-waves were a stable finding in the majority of the cases, in some

301 cases flat T-waves seems to be observable only in some of the ECG recordings. Finally, the

302 results may not be directly applicable to modern populations, as diagnostic tests and

303 treatments of cardiovascular disease have improved since the baseline examinations of the

304 Mini-Finland Health Survey in 1978–1980. However, this limitation is inevitable in this kind

305 of cohort studies with long follow-up periods.

306

307 *Conclusions*

308 Flat T-waves are a relatively common finding in the general population, but they are often a

309 sign of underlying cardiac disease. Furthermore, flat T-waves are independently associated

310 with increased SCD risk, although the prognosis is better than observed with negative T-

311 waves. More focus should be placed on these minor T-wave abnormalities in the future, as

312 individuals with these ECG patterns may benefit from a careful clinical evaluation and closer

313 monitoring.

399   # Figure legends

400   Figure 1 legend

401   Demonstration of different T-wave morphologies. A) A normal T-wave, B) a flat T-wave, and

402   C) a negative T-wave.

403

404   Figure 2

405   Figure 2 legend

406   Survival curves for A) SCD and B) all-cause mortality according to the T-wave morphology.

407   The Y-axis of A) graph is scale broken to better illustrate the SCD survival curves. Survival

408   curves were compared with Logrank test.

409   SCD = sudden cardiac death.

24

| | (1.8%) | (48.4%) |

421

422   Continuous variables are presented as mean values ± standard deviation and categorical variables as prevalences. Ns = not significant. LVH =

423   Left ventricular hypertrophy based on Sokolow-Lyon ECG criterion. QRS duration, QTc, and Tpeak-to-Tend were assessed from lead V5. ST-

424   segment depressions = negative ST-segment of ≥0.1 mV at 60 ms from the J point in ≥2 of the following leads: I, II, III, aVL, aVF, and V1–V6.

425   Between group comparisons were adjusted for age and sex.

426

427 *Table 3*

428 Prognostic significance of flat T-waves and negative T-waves during the 10-year follow-up

	Normal T-waves n=5679 (84.1%)	Flat T-waves n=856 (12.7%)	p-value	Negative T-waves n=215 (3.2%)	p-value
SCD					
No. of SCDs (% of subjects)	60 (1.0%)	32 (3.7%)		25 (11.6%)	
Age and sex adjusted HR (95% CI)	1	2.55 (1.62−4.00)	<0.001	6.50 (3.87−10.91)	<0.001
Multivariate adjusted HR (95% CI)	1	1.81 (1.13−2.91)	0.014	3.27 (1.85−5.78)	<0.001
Cardiac death					
No. of cardiac deaths (% of subjects)	194 (3.4%)	116 (13.6%)		79 (36.7%)	
Age and sex adjusted HR (95% CI)	1	2.25 (1.78−2.86)	<0.001	4.51 (3.40−5.98)	<0.001

26

Multivariate adjusted HR (95% CI)	1	1.57 (1.22−2.02)	<0.001	2.29 (1.68−3.11)	<0.001
Death from any cause					
No. of deaths (% of subjects)	547 (9.6%)	267 (31.2%)		131 (60.9%)	
Age and sex adjusted HR (95% CI)	1	1.87 (1.61−2.18)	<0.001	2.79 (2.28−3.41)	<0.001
Multivariate adjusted HR (95% CI)	1	1.54 (1.31−1.80)	<0.001	1.85 (1.48−2.30)	<0.001
