White Clover Establishment and Management Guide

Reviewed by Dennis Hancock, Crop and Soil Sciences Department

Original manuscript by John Andrae, Extension Forage Agronomist, Crop and Soil Sciences Department

White Clover Basics

White clover (*Trifolium repens* L.) is a cool season perennial legume of Mediterranean origin. White clover has been used as a forage in North American since Colonial times. Benjamin Franklin noted its prevalence in cleared and disturbed land as early as 1746. There are many reasons for white clover's popularity among forage producers. Several of these reasons are listed below.

White Clover Uses

Pasture Renovation. White clover has a creeping growth habit and spreads with rhizomes or "runners" (Figure 1). This growth pattern is one reason for the excellent grazing tolerance of white clover and helps to fill voids in the sward, which would otherwise be filled with weedy species.

Improved forage distribution. Because white clover fills voids in grass stands, forage yields are often increased, particularly when tall fescue and orchard-grass stands have thinned. In addition, white clover is a cool season forage so it can improve (at least as an annual) the forage distribution and production of warm season pastures like bermudagrass and bahiagrass on wetter soils. White clover is generally productive in late winter to late spring and mid-fall to mid-winter when warm season perennials are not productive or have low nutritive value.

Improved diet quality and animal performance. Because of the high quality of white clover, it is well suited for use as a complimentary forage in cool season perennials like tall fescue and orchardgrass. Table 1 (page 4) lists the approximate nutrient content of grazed grass and clover plant species.

The high total digestible nutrient (TDN) and crude protein content of white clover can increase animal performance on pasture simply due to increased nutri-

ent density. In addition, the higher level of magnesium in clovers decreases the potential risk of grass tetany in the spring months. The majority of tall fescue in Georgia is infected with a toxin-producing fungus that diminishes animal performance (see Novel Endophyte publication). White clover interseeded into toxic tall fescue pastures can reduce intake of these toxins. Animals selectively graze the clover, thereby reducing consumption of the toxic grass. This, in combination with the improved diet quality of the clover, greatly improves performance of animals grazing toxic tall fescue (Table 2).

Figure 1. White clover has "runners" or stolons that provide a secondary root system and energy storage for regrowth and grazing tolerance.

Table 1. Approximate nutrient content (% dry matter) of some common grass and clover pasture plants. (Hoveland, 2000)

Species	Crude Protein	TDN	Calcium	Phosphorus	Magnesium
	-----	-----	---%---	-----	-----
White clover	25	80	1.5	0.4	0.4
Red clover	20	70	1.5	0.4	0.4
Annual ryegrass	20	68	0.5	0.3	0.2
Orchardgrass	15	65	0.3	0.3	0.2
Tall fescue	13	62	0.3	0.3	0.2
Bermudagrass	10	54	0.3	0.2	0.2

Table 2. Beef steer performance as affected by white clover in endophyte-infected tall fescue. (Hoveland *et al.*, 1981)

	Average daily gain, lbs.	Gain/Acre, lbs.
Infected tall fescue	1.06	374
Infected tall fescue + clover	1.53	582

White clover can also be seeded into bermudagrass pastures on favorable soils to improve nutrient content of the sward. New grazing-tolerant white clover varieties have persisted for three years under grazing in bermudagrass sod in trials near Calhoun Georgia. Trials are currently underway with these new varieties near Eatonton and Tifton, Georgia, to evaluate white clover persistence in warm season grass sods.

Provide nitrogen to companion grasses. In addition to improving animal performance, a frequently mentioned benefit of including clover in pastures is nitrogen fixation. The earth's atmosphere is made up of about 80 percent nitrogen; this nitrogen is not, however, in a form plants can utilize. Nitrogen is "fixed" in clovers through a symbiotic relationship with rhizobium bacteria that infect roots. The plant provides energy for the bacteria, and bacteria provide the "machinery" necessary to convert atmospheric nitrogen to a form available to plants. Nitrogen fixation is one of many economically important features of clover, particularly when clover represents a substantial proportion of available forage. A vigorous stand of white clover will fix 100-150 pounds of nitrogen per year depending on soil and growing conditions (Table 3). At fertilizer nitrogen prices of \$0.30 per pound, this translates to \$30-\$45 per acre. The economic value of nitrogen fixation alone should more than pay for seed and establishment expenses.

Table 3. Approximate pounds of nitrogen annually fixed per acre by various legumes. (Source: Don Ball, Auburn University)

Legume Species	Annual lbs N/Acre	N value at \$.30 per lb.
Alfalfa	200-300	\$60-90
Red clover	100-200	\$30-60
White clover	100-150	\$30-45
Annual clovers (arrowleaf, crimson, etc.)	50-150	\$15-45

Direct benefits of nitrogen fixation are realized almost exclusively by clover plants. Studies have shown that mixed grass and clover stands can produce forage yields equivalent to those of nitrogen fertilized grass stands. In the clover-containing system, overall grass yields decrease, but clover yields offset these decreases. In addition to clover plants supplying forage without nitrogen fertilization, overall forage quality available to animals is higher in pastures containing clover.

Most people envision a "pipeline" that transports nitrogen directly from clover to grass. Unfortunately almost no nitrogen is contributed to grasses this way. Essentially all nitrogen supplied to grasses from clover is indirect. Because of this indirect route, nitrogen from clover root nodules is not immediately available to companion grasses. Root nodules must decompose and nitrogen must be converted into a form available to plants. This conversion or "mineralization" releases nitrogen slowly, much like a time release fertilizer. This slow, steady nitrogen supply from a healthy stand of white clover can keep perennial grasses green and productive through the growing season.

Fixed nitrogen from clovers is also supplied to grasses via grazing animals. Most of the nitrogen in consumed high quality clover plants is not digested or

deposited in the animal and returns to the pasture as dung or urine.

Variety Selection

White Clover Types

White clovers are frequently classified in one of three morphological groups: small, intermediate and large. Small types seldom exceed 3 inches in height and are found in closely grazed areas or lawns. These clovers have low productivity and contribute little to grazing animals. Large or ladino white clovers are larger leafed, later blooming and more upright growing than either small or intermediate white clover types. Under optimal fertility and management, ladino white clovers are more productive than other white clover types. However, ladino clovers are not dependable reseeder and have fewer stolons and leaves close to ground level. Because of these reasons, ladino clovers have lower grazing persistence. Intermediate clovers are exactly as their name implies: intermediate. Flowering period and leaf size fall between small and large-type white clovers. Intermediate types typically reseed more dependably than ladinos, possess many stolons and leaves at ground level, and produce more forage than small types. Because of these traits, intermediate types of white clover persist well in grazing situations.

Factors to Consider When Choosing A White Clover Variety

Many commercial varieties of white clover are available on the market. Choose a good yielding, persistent and disease resistant variety well suited to your growing environment. While varieties that yield high amounts of forage are attractive, producers must be able to effectively harvest these yields. In contrast, low yielding clovers (*i.e.*, “white dutch” or common cultivars) do not typically furnish adequate amounts of high quality forage in many Georgia environments. Most cultivars are susceptible to viruses that decrease productivity and shorten stand life. Recently, grazing-persistent varieties have been developed that produce good yields, have excellent tolerance to defoliation, and survive for many years. Consider all these factors when selecting a variety for establishment.

Most commercially available white clover varieties are the large or ladino type. Most available ladino varieties have performed similarly in tests across north Georgia. Regal is a variety developed in Alabama that has consistently yielded well in the Southeast. Regal

seed are readily available and well adapted statewide. Osceola is a Florida developed variety which is also a good performer. Colt and Will also produce good yields and will typically persist for two to three years under good fertility and proper grazing management. Ivory and Tripoli typically yield and perform well in Georgia for one to two years, but are probably the least persistent of the ladino types in this area.

Recently two white clover varieties, Durana and Patriot, were developed and released by Dr. Joe Bouton at the University of Georgia in collaboration with Drs. Derek Woodfield and John Caradus, AgResearch, New Zealand. These two new highly persistent white clovers persist well in grazed Georgia environments and offer excellent potential to improve animal performance and longevity of clovers in pasture situations.

Durana and Patriot Development

To improve grazing tolerance of white clovers, Dr. Bouton collected plants that had survived several natural hot, dry summers from several locations in Georgia. These plants, called *native ecotypes*, were dug from pastures where clover had not been planted for many years. After transplanting offspring of these ecotypes into the harsh environment of the Central Branch Research and Education Center near Eatonton, plants were subjected to heavy continuous grazing with grass competition. Productive survivors were crossed and a promising entry (ultimately named Durana) was increased for further development. Durana has smaller leaves than ladino clovers but produces many more “runners” or stolons, which allow aggressive spreading and excellent grazing tolerance. Durana flowers profusely for long periods, which may make it a more dependable re-seeder. Parent material that gave rise to Durana was also crossed with a virus-resistant ladino clover. The product of this cross, named Patriot, is also commercially available.

Small-plot testing of Durana under clipping at four-week intervals indicates it is highly persistent but slightly lower yielding than ladino-type white clovers during the establishment year (Tables 4 and 5, page 6). Even though Durana yields are lower than ladino varieties during establishment, Durana’s persistence overcomes yield reductions after two to three years when ladino stands ultimately fail in grass pastures. Patriot yield is more like the ladino type (Table 4), but its persistence is superior (Table 5). Note that clipping trials likely overestimate the persistence of Regal ladino clover. Patriot’s increased yields make it ideal for producers practicing rotational grazing who can effectively harvest this forage.

Table 4. Clipped dry forage yields of white clover varieties near Athens, Ga. Established Oct. 29, 1999. (Hoveland and Durham, unpublished data)

Entry	Establishment year 2000 yield (lb/A)	2000-2001 average (lb/A)
Regal	4172	3969
Durana	3218	3834
Patriot	3816	4180

Grazing persistence is a far better predictor of clover performance than yield clipping trials because grazed clovers are frequently defoliated and treaded upon. Table 5 is derived from a study conducted at the Northwest Georgia Branch Station by Dr. Carl Hoveland and Greg Durham. In this study, Durana, Patriot, and Regal clovers were fall planted in bermudagrass sod and continuously grazed. Ground coverage of all clover entries was similar at the beginning of the study. After one year of grazing, basal coverage of Regal ladino clover was significantly less than that of Durana or Patriot. This is important because basal coverage provides energy storage and growing points for good regrowth and survival of Durana and Patriot (Figure 2).

Table 5. Percent basal coverage within row of white clover entries continuously grazed in bermudagrass sod. Planted Oct. 1, 1999, at the Northeast Georgia Branch Station.

Entry	Percent basal cover March 31, 2000	Percent basal cover January 31, 2002
Regal	77	6
Durana	90	65
Patriot	85	75

Figure 2. Dense stolons of Durana white clover provide energy reserves for regrowth and survival under heavy grazing.

Figure 3. Beef steers grazing tall fescue overseeded with Durana white clover. As of 2003, this clover had persisted for 5 years at the Central Georgia Station near Eatonton, Ga. Approximately 45 percent white clover and 55 percent tall fescue on dry matter basis.

Performance of stocker steers grazing four year old pastures near Eatonton also demonstrates the benefits of Durana white clover persistence (Table 6). In this study, steers grazing toxic tall fescue and Durana gained almost 300 percent more per day and over 100 pounds more per acre than nitrogen fertilized toxic tall fescue. Regal ladino white clover had essentially failed as indicated by low average daily gains (no clover forage to offset intake of toxic tall fescue) and low gain per acre (low nitrogen fixation). We continued grazing the excellent Durana pastures (Figure 3) while Regal stands had to be reseeded. Tall fescue stands overseeded with Patriot at the Northwest Georgia Station have also persisted well and improved performance of animals grazing toxic tall fescue.

Table 6. Beef steer performance on tall fescue pastures planted fall 1998 with Durana white vs. Regal ladino clover in central Georgia, fourth year after establishment, March 28-June 14, 2002. (Bouton, Andrae and Hoveland, 2003)

Pasture	Average Daily Gain (lb/d)	Lbs gain per acre
Toxic tall fescue + N	0.60	187
Toxic tall fescue + Durana	1.79	296
Toxic tall fescue + Regal	0.89	136

Paddocks were not grazed the first year due to extreme drought.

Establishment

Soil and Site Requirements

White clover has several soil nutrient requirements for satisfactory establishment and growth. Soil acidity influences availability of several nutrients and decreases survival of *Rhizobium* bacteria, which are necessary for nitrogen fixation. Soil should be limed to a minimum pH of 6.0. **Clovers are highly responsive to potassium and phosphate, so adequate amounts of these nutrients are critical for establishment, persistence and productivity.** Below optimal levels of soil P and K are responsible for many clover failures in pastures. White clover performs well on wet soils and persists far better on these soils than red clover. White clover will also perform well on lighter soils, but avoid deep sands.

Include the proper *Rhizobium* inoculum (type B) at planting if white clover has not grown in the field for several years. Most clover seed is pre-inoculated, but check the seed tag to ensure that inoculum is present and has not expired. Inoculum is inexpensive (about 10 cents per acre) and should be included in all clover plantings to ensure that 100- 150 pounds of nitrogen annually fixed by white clover can be achieved.

Also be sure that no herbicide with residual broad-leaf activity has been applied to the field in the year prior to seeding. 2,4-D has only a short residual activity (2-3 weeks) and should not pose many problems, but dicamba (Banvel or Weedmaster) has a 120 day residual activity and picloram (Grazon P+D) has residual activity up to one year after spraying.

Establishing New Stands of White Clover And Cool Season Grass Simultaneously

White clover seedlings can be extremely competitive with tall fescue and orchardgrass seedlings, and establishment mixtures should be planted with caution. Because of the low, creeping growth habit of white clover, seedling grasses can be lost from “smothering.” Paddocks may need to be flash grazed (allowing animals access for a short period of time to remove excess growth) during establishment to minimize clover competition. Delaying clover seeding until after perennial grasses are well established is a preferable practice. Delaying clover establishment allows broad-leaf weeds to be controlled with herbicides while the cool season grass is establishing.

Establishing White Clover in Existing Pastures

The 2- to 3-pound per acre seeding rate of white clover appears low for a simple reason — seeds are tiny! On average there are more than 750,000 white clover seeds per pound. For a relative comparison, there are only 11,000 wheat seed per pound. Because of this small size, **clover seed must be planted at the proper depth for good emergence.** Seeding depth should not exceed ¼-½ inch. If seeds appear to be planted too deeply, they are.

It is difficult to adjust a standard grain drill to accurately deliver appropriate seed amounts at the proper rate and depth. Use drills with seed boxes designed for small seed metering and delivery (Figure 4). If planting with a no-till drill, use the coulters or disc openers to slice existing sod and **lightly** scratch

Figure 4. White clover can be established by sod-seeding with a no-till drill (left), broadcasting and dragging (right) or by broadcasting and trampling seed in with temporarily heavy stocking rates.

the soil surface. Use press wheels to establish good seed-soil contact at a shallow depth.

Because of the shallow seed depth requirements of clover, seed can be broadcast onto closely grazed sod during late winter and incorporated into soil surface by (1) dragging, (2) hoof treading with temporarily high stocking rates, or (3) frost. Using a chain drag is an inexpensive and rapid method that can be used either simultaneously with broadcasting or in two separate passes. Using animal hoof action is a cheap (but less dependable) alternative to a no-till drill. Frost can also be used to deliver clover seed to an ideal planting depth in far north Georgia. Freezing forms a “honeycomb” appearance on the soil and allows legume seeds to settle just below the surface after several freeze-thaw cycles. Broadcast seeding is more effective in February than in fall months, so first-year forage production will likely be decreased when broadcasting. Increase seeding rates by 25 percent if broadcast seeding methods are used.

Manage Pasture to Favor Clover Seedlings During Establishment

Clover seedling growth must be favored when planted in competitive established grasses like tall fescue or bermudagrass. Excess competition from companion grass is probably the most common reason for clover establishment failures. Remember that during establishment, **grass is the enemy!** Consider any practice favoring clover seedlings and penalizing existing grass (without completely killing it). Several management options are available to aid clover establishment.

(1) Remove excess forage and thatch just prior to seeding. This will prevent shading, improve seed-soil

Figure 5. Regal white clover established in a dense stand of tall fescue with a “chemical frost” of paraquat to suppress grass (left) and without suppression (right).

contact, and help clover seedlings survive. Ideally, excess forage should be removed with heavy grazing, but haying is also an acceptable alternative.

(2) “Chemical frosts” will suppress autumn tall fescue growth and favor clovers at establishment.

These chemical frosts are created by spraying low rates of Gramoxone onto well established tall fescue before clover seeding to suppress grass growth. Follow label requirements closely and calibrate the sprayer, as tall fescue can be excessively thinned or killed with improper herbicide rates or under environmentally stressful conditions. In many stands of tall fescue, clover can be established without chemical suppression. However, if tall fescue sod is dense, *light* applications of Gramoxone are helpful in suppressing sod and dependably establishing white clover (Figure 5). Banded applications of Gramoxone that treat approximately 40 percent of tall fescue can also be used to help minimize grass injury and allow good clover establishment.

(3) When establishing white clover in bermudagrass or other perennial warm season grasses, delay planting until after a killing frost to minimize grass competition. Plant clover into closely grazed sod in fall or early winter after warm season grasses are dormant to allow adequate clover establishment before green up. Spring plantings should be avoided in the Coastal Plain and Piedmont because of heavy grass competition with clover seedlings.

(4) Manage grazing during establishment. At establishment, white clover produces a primary stem and root. The primary stem produces runners which allow the plant to spread. Like bermudagrass, these stolons provide a secondary root system and allow white clover to perenniate. The primary root of white clover will eventually die, so it is critical to allow secondary root growth to occur soon after establishment. It is equally important to minimize grass shading and allow sunlight to reach the clover seedlings. Therefore, a balancing act must take place. Competing grass must be removed with minimal grazing damage to young clover seedlings. Flash grazing is a useful tool for balancing this grass/legume relationship. Once the white clover runners have rooted, it is safe to graze.

(5) Consider fertilizer and poultry litter effects on seedlings. During the first year of clover establishment, nitrogen fixed by clover is not mineralized and is unavailable to grasses. However, avoid applications of nitrogen fertilizer or poultry litter while clover is establishing as this will favor grass growth and increase competition. Light nitrogen applications (30-40 lbs per acre) should *only* be applied when grass production

Figure 6. A stand of ball clover that was treated with insecticide (right) and not treated (left) at establishment to curtail insect damage. White clover would respond similarly when insect pressure is present in the fall.

(1) is desperately needed and (2) can be reliably and effectively removed with grazing to prevent shading of clover seedlings. If nitrogen is added to these stands, pastures *must* be grazed in a controlled manner to prevent grasses from out-competing clover. Conduct grazing in a manner that avoids or minimizes clover injury. If controlled grazing methods are not feasible, do not apply nitrogen during the establishment year. Adequate levels of phosphate and potash, on the other hand, are necessary for competitive and productive clover plants. It is critical to conduct a soil test and, if necessary, apply these nutrients for successful clover establishment and persistence.

(6) Scout for insect damage in early fall. Insects can be a serious pest when planting legumes in the fall. Pygmy crickets can quickly and completely eliminate newly emerged seedlings (Figure 6). Scout fields closely and be ready to apply an appropriate insecticide if necessary. Crickets may be difficult to spot, but their presence will be indicated by small circular-shaped bites on clover seedling leaflets. Delaying planting until after a killing frost greatly decreases insect pressure.

Management of Established White Clover

Fertilization

Soil test pastures on alternate years and apply necessary lime, P and K to maintain healthy and productive stands. Although P and K are not removed in

large amounts under grazing, nutrients can be redistributed to shade, watering and other lounging areas where urine and dung are concentrated. This is particularly true in large continuously stocked pastures.

Grazing Management

Even though white clover is tolerant of close grazing, it is still sensitive to grazing pressure. For example, white clover can become a weed in lawns that are frequently mowed. Close defoliation allows light to reach white clover leaves and favors clover growth over tall fescue. In contrast, white clover is seldom found in ungrazed pastures or hay fields that are cut infrequently. The tall grass in these uncut fields shades clover and favors grass growth.

When pastures are rotationally grazed at frequent intervals to short residue heights, clover regrowth is favored over grass regrowth (Figure 7). Rotational grazing also increases use of grasses and allows storage of root carbohydrates. Graze pastures containing white clover to roughly a 1½ to 2 inch stubble height to encourage clover persistence. Rest periods of two to three weeks are generally adequate for white clover-bermudagrass mixtures, but three to four week regrowth periods may be necessary for tall fescue or orchardgrass pastures containing white clover.

If pastures are continuously grazed, monitor stocking rates closely. Spot grazing and clover shading will occur at low stocking rates while high stocking rates reduce animal performance and grass vigor.

Figure 7. Diagram depicting effects of grazing pastures to 1.5" stubble height (left) versus 3" stubble height (right) on grass and clover regrowth. From Blaser *et al.*, 1986, Virginia Polytechnic Institute Bulletin 86-7.

Weed Control

White clover is more tolerant than other clovers of 2,4-D applications, but effectiveness of these applications is dependent upon weather and maturity of weedy species. Two pints of 2,4-D per acre will injure white clover, but in most cases it will recover. Clover is highly sensitive to dicamba (Weedmaster, Banvel), picloram (Grazon P+D), and triclopyr (Remedy), and these chemicals will normally completely eliminate existing clover. Typically, if the proportion of clover has dropped to 5-10 percent of the stand dry matter and weed pressure is heavy, it is probably appropriate to kill weeds and reseed clover after the herbicide residual activity has expired.

Diseases of White Clover

Occasionally white clover can be affected by viruses (Figure 8). Peanut stunt virus, alfalfa mosaic virus, and clover yellow vein virus are all transmitted by insects like aphids or thrips. Many of these viruses cause reduced stolon growth, depressed leaf yields and decreased root growth and nodulation (Pederson, 1995). There are no controls and no true virus-resistant cultivars. If clover stands fail as a result of viruses, the only option is to reseed.

Preventing Bloat

Unfortunately the fear of bloat has prevented many producers from establishing perennial clovers in pastures. The lost animal performance from **not** including clovers, particularly in tall fescue pastures, greatly outweighs the improbable and infrequent losses from bloat when clovers are utilized. Bloating is rare — particularly when clovers make up less than 50 percent of available forage dry matter in a pasture. For reference, the forage in Figure 3 was made up of 45 percent white clover and 55 percent tall fescue on a dry matter basis. Stocker animals grazed this paddock in the spring and fall for four years with no incidence of bloat. Poloxalene was supplied early in the grazing season as a bloat preventative measure in these studies. It is uncommon for pastures to contain more than 50 percent clover in Georgia. The additional precautions below will further decrease bloat risks (Lacefield and Ball, 2000).

Figure 8. Two year old grazed white clover plant infected with a virus. Note yellow streaking pattern on the leaves.

1. Never turn hungry animals into a lush white clover stand. Fill animals with low quality hay and watch them closely for the first few hours after turning into a pasture containing large amounts of clover.
2. Cull chronic bloaters.
3. Do not initially put animals on lush white clover pastures if plants have large amounts of surface moisture (dew or rain) present.
4. If bloat risk is high, feed bloat preventing compounds (*i.e.*, poloxalene) and provide access to dry hay.

Summary

There are many animal and agronomic related reasons for establishing a productive stand of white clover in existing grass pastures. Below are a few tips to help ensure a productive stand:

- Choose a productive and persistent white clover variety.
- Establish white clover on fertile soils with a pH of at least 6.0.
- Minimize grass competition with grazing or herbicides until clover is well established.
- Manage soil fertility and grazing to favor clovers after establishment.
