ABSTRACT

The shape of the light curve during the rising phase of Type I X-ray bursts is determined by many factors including the ignition latitude, the accretion rate, and the rotation rate of the star. We develop a phenomenological model of the burst rise process and show that simple measures of the burst morphology can be robust diagnostics of ignition latitude and burning regime. We apply our results to the large sample of bursts from the low-mass X-ray binary 4U 1636–536, and find evidence for off-equatorial ignition for many of the bursts. We argue that such behaviour may be associated with the transition from hydrogen to helium ignition at accretion rates a few per cent of Eddington. We show that this model can also explain variations in the detectability of burst oscillations, and discuss the implications for other burst sources.

Key words: binaries: general – stars: individual: 4U 1636–536 – stars: neutron – stars: rotation – X-rays: bursts – X-rays: stars.

1 INTRODUCTION

Neutron stars in low-mass X-ray binaries (LMXBs) accrete matter from their low-mass companions via Roche lobe overflow. Nearly half of these systems show Type I X-ray bursts, thermonuclear flashes caused by rapid unstable burning of the accumulating hydrogen or helium after it settles and is compressed on the neutron star surface. A typical X-ray burst light curve has a rapid rise (less than 10 s), followed by a longer decaying tail persisting for seconds to minutes as the star's surface cools.

The basic properties of Type I X-ray bursts can be understood in terms of the stability of hydrogen and helium burning at different accretion rates (Fujimoto, Hanawa & Miyaji 1981; Fushiki & Lamb 1987; Bildsten 1998, 2000; Narayan & Heyl 2003; Woosley et al. 2004; Cooper & Narayan 2006; Peng, Brown & Truran 2007). The boundaries between the different burning regimes depend on the local accretion rate \dot{m} (accretion rate per unit area). Below a critical accretion rate $\dot{m}_{c1} \sim 1$ per cent of the Eddington rate \dot{m}_{Edd} , bursts are triggered by unstable hydrogen burning. Above this level, hydrogen burns stably via the hot CNO cycle, and bursts are triggered by unstable helium burning once a critical column depth is reached. For $\dot{m} > \dot{m}_{c1}$ but below a second critical rate \dot{m}_{c2} , expected to be a few per cent of \dot{m}_{Edd} , the hydrogen at ignition depth should burn before helium ignition, leading to a pure helium flash. At higher accretion rates, $\dot{m} > \dot{m}_{c2}$, hydrogen does not burn completely before the burst is triggered, leading to various classes of mixed H/He bursts. Bursting activity will cease when the accretion rate is sufficiently high, $\dot{m} > \dot{m}_{c3}$, that helium burning is also stable. The precise levels of the critical accretion rates \dot{m}_{c1} , \dot{m}_{c2} , \dot{m}_{c3} , are not known precisely

and will vary depending on factors such as the metallicity of the accreted material and the heat flux from the deep crust and core (Ayasli & Joss 1982; Fushiki & Lamb 1987; Brown, Bildsten & Rutledge 1998; Narayan & Heyl 2003).

There is now observational evidence for bursts in all three classes. The global accretion rate \dot{M} can be inferred from the X-ray luminosity, and this should (under the assumption that accretion is spherically symmetric) predict \dot{m} and hence the burning regime. Furthermore, within a given burning regime, burst rate should rise with accretion rate. For a large number of sources, however, these expectations are not borne out. Transition accretion rates can differ from the predicted values by up to an order of magnitude, and for many sources burst rate actually falls as \dot{M} increases (Cornelisse et al. 2003; Galloway et al. 2007). Why this should be the case is not yet clear but it may involve either additional stable burning processes (Bildsten 1995) or non-spherical accretion and slow fuel spread (so that local accretion rate \dot{m} differs from that inferred from \dot{M}) (Bildsten 2000). Alternatively, it may well be that X-ray luminosity is not a good predictor of accretion rate (Hasinger & van der Klis 1989). For a more in-depth discussion of these issues and other burst properties, we refer the reader to the recent articles by Strohmayer & Bildsten (2006) and Galloway et al. (2007).

In this paper, we concentrate on one particular aspect of burst physics – the properties of the burst rise. The shape and time-scale of the rising portion of the X-ray light curve is controlled by several factors: the point at which the burning layer ignites, the emission profile of any burning point after ignition (set by the nuclear heating and cooling time-scales), and the speed at which the burning front propagates across the stellar surface. Ignition is likely to occur at a point and spread, rather than occurring across the whole star simultaneously, because of the discrepancy between the very short burning time-scales and the much longer accretion time-scale (Shara 1982). Asymmetric initialization is also thought necessary to

[★]E-mail: maurer@mpa-garching.mpg.de (IM); anna@mpa-garching.mpg.de (ALW)

explain the detection during the rise of burst oscillations, variations in brightness on the surface of the neutron star that are modulated by the rapid stellar spin (Strohmayer & Bildsten 2006).

On a realistic neutron star, ignition location is unlikely to be random due to the various factors that break spherical symmetry. Accretion flow may not be spherically symmetric – it may occur through an equatorial boundary layer (Inogamov & Sunyaev 1999) or by channelling on to the magnetic poles (in which case the star may manifest as an X-ray pulsar). Whether either of these issues can affect local ignition conditions or lead to preferred ignition locations is not clear, since estimates suggest that fuel should spread rapidly across the stellar surface between bursts. Another factor that will certainly have an impact is stellar rotation. Most of the neutron stars that show Type I X-ray bursts are thought to be rapidly rotating, which reduces the effective gravity at the equator. Centrifugal effects, coupled with the deformation of the neutron star due to the rapid rotation, combine to reduce the effective gravity at the equator as compared to the poles. This results in a local accretion rate that is higher at the equator (Spitkovsky, Levin & Ushomirsky 2002). The column depth required for ignition is achieved more rapidly, and ignition should occur preferentially at this latitude. In fact there are accretion rates where off-equator ignition is still expected. Cooper & Narayan (2007a) considered the situation at high accretion rates $\dot{m} \approx \dot{m}_{c3}$, where helium burning is on the verge of stability. There will be a range of accretion rates (the more rapid the rotation, the larger this range) where $\dot{m} > \dot{m}_{c3}$ at the equator but not at other latitudes. Although not discussed by Cooper & Narayan (2007a), a similar region of off-equator ignition is to be expected at $\dot{m} \approx \dot{m}_{c1}$ (the transition to stable hydrogen burning).

Once ignition has occurred, the nuclear burning processes determine the emission from a given point. The burning layer will expand during a convective phase, and there is a delay before radiative processes take over and the light curve starts to rise. Light curves from a single point (ignoring spreading effects) have been generated by a number of authors (Taam 1980; Ayasli & Joss 1982; Fushiki et al. 1992; Taam et al. 1993; Woosley et al. 2004; Weinberg, Bildsten & Schatz 2006). The shape, time-scales and strength of the single point light curve can vary substantially depending on factors such as the burning regime and the composition of the accreted material. There are as yet no simple analytic models for this process that take into account all of the relevant parameters.

At the accretion rates of relevance to most burst sources, the burning front is expected to propagate by deflagration (Fryxell & Woosley 1982b; Hanawa & Fujimoto 1984; Bildsten 1995) rather than by detonation (Fryxell & Woosley 1982a; Zingale et al. 2001). In the simplest picture, spreading speed is set by the rate at which heat is transported across the burning front (by convective processes). Spitkovsky et al. (2002) have since shown that rapid rotation will also play a significant role: interaction between the uplift (vertical expansion) of burning material and a strong Coriolis force can act to slow spreading. The degree of asymmetry in the spread of the burning front is also relevant to the detectability of burst oscillations in the rise, if they are caused by a growing hot spot.

In this paper, we attempt the first systematic examination of how these various factors interact to affect the shape and time-scale of the rising portion of the light curve. Previous studies in this area have focused on small samples of bursts such as the rare multi-peaked bursts (Bhattacharyya & Strohmayer 2006a,b), or bursts from the accreting millisecond pulsars (Bhattacharyya & Strohmayer 2006c). In this study, we adopt a much broader remit, motivated by the wide variety of shapes exhibited by the bursts of the LMXB 4U 1636–536. This particular source is an excellent candidate for this

type of study: there are over 120 bursts from this source in the *Rossi X-ray Timing Explorer (RXTE)* archive, and it lies in a binary with relatively well-constrained properties. By comparing the burst properties with the results of parametrized simulations, we show that simple measures of the burst shape can be profound diagnostics of ignition latitude and burning regime.

This paper is structured as follows. In Section 2, we define simple measures of burst morphology and classify the bursts of 4U 1636–536 accordingly. Section 3 gives details of the parametrized simulations that we carried out to generate model light curves, and looks at the effects on shape using the same simple measures. In Section 4, we compare the results of our simulations with the data, and consider the implications in terms of ignition point and burning regime. We present a model that can explain our results (subject to the assumptions inherent in our simulations), and extend our analysis to other sources to test its feasibility. We conclude in Section 5.

2 OBSERVATIONAL DATA ANALYSIS

The bursting LMXB 4U 1636–536 is a persistent atoll source at a distance of ≈ 6 kpc (Galloway et al. 2006) in a 3.8 h binary orbit with a low-mass blue star, V801 Ara. The binary inclination i is in the range 36° – 60° (Casares et al. 2006). The bursts have been studied extensively with both *EXOSAT* (Lewin, van Paradijs & Taam 1993) and *RXTE* (Galloway et al. 2007). Burst oscillations at 581 Hz are seen in both normal bursts and superbursts, the latter being longer bursts triggered by unstable carbon burning (Strohmayer et al. 1998; Strohmayer & Markwardt 2002). We include in our study all of the bursts covered by the *RXTE* burst catalogue (Galloway et al. 2007). The catalogue includes over 1000 bursts observed by the *RXTE* Proportional Counter Array (PCA) from 1995 December 30 to 2005 October 29, 123 of which originate from 4U 1636–536.

In order to study the shape and time-scales of the bursts' rises, we started by constructing light curves from the PCA data, using Standard 1 data (0.125 s resolution) and using all available energy channels. For most of the bursts, this results in a smooth and monotonically increasing light curve. For a small group of bursts with peak fluxes below 5×10^{-9} erg cm $^{-2}$ s $^{-1}$ (bursts 11, 67, 71, 76, 78, 87, 88, 91, 118 and 122 for this source, using the numbering system of Galloway et al. 2007), the light curve is not smooth, so we exclude these bursts from our analysis. Burst 117 is also excluded because the rise is truncated. We also exclude for the moment bursts that are either kinked or multi-peaked when plotted with a coarser (0.5 s) time-resolution: that is to say bursts where the gradient of the light curve drops to zero or below during the rise. This group includes the strongly multi-peaked bursts (40, 48, 56 and 111) identified as such by Galloway et al. (2007) as well as a group that are either kinked or weakly multi-peaked (bursts 5, 18, 90, 110 and 113), see Fig. 1. We will discuss these bursts in more detail in Section 4.

In analysing the light curves of the remaining 103 bursts, we considered several different ways of quantifying the shape. The measure that we found to be most powerful, which we call convexity (\mathcal{C}), measures the degree to which the light curve is concave or convex. The physical significance of this parameter will become clear in Section 3, where we find that it can be used to diagnose the latitude at which the burst ignites. Convexity \mathcal{C} is calculated as follows. We define the burst rise to be the interval where the count rate rises from 10 to 90 per cent of the maximum count rate (corrected for the pre-burst persistent emission). We define rise time τ_R as the duration of that interval. In order to compare the shape of bursts of different durations and peak count rates, we then normalize both quantities so that they rise from 0 to 10 in dimensionless units. This process

Figure 1. Examples of kinked and multi-peaked structure in the burst rise for bursts from 4U 1636–536. The left-hand panel shows Burst 18 for this source (using the numbering system from Galloway et al. 2007): this burst shows a kinked rise. The right-hand panel shows Burst 40, which has a strongly multi-peaked rise.

Figure 2. Light curves at 0.125 s resolution for two bursts from 4U 1636–536, one convex and one concave. The left-hand panel shows Burst 1 and the right-hand panel Burst 52 (numbers from Galloway et al. 2007). The dashed lines mark the portion of the burst rise where the count rate lies between 10 and 90 per cent of the maximum (corrected for the pre-burst emission). It is this portion of the curve that we use to calculate convexity.

is illustrated in Figs 2 and 3. Taking c_i as the re-normalized count rate in each bin, and x_i as the identity function (shown as a diagonal line in Fig. 3), we define convexity \mathcal{C} as

$$\mathcal{C} = \sum_{i=0}^N (c_i - x_i) \Delta t, \quad (1)$$

where N is the number of re-normalized time bins and Δt is the re-normalized time bin size. Convexity is effectively the integrated area of the curve above or below the diagonal line – areas above the line being positive and areas below negative. For highly convex bursts, where most points lie above the diagonal, \mathcal{C} is positive, and for highly concave bursts it is negative. Our choice of re-normalization means that \mathcal{C} lies in the range -50 to 50 .

Fig. 4 plots the peak flux F_p of the bursts against convexity. At high peak fluxes, almost all of the bursts have $\mathcal{C} > 0$, whereas at low peak fluxes we find equal numbers of bursts with both positive and negative convexities. For convenience in later discussions, we assign the bursts to three broad groups, as indicated in the figure.

Figure 3. Re-normalized light curves for the two bursts from Fig. 2. As before, the left-hand panel shows Burst 1, and the right-hand panel Burst 52. Convexity \mathcal{C} , defined in equation (1), is the integrated area above or below the diagonal dashed lines, with areas above the line (convex bursts) taken to be positive and areas below the line (concave bursts) negative. For Burst 1, we find $\mathcal{C} = 14.8$, and for Burst 52 $\mathcal{C} = -20.5$.

Figure 4. Peak flux for the bursts of 4U 1636–536 (from Galloway et al. 2007) against convexity. The bursts divide naturally into two groups based on peak flux (above or below $50 \times 10^{-9} \text{ erg cm}^{-2} \text{ s}^{-1}$). For convenience in later discussions, we also split the low peak flux bursts into two groups depending on whether convexity is positive or negative. Only three bursts (those in the upper left-hand quadrant) sit outside this simple grouping. For these we use the presence or absence of radius expansion to determine group membership: Group 3 bursts show radius expansion while those in Group 1 do not. The lower dotted line shows the minimum peak flux for which we calculate convexity ($5 \times 10^{-9} \text{ erg cm}^{-2} \text{ s}^{-1}$).

Bursts with $F_p < 50 \times 10^{-9} \text{ erg cm}^{-2} \text{ s}^{-1}$ are assigned to Group 1 ($\mathcal{C} < 0$) or Group 2 ($\mathcal{C} > 0$), while the bright photospheric radius expansion (PRE) bursts with $F_p > 50 \times 10^{-9} \text{ erg cm}^{-2} \text{ s}^{-1}$ form Group 3. There are no PRE bursts in Group 1, and only one in Group 2.¹

Figs 5 and 6 show the relationship between accretion rate and burst rise time² τ_R for the bursts. Galloway et al. (2007) give two parameters that can be used to estimate the accretion rate at the time

¹ Burst 16, identified by Galloway et al. (2006) as a PRE burst with an anomalously low peak flux, due most likely to the presence of hydrogen.

² Note that we use a different definition of rise time from Galloway et al. (2007). These authors define rise time as the time taken for the count rate to rise from 25 to 90 per cent of the peak rate.

Figure 5. Normalized persistent flux γ (as a fraction of the Eddington rate, taken from Galloway et al. 2007) against rise time τ_R for the 4U 1636–536 bursts. Groups 1 and 2 cluster in the range $\gamma \approx 0.02$ – 0.04 . Group 3 bursts are seen at all values of γ and dominate at higher γ . Groups 1 and 2 have longer rise times than Group 3 (for which $\tau_R \approx 1$ s). There are only four Group 1/2 bursts at $\gamma > 0.05$. Two (partly obscured) have $\gamma \approx 0.07$. The Group 2 burst at $\gamma = 0.108$ is Burst 16, one of the anomalous PRE bursts identified in Galloway et al. (2006) (the other, Burst 18, is kinked and is not included on this plot). The Group 1 burst at the highest γ is Burst 19: the burst rise shape is unusual, being almost kinked.

Figure 6. Colour–colour diagram position S_z (Galloway et al. 2007) against rise time. Groups 1 and 2 dominate at lower S_z , while Group 3 dominates at higher values.

of the burst. The first, the normalized persistent flux γ , is the ratio of the persistent X-ray flux to the Eddington flux. This is thought to be a reasonable estimate of the global accretion rate \dot{M} as a fraction of the Eddington rate \dot{M}_{Edd} . The second measure, S_z , measures position in a colour–colour diagram: S_z is thought to increase as accretion rate rises. Both measures show the same trend. The bursts in Groups 1 and 2 cluster at low accretion rates (a few per cent of Eddington) and have longer rise times than those in Group 3. The Group 3 bursts have short rise times and dominate at higher accretion rates.

Table 1 summarizes the mean properties of the three groups of bursts. In addition to the parameters previously defined, we include burst fluence E_b (the integrated flux during the whole burst) and the burst time-scale τ_b (the ratio of burst fluence to peak flux), using data from Galloway et al. (2007). Group 3 bursts have higher fluences and shorter time-scales, whereas properties for Groups 1 and 2 are similar. We also indicate the percentage of bursts in each group

for which Galloway et al. (2007) state that oscillations are detected during the burst rise phase. Oscillations are far more prevalent in Group 3 than in Groups 1 and 2, as previously noted for this source by Munro et al. (2001).

3 SIMULATIONS

To understand what might cause the variations in shape and time-scale seen in the observational data, we developed a simple phenomenological model of the burst rise process and ran parametrized simulations to generate light curves. Our model consists of three main elements: a time-dependent temperature profile used to describe the emission from each point on the surface after ignition; a velocity model that describes the propagation of the burning front across the neutron star surface; and a light curve generation routine that models the propagation of photons from the neutron star surface towards a distant observer.

To generate light curves we use the Oblate Schwarzschild (OS) approximation of Morsink et al. (2007) to model relativistic light-bending, Doppler shifts and gravitational redshift. The OS model, which takes into account rotation-induced oblateness, is more appropriate for very rapidly rotating neutron stars than the more usual Schwarzschild + Doppler approximation (Poutanen & Gierliński 2003). Assuming that burst oscillation frequency is a good measure of stellar spin,³ 4U 1636–536 rotates at ≈ 580 Hz. The associated rotational deformation is a few per cent, depending on the assumed mass and nuclear equation of state, leading to a small but notable influence on the light curve (Morsink et al. 2007). We neglect both special relativistic time-delay and the additional time-delay experienced by initially inwardly propagating photons, since these delays are much smaller ($\sim 10^{-4}$ s, Poutanen & Beloborodov 2006) than the time bins we consider (~ 0.1 s). We specify stellar mass M and equatorial radius R_{eq} and then compute the deformed spherical surface using the OS model.

To start the burst, we specify an initial small burning area and then track the propagation of the burning front across the star. The stellar surface is divided into a grid of patches with area ~ 0.1 km², and we consider a patch to be ignited as soon as the burning front reaches the centre point of the patch. Once a patch has started burning, we need to specify how its emission varies with time. As discussed in Section 1, there are various numerically generated single-point emission models, but no simple analytic models. In this study, we follow Bhattacharyya & Strohmayer (2006a,b) and assume that the temperature of the burning front follows the following profile after ignition:

$$T = T_0 + (T_1 - T_0) \left[1 - \exp\left(\frac{-t}{t_{\text{r}}}\right) \right], \quad t \leq t_{\text{m}},$$

$$= T_{\text{m}} \exp\left(\frac{-t}{t_{\text{d}}}\right), \quad t \geq t_{\text{m}}, \quad (2)$$

where t_{m} is the time at which the temperature reaches its maximum $T_{\text{m}} = T_0 + 0.99(T_1 - T_0)$. The time-scale t_{r} sets the time-scale at which the temperature increases, while t_{d} sets the time-scale on

³ For the two accreting millisecond pulsars that also show burst oscillations, the burst oscillation frequency is at or very close to the known spin frequency (Chakrabarty et al. 2003; Strohmayer et al. 2003). The situation for the non-pulsing LMXBs is less clear (there are some differences in burst oscillation properties compared to the pulsars, see Watts & Strohmayer 2006). However, in all of the suggested models (Section 1) burst oscillation frequency lies within a few Hz of the spin frequency.

Table 1. Mean properties for the three groups of bursts. Most parameters are taken from Galloway et al. (2007) apart from rise time, where we use the definition given in this paper.

Property	Group 1	Group 2	Group 3
Number of bursts in group	31	30	42
τ_R (s)	3.3 ± 1.0	2.8 ± 1.6	1.2 ± 0.3
τ_b (s)	10.8 ± 4.9	13.7 ± 6.6	7.7 ± 2.2
E_b (10^{-6} erg cm^{-2})	0.24 ± 0.02	0.33 ± 0.03	0.48 ± 0.02
γ	0.033 ± 0.003	0.033 ± 0.003	0.052 ± 0.003
S_z	1.91 ± 0.06	1.69 ± 0.08	2.13 ± 0.03
F_p (10^{-9} erg cm^{-2} s^{-1})	22.7 ± 1.8	25.5 ± 1.9	62.7 ± 0.8
Percentage of bursts with oscillations in rise	7 per cent	23 per cent	36 per cent

Figure 7. A typical light curve for a single patch on the neutron star surface before taking into account propagation effects. Note that the y-axis is linear. The rise time-scale $t_{\text{fr}} = 0.1$ s, and the decay time $t_{\text{d}} = 6$ s. All single-point light curves for the assumed temperature profile are intrinsically convex: $\mathcal{C} \sim 10$ for $t_{\text{fr}} \sim 1$ s, falling as t_{fr} gets shorter.

which it decays. Unburnt patches are assumed to have a temperature T_0 until ignition. The parameters in this model depend primarily on the composition of the burning material, which will vary with accretion rate (see Section 1). Bursts which are helium-rich, for example, would be expected to have shorter time-scales than those which contain a higher fraction of hydrogen. Our parameter space must therefore be wide enough to take into account the expected level of variation. One follow-on question is whether this exponential temperature model remains valid across all burning regimes. It has been used successfully in detailed spectral modelling of bursts at different accretion rates by Bhattacharyya & Strohmayer (2006a,b), but ultimately one would like to see this confirmed by detailed nuclear physics calculations.

We then assume blackbody emission at the specified temperature from each patch. In Fig. 7, we show the typical single patch light curve. The rise portion is similar in shape to the bursts shown in Woosley et al. (2004). The decay portion does differ from that seen in some of the cases studied by Woosley et al. (2004), but because we are focusing on the rise we never reach the points late in the decay phase where the difference would become relevant. This relatively simple analytic formulation is therefore a reasonable approximation to a more realistic calculation, for the short rising phase that we are studying. To this we can then apply various different beaming functions.

In adopting this emission model, we have made two assumptions. We have assumed that each point on the star will have the same emission profile. This may not be the case, since emission could vary (as a result, say, of inhomogeneities in fuel deposition or composition). We have also neglected any delay between ignition and emission. If a convective zone develops, there will be a delay as the zone grows before radiative processes become a more efficient form of transport, and radiation starts to escape from the photosphere (Weinberg et al. 2006). If this delay is position-independent, then there will be no effect on the overall shape of the light curve; there could, however, be some position dependence here that would contribute to variations in emission profile across the star.

In modelling the spreading of the burning front, we use the expression for burning front speed, v_{flame} , developed by Spitkovsky et al. (2002). This speed depends on various nuclear burning parameters as well as the (poorly known) strength of frictional coupling between the top and bottom of the burning ocean. In general, the velocity is latitude-dependent (faster at the equator), because of the role of the Coriolis force. Spitkovsky et al. (2002) show that the burning front speed varies as

$$v_{\text{flame}} \sim \left[\frac{gh_{\text{hot}}}{t_n} \frac{1/t_{\text{fr}} + \eta/t_n}{f^2 + (1/t_{\text{fr}} + \eta/t_n)^2} \right]^{1/2}. \quad (3)$$

In this expression, g is the acceleration due to gravity at the surface, h_{hot} is the scaleheight of the hot burnt material, and $f = 2\Omega \cos \theta$ is the Coriolis parameter, Ω being the angular frequency of the star and θ the latitude. The parameter t_{fr} is the time-scale for frictional coupling between the top and bottom layers of the burning ocean. The parameter t_n is the nuclear time-scale of the thermonuclear burning (set by the composition of the burning material), and η is a constant of the order of unity. In the case of weak frictional coupling ($t_{\text{fr}} \gg t_n, 1/f$)⁴

$$v_{\text{flame}} = \frac{v_p}{\cos \theta}, \quad (4)$$

where the velocity at the pole, $v_p \sim \sqrt{gh_{\text{hot}}}/2\Omega t_n$. If frictional effects are stronger ($t_{\text{fr}} \leq t_n$), behaviour depends on how t_{fr} compares to $1/f$. Maximum flame speed is reached when $t_{\text{fr}} = 1/f$. In this case

$$v_{\text{flame}} = \frac{v_{\text{pm}}}{\sqrt{\cos \theta}} \quad (5)$$

⁴ Note that this approximation breaks down in a very small region near the equator, where $1/f \rightarrow \infty$. In this case we have to use the full expression for velocity.

with $v_{\text{pm}} \sim \sqrt{gh_{\text{hot}}/4\Omega t_n}$. In the high frictional coupling limit ($t_{\text{fr}} \ll 1/f$), the latitude dependence disappears, and

$$v_{\text{flame}} \sim \sqrt{\frac{gh_{\text{hot}}t_{\text{fr}}}{t_n}}. \quad (6)$$

The shape of the light curve depends on a whole host of parameters: however, some have a larger effect than others. We start by presenting results for a baseline scenario, where some of the parameters are fixed. Later in this section, we will show that varying these additional parameters has only a limited effect on our findings. In the baseline scenario, we assume a neutron star mass $M = 1.4 M_{\odot}$ and an equatorial radius $R_{\text{eq}} = 12$ km. We set the spin rate of the neutron star to 580 Hz, and assume a binary inclination $i = 50^\circ$, in the middle of the range inferred for 4U 1636–536 by Casares et al. (2006). In the spreading speed model, we assume that frictional coupling is weak (equation 4), so that flame speed is inversely proportional to $\cos \theta$. We start our simulations by setting an initial burning area with radius 1 km, similar to the expected width of the flame front (Spitkovsky et al. 2002). In the temperature model (equation 2), we fix the following parameters: $T_0 = 1$ keV, $T_1 = 2.8$ keV, and $t_{\text{id}} = 6$ s (as used by Bhattacharyya & Strohmayer 2006a). We also assume that beaming $\propto \cos \psi$, where ψ is the angle from the normal to the surface.

The parameters that we vary are the ignition latitude α_{ign} , the polar velocity v_p and the temperature rise time-scale t_{tr} . We vary ignition latitude in 30° steps from 0° (North Pole) to 180° (South Pole). The parameters v_p and t_{tr} both depend on the composition of the burning material, which will vary with accretion rate as the fraction of hydrogen changes. We choose ranges for these parameters wide enough to encompass the level of variation that might be expected as we move from pure helium bursts to hydrogen-rich bursts (Woosley et al. 2004; Weinberg et al. 2006). We consider $v_p = (1, 2, 4, 8, 16) \times 10^5 \text{ cm s}^{-1}$ (for velocities outside this range our simulations give rise times that are either much shorter or much longer than those observed). In the temperature profile, we consider $t_{\text{tr}} = 0.001, 0.1, 0.5, 1, 2$ s, a range wide enough to cover the values generated in the single-point light curve models of, for example, Weinberg et al. (2006).

Fig. 8 shows the results from our simulations. It is clear that ignition latitude has a dramatic effect on both convexity and rise times. We find the following key result: bursts ignited on the equator always have $\mathcal{C} > 0$, for the full range of v_p and t_{tr} considered. Convexity decreases as ignition latitude moves towards the poles, and can eventually become negative at high enough latitudes; negative convexity being much more easily achieved when ignition starts in the Northern hemisphere than in the Southern. Rise times do vary

Figure 8. Convexity \mathcal{C} against rise time τ_R for simulated bursts, showing the effect of changing v_p and t_{tr} . The range of v_p and t_{tr} studied covers the variation expected as the composition of the burning material changes from pure helium to a mix containing a substantial fraction of hydrogen. Each panel shows a different ignition latitude: $\alpha_{\text{ign}} = 0^\circ$ (North Pole), $\alpha_{\text{ign}} = 30^\circ$, $\alpha_{\text{ign}} = 90^\circ$ (equator), $\alpha_{\text{ign}} = 150^\circ$, and $\alpha_{\text{ign}} = 180^\circ$ (South Pole). The cases $\alpha_{\text{ign}} = 60^\circ$ and 120° are not shown but are very similar to the equatorial case. For ignition at the equator, convexity is always positive. Convexity decreases as ignition moves towards the poles, and can become negative. Negative convexity bursts are much more common for ignition in the Northern hemisphere than in the Southern. Rise times are shortest near the equator, increasing as ignition point moves towards the poles, with North Pole ignition bursts showing longer rise times than South Pole ignition bursts. The difference in behaviour between the poles reflects the fact that we have set $i = 50^\circ$.

Table 2. Fixed parameters for the 12 bursts that we used in testing the effects of the parameters that were held constant in the baseline scenario. For the equatorial ignition bursts, we considered a wider range of v_p because these values were a better fit for the observed rise times.

Burst ID	$\alpha_{\text{ign}} (^{\circ})$	$v_p (\times 10^5 \text{ cm s}^{-1})$	$t_{\text{lr}} (\text{s})$
1	0	2	0.1
2	0	2	0.5
3	0	4	0.1
4	0	4	0.5
5	90	2	0.1
6	90	2	0.5
7	90	8	0.1
8	90	8	0.5
9	180	2	0.1
10	180	2	0.5
11	180	4	0.1
12	180	4	0.5

slightly with ignition latitude but depend more strongly on spreading speed and the temperature rise time-scale. The differences between Northern and Southern hemisphere ignition are due to the fact that we are observing the star from a Northern hemisphere vantage point ($i = 50^{\circ}$). For bursts ignited at the South Pole, we do not observe the initial slow, concave, part of the rise that is visible to us if the burst ignites at the North Pole. A South Pole ignited burst therefore appears to have a higher convexity, purely by virtue of our viewing angle.

Let us now consider whether our results are robust when we vary the parameters that were held constant in our previous simulations: neutron star mass and radius, inclination angle, and the size of the initial burning area. We also vary the remaining temperature parameters, which are functions of composition and hence accretion rate. To do this, we took a representative sample of bursts (Table 2), varied the other parameters, and compared the results to the baseline scenario with the same ignition latitude, v_p and t_{lr} .

We considered neutron star masses in the range $M = 1\text{--}1.8 M_{\odot}$ and equatorial radii $R_{\text{eq}} = 10\text{--}14 \text{ km}$, in line with reasonable estimates for a range of equations of state (Lattimer & Prakash 2007). We varied inclination from $i = 0^{\circ}\text{--}90^{\circ}$ (a range much larger than that inferred for 4U 1636–536, but which will allow us to extend our results to other sources in Section 4). The radius of the initial burning region was varied from 200 m to 1 km. We took t_{ld} in the range 4–15 s, and tested the effect of increasing both T_0 and T_1 by a factor of 5. We also included the effect of the *RXTE* spacecraft response on our simulated bolometric light curves. To do this, we generated typical PCA response functions using some of the observed bursts analysed in Section 2. We then used *XSPEC* to fold our simulated light curves through the response functions, and re-computed convexity and rise times for the folded light curves.

Figs 9 and 10 show the deviations in convexity and burst rise time, respectively, as compared to the standard scenario, for inclinations in the range $40^{\circ}\text{--}60^{\circ}$ (the range appropriate for 4U 1636–536). The results of our previous analysis are clearly robust. In Fig. 11, we show results for a much wider range of inclinations. The range of variation is much wider, but again our main conclusions stand: negative convexity requires off-equatorial ignition.

We also checked the effects of several other parameters that are not shown in the figures. One thing that we tested was the effect of changing the beaming factor. We first tried removing the beaming

Figure 9. Convexity for the 12 test bursts (Table 2). The black line shows the baseline scenario. The dashed lines show the maximum deviation from this scenario when we vary t_{ld}, M, R , ignition patch size and include the *RXTE* response function, for inclinations in the range $40^{\circ}\text{--}60^{\circ}$ (the range appropriate for 4U 1636–536).

Figure 10. The same as for Fig. 9, but showing the effect on rise time.

Figure 11. The same as for Fig. 9, but for inclinations in the range $0^{\circ}\text{--}90^{\circ}$. At $i = 90^{\circ}$, as expected, North and South Pole ignition bursts become identical. As inclination falls, convexity increases: at $i = 0^{\circ}$, for example, the values are too high to explain the observations from 4U 1636–536.

factor: this had very little effect on bursts ignited in the Northern hemisphere or at the equator. Burst ignited in the Southern hemisphere, however, were more prone to having negative convexities. We also tried the more physically motivated grey atmosphere model (Miller & Lamb 1998). In this model, the temperature of each patch

$$T^4(\psi) = \frac{3}{4} T_{\text{eff}}^4 \left(\frac{2}{3} \cos \psi + 0.7 \right), \quad (7)$$

where T_{eff} is the effective temperature of the emitting layer and ψ is the angle from the normal. The effect on convexity was extremely small compared to the baseline scenario (as might be expected, since both have the same ψ dependence). We also varied the latitude dependence of spreading speed. In the baseline scenario, we assumed that we were in the low frictional coupling regime, where latitude dependence is strongest ($v_{\text{flame}} \propto 1/\cos \theta$). By the intermediate-friction regime, $v_{\text{flame}} \propto 1/\cos^{1/2} \theta$, while in the highest friction regime the dependence on latitude vanishes. We therefore considered two additional models, $v_{\text{flame}} = v_p/\cos^{1/2} \theta$ and $v_{\text{flame}} = v_p$. Interestingly, both of these models failed to reproduce the observed convexities. The constant-velocity case produced no negative convexity bursts at all. The intermediate-friction case did generate some bursts with $C < 0$ but the values were not sufficiently negative to match the observations.

4 DISCUSSION

4.1 Ignition latitude and burning regime

We start by summarizing the most-important results from the preceding sections. In our analysis of the bursts of 4U 1636–536, we identified three populations: one group with higher peak fluxes and two groups with lower peak fluxes. The high peak flux group dominate at higher accretion rates and have short rise times. All but two of the members of this group have positive convexity. The lower peak flux bursts divide into two groups of similar size: one with positive convexity and one with negative convexity. Rise times in this group are longer than for the high peak flux group, suggesting a different burning regime.

In our simulations, both composition of the burning material (hydrogen fraction) and ignition latitude have a strong influence on convexity (Fig. 8). However, only bursts that ignite near the poles have negative convexities: bursts ignited on or near the equator always have positive convexity. In addition, bursts ignited near the North Pole always have lower convexity than those ignited near the South Pole. We can therefore draw the following conclusion.⁵ The Group 1 bursts, which have negative convexity, must be triggered by polar ignition. In the rest of the section, we will outline a simple model that might explain why this should be the case.

As discussed in Section 1, there may be a region of polar ignition at high accretion rates at the point where He ignition is transitioning

⁵ Subject, of course, to the assumptions in our modelling. Negative convexity bursts could, for example, be generated by equatorial ignition if the single-point light curves were concave rather than convex (see Fig. 7). Although we are not aware of any physical motivation for such an assumption, we ran several simulations with concave single-point light curves to study the possibility. In these simulations, however, we could no longer generate positive convexity bursts with long rise times. To explain the presence of both positive and negative convexity bursts at low accretion rates, we would therefore require both types of single-point light curve (temperature profile) to operate simultaneously.

to stability (Cooper & Narayan 2007a). However, the same arguments should also apply at much lower accretion rates ($\dot{m} \approx \dot{m}_{\text{c1}}$), where H ignition is on the verge of stability. We therefore propose the following model. At the lowest accretion rates, the bursts of 4U 1636–536 are mixed H/He bursts, triggered by unstable H ignition. The star is, however, close to the transition where H burning stabilizes, in the range of accretion rates where off-equatorial ignition is preferred. We expect this range to be reasonably broad for 4U 1636–536 because of the rapid stellar rotation. As accretion rate increases H ignition stabilizes,⁶ and there is a transition to He-ignited bursts. Above the transition ignition moves back to the equator.

Within this picture the Group 1 and Group 2 bursts are mixed H/He bursts triggered by off-equatorial H ignition. We would expect similar numbers of bursts to be triggered in the Northern and Southern hemispheres. We therefore suggest that most of the Group 1 bursts, which have negative convexities, ignite in the Northern hemisphere, while most of the Group 2 bursts ignite in the Southern hemisphere (for which positive convexities are more likely).⁷ The two groups should have similar peak fluxes and rise times, in accordance with our observations. The properties of the bursts in these groups are in accordance with those expected for mixed H/He bursts triggered by H ignition: low peak fluxes, rise times of a few seconds, and durations longer than 10 s. The value of γ at which the transition takes place ($\gamma \approx 0.03$) is perhaps a little higher than expected (in Peng et al. 2007, H ignition no longer triggers mixed H/He bursts above ≈ 1 per cent Eddington), but the precise values of the transitions will depend on factors such as heating from the deep crust, and γ is not a perfect measure of accretion rate.

The Group 3 bursts would in this picture be triggered by He ignition on the equator. At accretion rates immediately above the transition, one would expect the bursts to be nearly pure He, with the amount of H involved in the bursts increasing as accretion rate rises. The properties of the Group 3 bursts are in line with those expected for He-dominated bursts: high peak fluxes (with radius expansion), rise times $\lesssim 1$ s, and durations $\lesssim 10$ s. We note that a transition to short rise time radius expansion bursts at a few per cent of the Eddington rate was also seen in the *EXOSAT* data (Lewin et al. 1987).

A transition from mixed H/He burning triggered by H ignition, to He burning, should result in a drop in burst rate and an increase in α (the ratio of the energy released by stable burning between the bursts to the energy released in bursts). If our interpretation is correct, this should occur when the accretion rate is ≈ 3 –5 per cent \dot{M}_{Edd} , and this is indeed what is observed (see fig. 16 of Galloway et al. 2007). This picture might also explain some unusual features of the PRE bursts for this source. Galloway et al. (2006) found that while most of the PRE bursts reached the Eddington limit for pure He, two had lower peak fluxes, requiring some H in the mix. These two exceptional PRE bursts occur, as discussed in Section 2, at the

⁶ The transition is actually rather more complex. Between the regime where H ignition triggers mixed H/He bursts, and the higher accretion rate regime where H burning is stable, there exist a range of accretion rates where hydrogen burns unstably via weak flashes (Cooper & Narayan 2007b; Peng et al. 2007). The flashes do not trigger associated He burning, so are faint and most likely undetectable above the persistent accretion luminosity. The weak hydrogen flashes may also show a move from equatorial to polar ignition as accretion rate rises.

⁷ Some of the Group 2 bursts could ignite on the equator, as this would also give rise to positive convexity. This might be expected at the lowest accretion rates, and could explain the apparent excess of Group 2 bursts at the lowest values of S_z , see Fig. 6.

highest accretion rates. At these rates, pure He bursts are no longer likely and bursts should have some mixed H/He character again, reducing the peak flux reached by the PRE bursts. As shown by Galloway & Cumming (2006), there can be a substantial percentage of H in the mix before the Eddington limit starts to fall below that expected for pure He.

The values of convexity that we measured for the bursts of 4U 1636–536 ranged from -20 for the Group 1 bursts up to $+20$ for the Group 3 bursts. Although our simulations generated bursts with negative convexities in the right range, convexities > 10 were harder to generate (Fig. 8). One reason for this is that our simulations did not take into account PRE (which all of the Group 3 bursts show). PRE tends to flatten the top of the light curve: when we include this in our simulations it results in an increase in convexity of sufficient magnitude to explain the discrepancy. Changing the parameters from the baseline scenario can also increase convexity (compare Figs 8 and 9). A rise in peak temperature, for example (as might be expected for He-rich bursts), increases convexity.

By comparing the observed values of convexity and rise time with those generated by the simulations, we can infer the range of t_{r} and v_{p} required to explain the observations (comparing Figs 4–5 and 8). For the Group 3 bursts, for example, we need $t_{\text{r}} \lesssim 0.5$ s independent of v_{p} , while for the Group 2 (and hence also the Group 1) bursts we require $t_{\text{r}} \gtrsim 0.1$ s. We can therefore ask whether the values that we infer are in line with the values predicted for the suggested burning regimes. The single point light curve models of Weinberg et al. (2006) predict a temperature rise time-scale of ~ 0.01 s for He bursts, rising to ~ 0.1 s as H fraction increases. The time-scales derived by Woosley et al. (2004) using multizone models are slightly longer. The limits that we derive are therefore broadly compatible with these models. What is harder to check is the validity of the inferred values of v_{p} . Spreading speed (equation 3) depends on the nuclear time-scale, the scaleheight of the burnt atmosphere and the strength of frictional coupling in the burning layers. Naively, one would expect the nuclear time-scale to be related to the temperature rise time-scale (although the degree to which convection develops could skew this relationship). The dependence of the frictional coupling on the burning regime, however, is very poorly understood. Without a better understanding of the burning and spreading process, it is difficult to say whether the values of v_{p} suggested by our simulations accord with the values expected for the different burning regimes.

4.2 Accretion disc effects

One issue that we have not considered in our modelling is the role of the accretion disc. An optically thick accretion disc extending down to the stellar surface could obscure the Southern hemisphere of the star. At the lowest accretion rates, the disc is likely to be truncated sufficiently far from the star for our unobscured models to be valid (Done & Gierliński 2003). As accretion rate increases, however, the inner disc is expected to move in towards the stellar surface, obscuring the Southern hemisphere.

Radiation pressure from a bright burst may be able to push the disc back, revealing the Southern hemisphere once more (Shaposhnikov, Titarchuk & Haberl 2003). Even if the Southern hemisphere were obscured, however, there would be little impact on our results. Bursts ignited in the Northern hemisphere would still have negative convexities, and bursts ignited at the equator would still be positive, although peak count rates would be lower and apparent rise times shorter than in our simulations. The largest impact would be on bursts ignited in the Southern hemisphere: these would

Figure 12. Dynamical power spectra from simulated bursts with ignition starting just off the North Pole ($\alpha_{\text{ign}} = 10^\circ$), at the equator ($\alpha_{\text{ign}} = 90^\circ$) and just off the South Pole ($\alpha_{\text{ign}} = 170^\circ$). Note that we start just off the poles because bursts ignited exactly at the pole spread in a totally axisymmetric fashion and there would be no burst oscillations. For these simulations, we used the baseline scenario with $v_{\text{p}} = 4000 \text{ m s}^{-1}$ and $t_{\text{r}} = 0.1$ s. The peak count rate for the polar bursts is $2000 \text{ counts s}^{-1}$, while the peak count rate for the equatorial burst is $4000 \text{ counts s}^{-1}$ (see the explanation in the text). We use 0.25 s time windows (to match those used for oscillation detection by Galloway et al. 2007), overlapping by 0.05 s. The contours start at a power of 5 and rise in increments of 5. Note the variation in strength and duration.

only be visible to us once the burning front traversed the equator, so all would have positive convexities.

4.3 Burst oscillations

In Table 1, we summarized the detectability of burst oscillations, as reported by Galloway et al. (2007), for the rising phase of bursts from 4U 1636–536. The detectability criteria used were based on power exceeding a certain threshold in short time bins (0.25 s). Oscillations were most likely to be detected in Group 3 and then in Group 2. Group 1 bursts were far less likely to show oscillations. Can this be explained by the pattern of flame spreading if the bursts in Groups 1 and 2 result from polar ignition, while those in Group 3 result from equatorial ignition? Detectability will depend on relative amplitude of the asymmetry, the length of time for which it persists, and the overall count rate. A long-lived lower amplitude asymmetry may be more detectable than a short-lived high amplitude asymmetry if the time window used for the power spectral analysis is long.

We carried out a number of simulations to test whether our model is compatible with the observations. In Fig. 12, we show dynamical power spectra from simulated bursts ignited at different latitudes. To mimic the differences between the different groups, we assumed a higher peak count rate for the equatorial ignition burst. We find that oscillations are most detectable in the bright equatorial ignition bursts (our model for the Group 3 bursts). For the bursts with lower peak count rates, oscillations are more detectable for bursts that ignite in the Southern hemisphere. This fits with our interpretation in which Group 2 bursts are ignited near the South Pole and Group 1 bursts near the North Pole.

4.4 Multi-peaked and kinked bursts

4U 1636–536, like many other neutron stars, shows both multi-peaked bursts and bursts with kinks (at least two points of inflection)

in the rise. This group includes those that we excluded from our analysis in Section 2 as well as bursts with weaker kinks such as Burst 19 (see Fig. 5) and the two bursts with negative convexities in Group 3 (Fig. 4). The simulations described in Section 3, which involved single-point ignition and subsequent smooth spread, produced no simulated light curves with more than one point of inflection.

We therefore extended our simulations to investigate the effect of near simultaneous ignition at equivalent latitudes in the Northern and Southern hemispheres. We wanted to see whether a second burning front igniting before it could be engulfed by a burning front spreading from the other hemisphere could give a multi-peaked or kinked light curve. We ran a series of simulations where North and South Poles were ignited either simultaneously or at intervals from 0.5 to 4 s. In no case were we able to replicate either multi-peaked or kinked shapes.

We conclude that some additional physics is still required to explain the multi-peaked and kinked bursts. Bhattacharyya & Strohmayer (2006a,b) put forward a scenario in which multi-peaked bursts were caused by polar ignition in one hemisphere, some kind of stalling on the equator, followed by the burning front re-activating and propagating on towards the other pole. In Watts & Maurer (2007), we argued against this model on the grounds that polar ignition was only expected at the highest accretion rates (Cooper & Narayan 2007a), whereas the multi-peaked bursts are actually seen at low and intermediate rates. However, as we have pointed out in this paper, polar ignition is also likely to play a role at the transition to stable H burning. A mechanism involving polar ignition may therefore still be responsible, provided that a viable stalling mechanism can be identified. Interestingly, three of the multi-peaked bursts from 4U 1636–536 sit at the accretion rates where we are postulating polar ignition. The fourth, which looks rather different, however, sits at slightly higher rates (Watts & Maurer 2007).

4.5 Application to other sources

If ignition does indeed move towards the pole as we reach the upper limits of the accretion rate where H ignition is still feasible – and then back to the equator when He ignition begins – then we would expect to see similar trends in other sources. Assuming a favourable inclination, we would also expect to see positive convexity bursts at the very lowest accretion rates (when H ignition should occur at the equator), and negative convexity bursts at the very highest accretion rates (when He ignition moves off-equator towards the pole). Fig. 13 illustrates the type of behaviour that we expect, and the regions where polar ignition should occur. In what follows, we will refer to this plot as the F diagram.

We selected a number of additional sources that are thought to accrete a mix of H/He from the *RXTE* burst catalogue (Galloway et al. 2007). We chose the sources that span the widest range of accretion rates (those for which Galloway et al. 2007 compute a colour–colour diagram position S_2).⁸ We also included two additional sources: the eclipsing system EXO 0748–676, which has a large sample of bursts at low accretion rates that are thought to be triggered by H ignition, and the accreting millisecond pulsar XTE J1814–338, which has a large burst sample but where magnetic confinement may also play a role in setting ignition latitude. Our

⁸ We excluded 4U 1728–34 because this source is thought to accrete from an H-poor donor, and XTE 2123–058 because there are only six bursts in the catalogue.

Figure 13. A schematic of the type of behaviour we expect in a plot of γ (a proxy for accretion rate) against burst rise time for a rapidly rotating neutron star: in the text we refer to this as the F diagram. At the lowest accretion rates, bursts are triggered by H ignition and ignite at the equator. As accretion rate rises, ignition moves off-equator and rise times increase, forming the lower horizontal stroke of the F. When H burning stabilizes, ignition (now by He) moves back to the equator and we move up the vertical stroke of the F. Rise times should increase as the proportion of H in the bursts increases, and we may move on to the upper horizontal stroke of the F before He ignition moves off-equator at the highest accretion rates.

simulations can be very easily extended to neutron stars with different rotation rates: spreading speed is inversely proportional to rotation rate, so a more slowly rotating star will have a higher v_p than a star with more rapid rotation, all other factors being identical. The change in oblateness has a very small effect on convexity and rise time.

We need to be somewhat cautious in comparing different sources, as burst properties will differ. These differences will reflect variations in the composition of accreted material, deep crustal heating, and accretion history. The F diagram for one source may be offset from the F diagram for another, or different regions of the diagram may be populated, depending on the source. A star with an H-poor donor, for example, would not trace out the lower portions of the F diagram. However, if our model is correct, then there should be two transitional accretion rates for each source, for which ignition occurs at the pole rather than at the equator. As our simulations show, not all polar ignition will result in negative convexity bursts. However, all negative convexity bursts should indicate polar ignition. We therefore expect to find negative convexity bursts on the horizontal strokes of the F diagram.

In Fig. 14, we plot F diagrams for the other sources examined, marking those bursts with negative convexity. As for 4U 1636–536, we excluded both the faintest bursts and those with kinked or multi-peaked rises. For the accreting millisecond pulsar XTE J1814–338, the Eddington luminosity has not been measured so we show unscaled persistent flux rather than γ . The properties of the sources examined are summarized in Table 3. Inclination is for most sources unconstrained (although it is expected to be $< 70^\circ$ due to the absence of dips or eclipses). The exception is EXO 0748–676, which is a high-inclination eclipsing system. We expect the range of accretion rates for which polar ignition is important to be larger for the more rapidly rotating sources (although whether or not we see negative convexity bursts would of course depend on the inclination).

Figure 14. Normalized persistent flux (γ) against burst rise time for various burst sources. Crosses: bursts with positive convexity. Asterisks: bursts with negative convexity. Rise time is τ_R , the time taken for the light curve to rise from 10 to 90 per cent of the peak value. Values for γ (or, in the case of XTE J1814–338, persistent flux in units of 10^{-9} erg cm $^{-2}$ s $^{-1}$) are taken from Galloway et al. (2007).

Table 3. Properties of the sources depicted in Fig. 14. The frequency given is burst oscillation frequency except for the pulsar XTE J1814–338, for which the spin frequency is known.

Source	Frequency (Hz)	Bursts analysed (total in catalogue)	Number with $C < 0$
4U 1608–52	619 [1]	27 (31)	3
4U 1702–429	329 [2]	38 (44)	0
4U 1705–44		30 (39)	9
KS 1731–26	524 [3]	24 (27)	1
4U 1746–37		20 (30)	7
EXO 0748–676	45 [4]	72 (83)	50
Aql X-1	549 [5]	35 (40)	4
XTE J1814–338	314 [6]	28 (28)	18

References. [1]: Hartman et al. (2003); [2]: Markwardt, Strohmayer & Swank (1999); [3]: Smith, Morgan & Bradt (1997); [4]: Villarreal & Strohmayer (2004); [5]: Zhang et al. (1998); [6]: Strohmayer et al. (2003).

The picture that emerges is certainly not clear-cut. All but one of the sources (4U 1702–429) show some negative convexity bursts, and many of these sit on what we might interpret as the lower horizontal stroke of the F diagram. 4U 1746–37 is interesting in that it seems to trace out the entire upper portion of the F diagram, with two negative convexity bursts at high accretion rates that might be polar ignition bursts triggered by He burning. There are, however, a few negative convexity bursts at intermediate accretion rates (as there were for 4U 1636–536). EXO 0748–676 has a large percentage of negative convexity bursts: if these are caused by polar ignition then this may seem a little surprising, since this source is thought to have

a much slower spin rate. This source does span a very narrow of accretion rates, however, and as a high-inclination system we also expect the South Pole ignition bursts to have negative convexities. However, if the accretion rate is not extremely finely-tuned, then there may be some other factor (such as a strong magnetic field) that is controlling fuel deposition and hence ignition latitude. The relatively slow spin inferred for this source suggests that magnetic field effects might be important. In this respect, the results from the pulsar (XTE J1814–338) are also extremely interesting. This source too shows a large number of negative convexity bursts, as one might expect if ignition were occurring off-equator at the magnetic pole.

The phase-locking of persistent pulsations and burst oscillations in this source also suggests that this may be the case (Strohmayer et al. 2003).

5 SUMMARY AND CONCLUSIONS

We have shown, using parametrized simulations, that burst rise shape can be a valuable diagnostic of the burning process. Changes in ignition latitude, in particular, can have a major impact on burst morphology, and such changes may explain the variation in burst rise shape seen in the well-studied source 4U 1636–536. We have argued that a change from off-equatorial to equatorial ignition might be the hallmark of the transition from H-triggered mixed bursts to He-triggered bursts at low accretion rates. Such a model can also plausibly explain variations in the detectability of burst oscillations. There are also areas, however, where additional physics is clearly required. Our spreading and burning models were not, for example, able to generate multip peaked or kinked burst rises.

Our goal with this work was to develop a simple phenomenological model to study the interactions between the various processes operating during the burst rise, and their influence on light curve shape. What we have done is clearly simplistic: the various elements of the model will be more closely connected than we have considered here, and we have made a number of assumptions that may not be valid. The parameter space that we have considered, however, is extremely wide, giving us confidence in our conclusions. What we have done also demonstrates the power of simple measures of the burst shape: if our model is valid we have been able to identify ignition latitude and rule out latitude-independent flame spreading speeds (see also Bhattacharyya & Strohmayer 2007). This type of study could and should be repeated as more detailed models of the nuclear burning, spreading and emission process become available.

ACKNOWLEDGMENTS

We would like to thank Edward Brown, Randall Cooper, Andrew Cumming, Fang Peng, Mike Revnivtsev, Henk Spruit, Rashid Sunyaev and the anonymous referee for helpful comments. This research has made use of data obtained from the High Energy Astrophysics Science Archive Research Centre (HEASARC) provided by NASA's Goddard Space Flight Center.
