75 **Abstract**

76 Refractive error is a complex eye condition caused by both genetic and environmental factors. Common  
77 genetic risk factors have been identified by genome-wide association studies (GWAS), but a great part of  
78 the refractive error heritability is still missing. Some of this heritability may be explained by rare variants  
79 (minor allele frequency [MAF]  $\leq 0.01$ ). We performed multiple gene-based association tests for rare  
80 variants on exome array data from the Consortium for Refractive Error and Myopia (CREAM). The  
81 dataset consisted of over 27,000 total subjects from five cohorts of Indo-European and Eastern Asian  
82 ethnicity. We identified 129 unique genes associated with refractive error, many of which were  
83 replicated in multiple cohorts. Our best novel candidates included the retina expressed *PDCD6IP*, the  
84 circadian rhythm gene *PER3*, and *P4HTM*, which affects eye morphology. Future work will include  
85 functional studies and validation.

## 107 **Introduction**

108 Refractive error has become a major worldwide health concern, with the prevalence of the disease,  
109 particularly myopia (nearsightedness), becoming more frequent in both the United States<sup>1</sup> and Europe<sup>2</sup>  
110 and reaching epidemic proportions in parts of East Asia<sup>3,4</sup>. Refractive error is caused when the optics of  
111 the eye fail to project the focal point of light on the retina, causing a blurred image. Myopia is the  
112 refractive error mostly resulting from eye elongation, which can lead to serious ocular complications like  
113 myopic macular degeneration, glaucoma and retinal detachment<sup>5-8</sup>, and is the second most common  
114 cause of blindness<sup>9-11</sup>.

115 Refractive error is a highly complex trait that is known to have both an environmental and genetic  
116 etiology. Established environmental factors include prolonged near work, education, and little outdoor  
117 exposure<sup>12</sup>. Genome-wide association studies (GWAS) and genetic linkage studies have identified  
118 multiple associated variants for refractive error<sup>13-18</sup>. The Consortium for Refractive Error and Myopia  
119 (CREAM) has reported numerous risk variants using large-scale, multiethnic datasets<sup>19-22</sup>, explaining  
120 approximately 18% of phenotypic variance<sup>22</sup>.

121 Despite estimates that 50% to 80% of refractive error variance is determined by genetic factors<sup>23-26</sup>,  
122 much of the refractive error heritability remains unaccounted for<sup>19,21</sup>. Since GWAS are particularly  
123 designed to identify common variants, some of the missing heritability may lie with rare variants (minor  
124 allele frequency [MAF]  $\leq 0.01$ ), which may be highly penetrant and exert a large effect on the  
125 phenotype<sup>27</sup>. Gene-based association tests, such as burden-style tests<sup>28,29</sup>, offer increased power to find  
126 rare variants not identified by GWAS.

127 This study performs the first large-scale rare variant analysis on refractive error using multiethnic  
128 cohorts from CREAM. We used an initial discovery dataset consisting of over 13,000 Indo-Europeans and  
129 four replication datasets consisting of European ancestry Americans, European ancestry Australians,  
130 European ancestry Britons, and Eastern Asian ancestry Singaporeans. Gene-based tests were performed  
131 on each of the five cohorts and meta-analysis was performed subsequently. Pathway analysis was  
132 conducted on genome-wide significant genes and genes were prioritized based on annotation and  
133 biologic relevance to the trait.

## 134 **Methods**

### 135 *Cohort Details, Genotyping and Joint Recalling of Exome Array Data*

136 Fourteen population-based CREAM cohorts that had exome chip genotypes on individuals with  
137 refractive error measurements were used in this study. These 14 cohorts were: Singapore Chinese Eye  
138 Study (SCES), Singapore Malay Eye Study (SiMES), Singapore Indian Eye Study (SINDI), Age Related Eye  
139 Study (AREDS), Rotterdam Study I (RSI), Erasmus Rucphen Family (ERF), Raine Eye Health Study (REHS) of  
140 the Raine Study, Beaver Dam Eye Study (BDES), Estonian Genome Center for the University of Tartu  
141 (EGCUT), Finnish Twin Study on Aging (FITSA), Ogliastra, Croatia-Korcula, TwinsUK, and EPIC-Norfolk.  
142 Each individual cohort is described in further detail in the Supplementary Methods. All studies were  
143 performed in accordance with the Declaration of Helsinki and approved by the institutional review  
144 boards of the participating institutions. All participants provided written informed consent. The  
145 Institutional Review Board of the National Institutes of Health (NIH) determined that the analyses of

146 deidentified data performed in the current study and the meta-analysis qualified as “not human subjects  
147 research” and did not require specific protocol approval. The study was performed under guidelines  
148 agreed to in Data Use Agreements between the individual participating studies and the NIH and the  
149 Erasmus Medical Center where these analyses took place.

150 Thirteen cohorts had been genotyped on the Illumina HumanExome-12 v 1.0 or v 1.1, or the Illumina  
151 HumanCoreExome-12 v1.0; EPIC-Norfolk was genotyped on Affymetrix UK BioBank Axiom Array. The 13  
152 cohorts on the Illumina arrays were jointly recalled to obtain a larger sample size of rare variants (here  
153 defined as variants with a  $MAF \leq 0.01$ ), as recalling genotypes simultaneously across all samples  
154 increases the ability to call rare variants with more discrete distinction between allele calls and  
155 sensitivity for low-frequency (high-intensity) loci. All data were recalled using GenomeStudio® v2011.1  
156 (Illumina Inc., San Diego, CA, USA) per microarray platform and PLINK<sup>30</sup>. We note that these exome-  
157 based genotyping arrays consist of previously validated, high confidence rare variants, reducing the  
158 likelihood that findings might be the result of artifacts or genotyping errors that might affect sequencing  
159 studies. Further, since the imputation of very rare variants is difficult, only genotyped rare variants were  
160 used in this study; there were no imputed variants.

### 161 *Combination of Cohorts for Mega-analysis*

162 To increase power on rare variants, we sought to combine as many cohorts as possible into a mega-  
163 analysis. We thus performed principal components analysis (PCA) on all our cohorts after pruning the  
164 datasets for linkage disequilibrium using the pcair, part of the R package GENESIS. Pcair is designed to  
165 perform PCA in samples with cryptic relatedness and provides accurate ancestry inference that is not  
166 confounded by family structure<sup>31</sup>. For reference, we included individuals from all 11 HapMap reference  
167 panels in the PCA.

168 PCA showed two major groupings based on known ethnicity. The first consisted of the Han Chinese SCES  
169 and Malaysian SiMES cohorts, which were combined into the Eastern Asian combined cohort (EACC); we  
170 realize that technically the Malaysian population are Southeast Asians, but for simplicity will refer to this  
171 cohort as Eastern Asian. The second dataset consisted of the eight European cohorts (RSI, Croatia-  
172 Korcula, FITSA, EGCUT, TwinsUK, ERF, AREDS, and Ogliastra) and the one Indian cohort (SINDI). These  
173 cohorts were combined into the Indo-European combined cohort (IECC).

174 Analysis was performed on five discrete cohorts – IECC, EACC, EPIC-Norfolk, BDES, and REHS. The IECC  
175 analysis was performed in the Netherlands, while the EACC was performed in the United States as well  
176 as in the Netherlands. The BDES, EPIC-Norfolk, and REHS analyses were performed in their countries of  
177 origin (the United States, the United Kingdom, and Australia, respectively) as was legally required; these  
178 studies served on a per study basis as replication cohorts. A breakdown of all cohorts and the combined  
179 cohort with which they are grouped is provided in Supplementary Table 1.

180  
181

### 182 ***Statistics and Reproducibility***

#### 183 *Quality Control*

184 For the combined cohorts, all raw cohort data were merged into a single file. All five cohorts then  
185 underwent identical quality control using PLINK<sup>30</sup>. Any individual not genotyped at 99% of all variants  
186 was removed and any variant not genotyped at 99% was also removed. Variants with a HWE p-value less

187 than a Bonferroni-corrected p-value (defined as  $0.05 / \text{total number of variants in the dataset}$ ) were also  
188 excluded. We also checked for batch effects and calculated the identity-by-descent (IBD) value of all  
189 individuals in the cohort, removing duplicates and twins. Many of the datasets exhibited cryptic  
190 relatedness amongst subjects (especially the Ogliastra study, which collected on the Italian island of  
191 Sardinia). Related individuals were not removed from the cohorts, as our analysis methods corrected for  
192 relatedness.

### 193 *Final Sample Sizes*

194 After QC, IECC had 13,037 individuals with 150,619 variants, EACC had 4,867 individuals with 98,750  
195 variants, BDES had 1,740 individuals with 105,671 variants, REHS had 1,020 individuals with 92,313  
196 variants, and EPIC-NORFOLK had 6,282 individuals with 637,160 variants.

### 197 *Refractive Error Phenotype*

198 Refractive error was defined as the quantitative phenotype spherical equivalent (SER), measured in  
199 diopters (D). Refractive error measurements in both eyes were taken from all participants and SER was  
200 calculated by adding the spherical refractive error + half the cylindrical refractive error in each eye, then  
201 taking the mean of both eyes. Individuals who had undergone procedures that could alter refraction,  
202 e.g., cataract surgery, laser refractive error procedures, retinal detachment surgery, and other  
203 ophthalmic conditions that may influence refraction were excluded from these analyses. The average  
204 spherical equivalents and standard deviations of each cohort are provided in Supplementary Table 1.

### 205 *Gene-based Analysis using EMMAX-VT and EMMAX-CMC*

206 Gene-based analysis was performed using a gene-based version of EMMAX.<sup>32,33</sup> EMMAX uses a kinship  
207 matrix to correct for population stratification and cryptic relatedness, which are present in these  
208 cohorts. EMMAX has been modified to perform gene-based burden-style tests, including the variable  
209 threshold (VT)<sup>29</sup> and the combined multivariate and collapsing (CMC)<sup>28</sup> methods through the software  
210 EPACTS (<https://genome.sph.umich.edu/wiki/EPACTS>), which we will term EMMAX-VT and EMMAX-  
211 CMC, respectively.<sup>34</sup>

212 We analyzed all five cohorts with EMMAX-VT and EMMAX-CMC using a maximum MAF = 0.01. We only  
213 included variants that were in an exon of a gene (as defined by RefSeq), including both nonsynonymous  
214 and synonymous variants. Common variants (MAF > 0.01) and variants with a MAF ≤ 0.01 that mapped  
215 to an intergenic region were excluded from the analysis. Any gene with a minor allele count (MAC) of  
216 less than three for the cohort was dropped from the analysis.

217 Initial analyses were performed without any covariates. We performed two follow-up analyses using  
218 age, sex, and education level (low, intermediate, and high). One covariate analysis included all three  
219 covariates, while the second used age and sex only (education level removed). We note that the  
220 inclusion of covariates resulted in no significant difference between significant genes; for brevity we  
221 only discuss the results without covariates. In addition, the Ogliastra cohort did not have data on age  
222 and education, thus approximately 3,000 individuals were removed from the IECC covariate analyses.  
223 Hence, the covariate analyses are underpowered with respect to the analyses without covariates

### 224 *Gene-based Analysis using ACAT*

225 The Aggregated Cauchy Association Test (ACAT)<sup>35</sup> is a novel method that allows individual p-values to be  
226 combined into a gene-based p-value that is particularly useful for rare variants. To take advantage of  
227 this method, we analyzed all variants with a MAF  $\leq 0.01$  (with a minimum allele count of 3) using the  
228 original, single variant-based version of EMMAX.<sup>32,33</sup> We then combined the EMMAX p-values for each  
229 gene using the ACAT package implemented through R. Only nonsynonymous and synonymous exonic  
230 variants were included in the analysis.

### 231 *Meta-Analysis and Replication*

232 The burden-style tests that created a single p-value for a gene precluded the use of popular meta-  
233 analysis programs such as METAL, which require the input of reference and alternative alleles. Instead  
234 the gene-based p-values from the EMMAX-VT, EMMAX-CMC and ACAT were combined across studies  
235 using the classic method described by Fisher<sup>36</sup>. Fisher's method was implemented through the R  
236 package *metap*<sup>37</sup>. We defined genome-wide significant as  $1 \times 10^{-5}$ , based on the standard for gene-based  
237 studies. Replication was defined as a having a  $P \leq 0.05$  in one cohort after being found to be genome-  
238 wide significant in one of the other four cohorts. We note that this replication value is liberal and may  
239 lead to an inflation in false positives. However, as this is a discovery analysis, we were willing to allow  
240 some extra false positives in order to capture as many true positives as possible. A more stringent  
241 replication p-value of  $3.9e-04$  was also used to adjust for 129 attempted replications and these more  
242 stringently replicated genes were also reported.

243 We performed two separate meta-analyses. The first combined all five cohorts (IECC, EACC, BDES, EPIC-  
244 Norfolk, and REHS), which will be referred to as the multiethnic meta-analysis. The second combined the  
245 four ethnically Indo-European cohorts (IECC, BDES, REHS, and EPIC-Norfolk), which will be referred to as  
246 the Indo-European meta-analysis. The Indo-European meta-analysis was designed to identify any genes  
247 that might be significant in Indo-European-derived individuals but not significant in Eastern Asians; thus,  
248 we also report the Eastern Asian analyses p-values.

249 To investigate whether signals identified by the rare variant analysis were being partially driven by  
250 common variants, we calculated polygenic risk scores (PRS) for all cohorts using common variants  
251 identified in previous GWAS<sup>22</sup>. PRS were calculated for each subject using PLINK (Supplementary Table  
252 2). All rare variant analyses were then repeated using the PRS values for each subject as a covariate. We  
253 compared the explained variance ( $R^2$ ) of our top individual genes between the analysis with and without  
254 including PRS (Supplementary Table 3-4).

255 Independent replication of the genome-wide significant genes was performed in the UK Biobank (UKBB)  
256 via extraction of all rare variants comprising the genome-wide significant genes and repeating the same  
257 analyses.

### 258 *Pathway and Expression Analysis*

259 All genome-wide significant genes in the four meta-analyses and the EACC analyses were analyzed using  
260 Ingenuity Pathway Analysis (IPA) (QIAGEN Inc., [https://digitalinsights.qiagen.com/products-  
261 overview/discovery-insights-portfolio/analysis-and-visualization/qiagen-ipa/](https://digitalinsights.qiagen.com/products-overview/discovery-insights-portfolio/analysis-and-visualization/qiagen-ipa/))<sup>38</sup>. We performed various  
262 analyses through IPA, including canonical pathway analysis (identifying which genes are in known  
263 pathways), upstream regulator analysis (which identifies genes, RNAs, and proteins that regulate the  
264 genes in the dataset), and causal network analysis (which expands the pathway analysis to include the  
265 upstream regulators in the pathway analysis). IPA also identified disease phenotypes, cellular/molecular

266 functions, and physiological networks associated with the genes in the dataset. Additional pathway and  
267 expression analysis were also performed with Functional Mapping and Annotation of GWAS<sup>39,40</sup> (FUMA),  
268 which provided tissue-enrichment information from GTEx and gene-group information from MsigDB.  
269 We repeated the IPA and FUMA analyses for our top prioritized genes from the schema proposed below.

#### 270 *Gene Prioritization based on Biological Function*

271 To prioritize genes according to biological background, we evaluated genes following a modified  
272 schedule proposed by Fritsche et al.<sup>41</sup> and further adapted by Tedja et al.<sup>21</sup> Genes were ranked based on  
273 points equally assigned for the presence of replication, expression and biological plausibility. Evidence  
274 for ocular expression was based on single-cell expression data from adult human retina and developed  
275 organoids<sup>42</sup>. Biological plausibility was based on the presence of an ocular phenotype in OMIM and/or  
276 DisGeNET<sup>43</sup> as well as an ocular phenotype in a knock-out mouse model of this gene (Mouse Genome  
277 Informatics and International Mouse Phenotyping Consortium databases). The prioritization score  
278 ranged from zero to seven. In addition, we performed a look-up of the top-genes to screen for drugs  
279 that had these genes as target using SuperTarget<sup>44</sup>, PharmGkb,<sup>45</sup> STITCH v5.0<sup>46</sup> and DrugBank v5.0.<sup>47</sup>

#### 280 *Variant Annotation for Potential Causal Variants*

281 We performed annotation to identify potential causal variants within the significant genes. Therefore,  
282 we annotated all exonic variants from genome-wide significant genes using wANNOVAR<sup>48-50</sup>, which  
283 collates functional predictions from popular prediction algorithms like SIFT<sup>51</sup>, PolyPhen2<sup>52</sup>,  
284 MutationTaster<sup>53</sup>, CADD<sup>54</sup>, and FATHMM<sup>55</sup>. We initially looked at the top-ranked genes in the  
285 prioritization approach described above, giving preference to variants that appeared to either be driving  
286 the gene-based association analysis or variants that the five annotation algorithms agreed upon as being  
287 damaging. We further expanded this approach to all significant genes identified in the meta-analyses.

#### 288 *Structural Analysis of Variants*

289 We also performed structural analysis of all coding variants within our top prioritized genes, as well as  
290 all mutations predicted to be deleterious in all genome-wide significant genes. Crystal structures were  
291 obtained from the Protein Data Bank<sup>56</sup>; when crystal structures were not available, homology models  
292 were used for visualization and energy calculations. We used both FoldX RepairPDB and Position Scan<sup>57</sup>  
293 to predict differences in free energy between the wildtype and mutant proteins ( $\Delta\Delta G$ , measured in  
294 kcal/mol). ChimeraX<sup>58</sup> was used to visualize affected proteins. We also incorporated prior information  
295 from publicly available databases (OMIM, Pfam, ClinVar, gnomAD, UniProt, RCSB PDB) and predicted  
296 functional effects (Missense3D<sup>59</sup>).

## 297 **Results**

### 298 *Overview of all Analyses*

299 Across the three (i.e., VT, CMC and ACAT) multiethnic meta-analyses, the three Indo-European meta-  
300 analyses and the three EACC analyses, we identified a total of 129 unique genes that were significantly  
301 associated with the refractive error phenotype (Supplementary Tables 3-5). We found no statistically  
302 significant difference in p-value or the number of unique genome-wide significant genes when adding  
303 the PRS as covariates.

### 304 *Multiethnic Meta-analyses*

305 Forty-three genome-wide significant genes were found using EMMAX-VT (Figure 1A), 11 genome-wide  
306 significant genes using the EMMAX-CMC (Figure 1B), and 28 genome-wide significant genes using ACAT  
307 (Figure 1C).

308 Sixty-eight unique genes were identified across the three tests (Figure 2). Four genes were significant  
309 across all three tests - *GDF15* (19p13.11), *PDCD6IP* (3p22.3), *RRM2* (2p25.1), and *ST6GALNAC5* (1p31.1).  
310 *GDF15* (19p13.11) was one of the top two significant genes in all three approaches (EMMAX-VT P =  
311  $5.12 \times 10^{-9}$ , EMMAX-CMC P =  $1.12 \times 10^{-9}$ , ACAT P =  $1.95 \times 10^{-9}$ ). *GDF15*, *PDCD6IP*, and *RRM2* all replicated in  
312 at least one cohort; *ST6GALNAC5* only appeared in IECC and thus could not be replicated.

313 Overall, using a replication p-value of 0.05, 25 genes were replicated using the EMMAX-VT approach: 11  
314 in the ACAT approach and 4 in the EMMAX-CMC approach. Three genes — *HCAR1*, *CCDC9*, and *NINJ2* —  
315 were replicated in more than one replication cohort, all in the EMMAX-VT approach. *MRPS27* in  
316 EMMAX-VT (REHS and EPIC-Norfolk) and *GDF15* in ACAT (IECC and REHS) had genome-wide significant p-  
317 values in two cohorts. If we use the more stringent replication threshold of  $3.87 \times 10^{-4}$ , then replications  
318 are observed for *GDF15* (VT, CMC, ACAT) and *MRPS27* (VT) with *PDCD6IP* (VT), *NDC80* (VT) and *LOXHD1*  
319 (ACAT) all having replication p-values very close to these thresholds. The list of all genome-wide  
320 significant genes for each test can be found in Supplementary Tables 6-8, while the full results of all p-  
321 values can be found in Supplementary Tables 9-11. Note that beta is provided for the individual CMC  
322 analyses and a direction for the individual VT analyses, as VT does not output a beta.

### 323 *Indo-European Meta-analyses*

324 As it is possible that Eastern Asians differ in genetic risk factor profile from Indo-Europeans, we  
325 performed meta-analyses on the four Indo-European ancestry cohorts. Forty-nine genes were genome-  
326 wide significant in the EMMAX-VT approach (Figure 3A), 13 genes in the EMMAX-CMC approach (Figure  
327 3B), and 29 genes in the ACAT approach (Figure 3C). Four genes overlapped between all three tests —  
328 *GDF15*, *PIK3CA*, *RRM2*, and *ST6GALNAC5* (Figure 4). The signal at *PIK3CA* was unique to the Indo-  
329 European meta-analysis. *GDF15* and *RRM2* were both replicated in one cohort, while *PIK3CA* and  
330 *ST6GALNAC5* only appeared in IECC.

331 Overall, 24 genes were replicated at p=0.05 in EMMAX-VT, 8 genes in ACAT, and 4 genes in EMMAX-  
332 CMC. *NINJ2* in the EMMAX-VT and *STON1* and *SND1* in EMMAX-CMC were replicated in multiple  
333 cohorts. The list of all genome-wide significant genes for each test can be found in Supplementary  
334 Tables 12-14, while the full results of all p-values can be found in Supplementary Tables 15-17.

### 335 *EACC Analysis*

336 We also report the standalone results of EACC analysis. Thirty-one genome-wide significant genes were  
337 found in EACC using EMMAX-VT (Figure 5A), 5 genome-wide significant genes using EMMAX-CMC  
338 (Figure 5B), and 22 genome-wide significant genes using ACAT (Figure 5C). *GSTM5* (1p13.3) and *WEE1*  
339 (11p15.4) overlapped in all three tests (Figure 6). *SERTAD3* (chromosome 19) and *ZNF25* (chromosome  
340 10) were genome-wide significant and only appeared in EACC, i.e., rare variants in these two genes did  
341 not exist in the other cohorts. 51 unique genome-wide significant genes were identified, 39 novel to the  
342 EACC analyses. The list of all genome-wide significant genes for each test can be found in Supplementary  
343 Tables 18-20.

### 344 *Cohort Unique Genes*

345 In addition to the two genes in the EACC EMMAX-VT analysis, there were 6 significantly associated genes  
346 that only had rare variants within a single cohort; no other rare variants existed in the other cohorts for  
347 these genes. *EDN3* and *CHMP1B* in the IECC EMMAX-VT analysis and *PRLH* in the IECC ACAT analysis.  
348 *KLF1* appeared only in the EPIC-Norfolk cohort, in both the EMMAX-VT and EMMAX-CMC analyses. The  
349 list of cohort unique genes appears in Supplementary Table 21.

#### 350 *Independent Replication in UK Biobank*

351 We extracted the variants from the 129 significant unique genes and performed replication analyses in  
352 the UK Biobank. There were 7 genes with a  $P < 0.05$  in EMMAX-CMC and 9 genes with a  $P < 0.05$  in  
353 EMMAX-VT (Supplementary Table 22). *P4HTM*, *CCDC170*, and *CPB1* were found in both analyses. *STON1*  
354 was also replicated in the UK Biobank analyses; this gene had a significant meta-analysis p-value in the  
355 EMMAX-CMC analysis. Interestingly, the p-value in all cohorts was  $< 0.053$ .

#### 356 *Pathway and Expression Analysis on all Significant Genes*

357 We performed IPA pathway analysis on the 129 unique genes. While this did not result in any genome-  
358 wide significant canonical pathways, the upstream regulators analysis identified over 172 associated  
359 transcription factors. The two highest were the cytokine *CSF2*, which is known to regulate neuroglia  
360 after retinal injuries<sup>60</sup>, and the Transcription factor (TF) *MEF2C*, which is known to be expressed in the  
361 retina and controls photoreceptor gene expression<sup>61</sup> (Supplementary Table 23). The fourth ranked p-  
362 value was the Raf kinases, which are known to be involved in retinal development<sup>62</sup> and cell survival<sup>63</sup>;  
363 the fifth ranked p-value was *TBX5*, which is expressed in the retina and involved in eye  
364 morphogenesis<sup>64,65</sup>. Causal network analysis identified 288 associated pathways (Supplementary Table  
365 24), including the *TRPC5* pathway, which regulates axonal outgrowth in developing ganglion cells<sup>66</sup>.

366 The top overall associated physiological system functions were organ morphology, organismal  
367 development and embryonic development, while the top molecular/cellular functions were cell cycle  
368 and cellular assembly/organization. Cancer and organismal injuries/abnormalities were the top overall  
369 associated phenotypes (Supplementary Table 25). Six genes were associated with ophthalmic  
370 phenotypes: *CHST6*, *GCNT2*, *P4HTM*, *USH2A*, *GRHL2*, and *MAPT*.

371 FUMA analysis found that the top enriched tissues were heart, brain, muscle, and adipose tissue  
372 (Supplementary Figure 1A). The top functional categories were cytoskeleton organization, cell cycle  
373 processes, mitotic nuclear division, and organelle organization (Supplementary Figure 1B).

#### 374 *Biological Plausibility and Prioritization of Genes*

375 Of the 129 genome-wide significant genes from the six meta-analyses, 27.9% (36/129) have a known  
376 expression in human ocular tissue. 51.2% (66/129) of these genes showed evidence for a human ocular  
377 phenotype.

378 Seven genes had a biological plausibility score higher than 3 — *PER3* (internally replicated, expressed in  
379 ocular tissue and associated ocular phenotype, i.e., score of 5) and *PDCD6IP*, *MAPT*, *CHST6*, *GRHL2*,  
380 *USH2A*, and *P4HTM* (all with a score of 4). An additional 11 genes had a score of 3 — *GDF15*, *RRM2*,  
381 *HSPH1*, *TPR*, *KRT81*, *SPHK1*, *GSTM5*, *THSD7A*, *WEE1*, and *BUB1B* (Figure 7). Detailed background for the  
382 prioritization of the genes can be found in Supplementary Tables 26A-F. Table 1 provides the p-values  
383 and effect sizes (when available) for each gene. Supplementary Table 27 provides the average SER for  
384 minor allele carriers versus non-carriers for each variant in these prioritized genes; please note that this

385 table uses the single variant results which is restricted to MAC  $\geq 3$ ; some variants with MAC  $< 3$  were  
386 used in the gene-based tests but will not be present in Supplementary Table 27. P-values and betas for  
387 each of the individual rare variants are also provided. In general, *PDCD6IP*, *MAPT*, and *USH2A* variants  
388 had the most negative average SER for carriers of the given rare variant (cases in the table), although  
389 genes *GRL2*, *CHST6*, *PDCD6IP*, and *USH2A* all had variants with high positive SER for rare variant carriers  
390 as well. Betas tended to conform with difference between rare variant carrier SER and SER in  
391 noncarriers (controls in the table), with many of the top variants having large betas. Perhaps the most  
392 interesting fact with respect to the betas is that most of the single variant betas tended to be positive  
393 and led to increased myopization (negative SER). However, there were still negative betas for some  
394 variants with more hyperopic mean SERs in carriers versus non-carriers, particularly in the IECC and the  
395 genes *PDCD6IP* and *USH2A* across cohorts.

396 The highest overall biological plausibility score belonged to the circadian rhythm gene *PER3* (1p36). It  
397 was genome-wide significant in both the all cohorts ACAT and Indo-European only meta-analyses ( $P =$   
398  $1.08 \times 10^{-6}$  and  $1.15 \times 10^{-6}$ , respectively); it was genome-wide significant in REHS and replicated in IECC.  
399 CMC betas were 0.1666, 0.1574, -0.1976, -0.1102, -0.518 for IECC, EACC, BDES, EPIC-Norfolk, and REHS  
400 respectively; none of the CMC p-values were significant, however (Supplementary Table 28). Circadian  
401 rhythm genes have been shown to be associated with refractive error<sup>22</sup> and *PER3* is located near the site  
402 of a known myopia locus (MYP14) at which the causal gene has not been identified<sup>67-69</sup>. *PER3* was  
403 expressed in ON and OFF bipolar cells. Defects in this gene are associated with familial advanced sleep  
404 phase syndrome (OMIM 616882) and may contribute to other circadian phenotypes by altering the  
405 sensitivity to light<sup>70</sup>. In defocus experiments in chicks using -15D lenses, *PER3* expression decreased by -  
406 1.26-fold in the retina<sup>71</sup>. Further chick defocusing experiments, showed that *PER3* expression in the  
407 retina varies under altered visual conditions<sup>72</sup>. Recently published data from the Raine Study suggest  
408 that falling asleep later was associated with a higher risk of myopia progression<sup>73</sup>.

409 Five genes had a score just below *PER3*, including the apoptosis gene *PDCD6IP* (3p22.3). This gene was  
410 found to be genome-wide significant in all-cohorts meta-analyses using all three tests ( $P = 1.07 \times 10^{-7}$ ,  
411  $1.45 \times 10^{-7}$ , and  $4.88 \times 10^{-6}$ , respectively). Further *PDCD6IP* had a P of  $< 0.006$  in both the EACC and IECC  
412 cohorts and did not appear in the other cohorts. Both betas in the CMC test were negative and with a  
413 large effect size for IECC (beta = -2.5) (Supplementary Table 28). Most rare variants in this gene in the  
414 EACC and IECC samples result in mean SER's in carriers that were smaller (more negative) than in non-  
415 carriers, which meant that the CMC test would be powerful to detect this association (Supplementary  
416 Table 27). It is particularly interesting because *PDCD6IP* has two low single variant p-values in both IECC  
417 and EACC (0.00556 and 0.00548, respectively) and there are no rare variants in this gene in any of the  
418 other cohorts. *PDCD6IP* is expressed in ganglion cells of peripheral retina and plays a role in  
419 programmed cell death in uveal melanoma<sup>74</sup> and may play a role in cornea lymphangiogenesis and  
420 vascular responses.<sup>75</sup>

421 *MAPT* (17q21.32) encodes tau proteins responsible for stabilizing microtubules; it was found to be  
422 genome-wide significant in the all cohorts EMMAX-VT analysis ( $P = 8.57 \times 10^{-7}$ ). It was genome-wide  
423 significant in REHS and replicated in EPIC-Norfolk. Betas from the CMC test were -0.4342, 0.3137, -  
424 0.4965, -0.171, and -0.8015 for IECC, EACC, BDES, EPIC-Norfolk, and REHS respectively (Supplementary  
425 Table 28). Again, none of the CMC test p-values were significant. Abnormal *MAPT* was present in  
426 human glaucoma patients with uncontrolled intraocular pressure<sup>76</sup> Cowan et al. showed that *MAPT* was  
427 expressed in several cell types in both the peripheral and foveal human retina: horizontal cells, rod

428 bipolar cells, ON and OFF bipolar cells GLY and GABA amacrine cells and ganglion cells<sup>42</sup>. A knock-out  
429 mouse model showed decreased total retina thickness.

430 *CHST6* (16q23.1) was genome-wide significant in both the all cohorts and Indo-European only EMMAX-  
431 VT meta-analyses ( $P = 8.99 \times 10^{-7}$  and  $2.42 \times 10^{-7}$ , respectively). The gene was genome-wide significant in  
432 IECC and replicated in BDES; it was also nearly replicated in EPIC-Norfolk. Though the CMC p-values  
433 were not significant, the beta for BDES was particularly large (0.95) (Supplementary Table 28). *CHST6*  
434 plays a role in maintaining corneal transparency. Mutations in this gene may result in macular corneal  
435 dystrophy (OMIM 217800), which is characterized by bilateral, progressive corneal opacification and a  
436 reduction of corneal sensitivity.<sup>77</sup> The mouse phenotype of a knock-out model corresponded to that of  
437 human, i.e. abnormal cornea morphology and decreased corneal (stroma) thickness. Since our reference  
438 expression database did not contain any corneal tissue, we couldn't score this category.

439  
440 The transcription factor *GRHL2* (8q22.3) was genome-wide significant in the all cohorts EMMAX-VT  
441 meta-analysis ( $P = 1.42 \times 10^{-6}$ ). It was genome-wide significant in REHS and replicated in IECC. Though  
442 the p-values for EMMAX-CMC were not significant, REHS had a large beta value of 0.87 (Supplementary  
443 Table 28). Mutations in *GRHL2* may lead to posterior polymorphous corneal dystrophy<sup>78</sup> (OMIM  
444 618031), characterized by a variable phenotype ranging from an irregular posterior corneal surface with  
445 occasional opacities, corneal edema, reduced visual acuity, secondary glaucoma, and corectopia.

446 The transmembrane prolyl hydroxylase *P4HTM* (3p21.31) was only genome-wide significant in EACC  
447 using EMMAX-VT ( $P = 1.00 \times 10^{-7}$ ). However, this gene was replicated independently in the UKBB  
448 analysis. Betas for the non-significant EMMAX-CMC test were -0.1769, -2.025, 0.6106, -0.1632, -0.1177  
449 for IECC, EACC, BDES, EPIC-Norfolk, and REHS respectively (Supplementary Table 28). *P4HTM* has been  
450 shown to be expressed in different ocular cells (including horizontal cells and bipolar cells). It is  
451 associated with HIDEA, a severe autosomal recessive disorder that is characterized by multiple  
452 symptoms, including eye abnormalities<sup>79</sup> (OMIM 618493) and knock-out mice models have shown  
453 abnormal eye morphology<sup>80</sup>.

454 The membrane gene *USH2A* (1q41) was genome-wide significant in the EACC ACAT analysis ( $P = 7.55 \times$   
455  $10^{-9}$ ). The EMMAX-CMC tests were not significant which is reflected in the betas which were all quite  
456 small except for 0.82 in the BDES sample (Supplementary Table 28). This reflects the wide variation in  
457 effect on SER exhibited by different rare variants in this gene, with some individual variants leading to  
458 much more myopic mean SER's in carriers compared to non-carriers while other rare variants led to  
459 more hyperopic mean SERs in carriers compared to non-carriers. (Supplementary Table 27). *USH2A* is  
460 well known to cause both Usher syndrome, which includes retinitis pigmentosa (RP) and mild to  
461 moderate hearing loss, as well as RP without hearing loss<sup>81</sup>. It is known to be expressed in the retina<sup>82</sup>  
462 and has been recently shown to be associated with high myopia<sup>83</sup>

#### 463 *Pathway and Expression Analysis on Top Prioritized Genes*

464 We ran the IPA and FUMA analyses on the seven top prioritized genes. IPA did not identify any canonical  
465 pathways as significant; the only pathway shared across the genes was the 14-3-3-mediated signaling  
466 pathway (*MAPT* and *PDCD6IP*). The 14-3-3 proteins are a diverse group of signaling proteins.

467 Upstream regulator analysis found several transcription regulators of at least two genes include *NKX2-1*  
468 (*GRHL2* and *MAPT*), *PSEN1* (*MAPT* and *PER3*), and *SIRT1* (*MAPT* and *PDCD6IP*) (Supplementary Table 29).  
469 In the causal network analysis, the master regulator with the highest p-value covering multiple genes

470 was the cytokine macrophage migration inhibitory factor (*MIF*) (Supplementary Table 29), which  
471 covered five genes. Interestingly, *MIF* is an essential factor in the development of zebrafish eyes<sup>84</sup> and  
472 has been found to be a potential regulator of diabetic retinopathy<sup>85</sup>. *MIF* inhibitors may also be  
473 protective to photoreceptors<sup>86</sup>. The top functional analysis for disease result was hereditary eye disease  
474 (Supplementary Table 31). FUMA showed the top tissue expression occurred in the small intestinal  
475 terminal ileum, skeletal muscle, and the brain cortex; the latter being probably the best proxy for eye  
476 tissue (Supplementary Figure 2A). A heat map of the expression of the seven genes across all GTEx  
477 tissues is given in Supplementary Figure 2B).

478

#### 479 *Potential Causal Variants in the Prioritized Genes*

480 We used annotation from wANNOVAR to identify potential causal variants within the top genes  
481 identified by the prioritization method (Table 2). For the two prioritized genes that were significant in  
482 the ACAT analyses, we were able to look at single variant p-values in addition to annotation to  
483 determine potential causal variants. There were three good candidate variants in *PDCD6IP*, which was  
484 genome-wide significant in IECC and replicated in EACC. rs199990824 (3:3879764) appeared in the  
485 EACC only, was predicted to be damaging by SIFT and MutationTaster, and had a CADD score of 26. The  
486 minor allele of rs199990824 appeared in 37 carriers (all heterozygotes) with an average SER of -2.04 D  
487 (SD = 3.29) compared to the non-carrier average of -0.44 D (SD = 2.27) and the overall cohort average of  
488 -0.45 D (SD=2.28); the single variant P was 0.000183. In the IECC, the best potential causal variant was  
489 rs62620697 (3: 33905532), which was predicted damaging by MutationTaster, had a CADD score of 23.8,  
490 and had a low single variant p-value of 0.002632. Carriers (N=9) of rs62620697 had an average SER of  
491 -2.17D (SD = 6.87) compared to that of non-carriers with an average SER of 0.20 (SD = 2.27).  
492 rs145293758 also had a low p-value (0.000311) but was not predicted damaging.

493 Potential candidate variants were also identified in *PER3*, which was genome-wide significant in REHS  
494 and replicated in IECC. The REHS signal was primarily driven by two variants - rs147327372 and  
495 rs144178755, which had single variant p-values of  $1.72 \times 10^{-8}$  and 0.004953, respectively. However,  
496 neither variant was predicted to be damaging by the prediction algorithms nor appeared in the other  
497 European cohorts and were not significant individually, although rs147327372 did have a p-value of  
498 0.046 in EPIC-Norfolk in the single variant tests.

499 The signals in the other four genes, identified primarily by the two burden-style tests, were driven by a  
500 cumulative effect of several variants. In this case, we relied primarily on annotation and reported  
501 variants that were generally agreed upon by multiple prediction programs. Five good candidate variants  
502 were located in *MAPT*: rs139796158 (17:44055786) , rs76375268 (17:44060807), rs63750072  
503 (17:44060859), rs143956882 (17:44067341) and rs63750191 (17:44101481). All these variants were  
504 nonsynonymous variants and predicted damaging by three of the four databases (except for  
505 rs76375268, which was predicted damaging by two). rs139796158, rs143956882, and rs63750191 all  
506 had CADD scores > 26. In *CHST6*, the best candidate variant was the missense variant rs140699573  
507 (16:75512734). It was predicted damaging by SIFT, PolyPhen2, MutationTaster, and FATHMM and has a  
508 CADD score of 27.4. In *GRHL2*, the best candidate variant was rs142411476 (8:102570910). It was  
509 predicted damaging by two databases and had a CADD score of 22. In *P4HTM*, two variants of interest  
510 were identified: rs140290144 (3:49002551) and rs144279528 (3:49043292). These variants were  
511 predicted damaging by MutationTaster and had CADD scores of 22.1 and 27.3, respectively. Finally, in

512 *USH2A*, three variants (rs554957414 (1:216138793), rs148135241 (1:216373416), and rs201527662  
513 (1:216419934) were all predicted damaging by the five prediction algorithms and had CADD scores  
514 above 22.

#### 515 *Structural Analysis of Prioritized Candidate Proteins*

516 In addition to the annotation, we also performed protein structural modeling of all coding variants  
517 within the prioritized genes (98 variants across 6 genes/proteins) and calculated free energy difference  
518 ( $\Delta\Delta G$ ) between wildtype and mutant proteins (Supplementary Table 32); positive  $\Delta\Delta G$  indicates a shift  
519 from a more stable to a less stable isoform. More detailed information on the structural analysis can be  
520 found in the Supplemental Methods.

521 In *PDCD6IP*, both rs145293758 (3:33905587) and rs200697599 (3: 33840234) were predicted to be  
522 highly destabilizing to protein structure (Supplementary Figure 3A). The variant rs145293758 leads to  
523 replacement of a proline (Pro737) for an asparagine near phosphorylation sites in the protein's self-  
524 associating domain, which could disrupt phosphorylation. rs200697599 (Ile5) and rs199990824 (Asp376;  
525 3:33879764) result in changes to the protein's BRO1 domain, which is involved in endosomal targeting.  
526 The isoleucine to serine mutation at rs200697599 could introduce a phosphorylation site at the N-  
527 terminus while the asparagine to aspartic acid mutation at rs199990824 could disrupt hydrogen bonds.  
528 Recall that both rs145293758 and rs199990824 were identified as potential causal variants for refractive  
529 error in IECC and EACC, respectively, based on their annotation, and single variant p-values  
530 (Supplementary Table 27).

531 For *PER3*, several variants may affect structure, including rs140974114, which results a serine (Ser751)  
532 to aspartic acid substitution at the protein's nuclear localization signal and could disrupt hydrogen bonds  
533 and rs200140283, which results in an alanine (Ala681) to glycine substitution in the CSNK1E binding  
534 domain. Further potential disruptions occur at rs139315125 (His416), which takes place in the nuclear  
535 export signal 3 and rs77418803 (Ser919), which occurs near the nuclear export signal 2. The model is  
536 provided in Supplementary Figure 3B).

537 Of the variants in *MAPT*, two were predicted to be destabilizing (rs76375268 at Gly213 and rs63750191  
538 at Gln741) (Supplementary Figure 3C). Further, rs73314997 (Ser318) and rs143956882 (Ser427) are  
539 located near known pathogenic mutations for frontotemporal dementia and Pick disease of the brain,  
540 respectively.

541 Three variants on the luminal domain of *CHST6* were found to have a mild effect on protein stability.  
542 Two of these variants (rs201349198 at Ala326 and rs140699573 at Gln331) are positioned near variants  
543 known to cause macular corneal dystrophy (MCD) near the C-terminus. This suggests the C-terminus is  
544 sensitive to mutations enabling interference with keratan sulfation, which could cause a loss of function  
545 that can lead to a milder disease phenotype such as refractive error. The model can be found in  
546 Supplementary Figure 4A.

547 In *GRHL2*, variants were only predicted to have a mild effect on protein structure and were not located  
548 near known pathogenic variants (Supplementary Figure 4B).

549 For *P4HTM*, rs140290144 is predicted to be moderately destabilizing (Supplementary Figure 4C). It  
550 substitutes a valine for a buried isoleucine (Ile227) between two calcium binding sites; potential  
551 disruption of these calcium binding sites can result in loss of function. Similarly, rs144279528 occurs in  
552 the Fe-dependent 2-OG dioxygenase domain close to an iron binding residue. Substitution of asparagine

553 from the wildtype aspartic acid (Asp386) could have an impact on iron binding by introducing a  
554 glycosylation (due to location on protein surface) or disruption of hydrogen bonding.

555 Of particular interest in the protein modeling was that of usherin (*USH2A*), the known retinitis  
556 pigmentosa gene. Five variants were predicted to be highly destabilizing, particularly rs554957414 with  
557 a  $\Delta\Delta G$  value of 99.19 kcal/mol). Three of these variants, including rs554957414 (Pro2329), result in the  
558 loss of proline and the loss of that ring structure could cause an increase in conformational flexibility and  
559 account for such high destabilization predictions (Supplementary Figure 5). Further, a mutation at  
560 rs201527662 (Cys934) results in the replacement of cysteine with tryptophan and will disrupt a disulfide  
561 bond between two cysteines.

562 We also compared the  $\Delta\Delta G$  of these five candidate variants with the  $\Delta\Delta G$  of all *USH2A* ClinVar ( $n = 63$ )  
563 and gnomAD ( $n = 1870$ ) variants using the Wilcoxon rank sum test. A significant difference between the  
564 ClinVar variants and gnomAD variants was found ( $P = 0.0008$ ) and the  $\Delta\Delta G$  values of our candidate  
565 variants was much more similar to the known pathogenic variants than the putatively benign GnomAD  
566 variants (Supplementary Figure 6).

#### 567 *Potential Causal Variants in Other Genome-wide Significant Genes*

568 We also identified variants within the other 122 genome-wide significant genes that had a high potential  
569 to be damaging. This included 25 variants across the five cohorts; the results are found in  
570 Supplementary Table 33. Like our prioritized genes, we also performed protein modeling on these  
571 variants (Supplementary Table 34).

572 Notable findings from the structural analysis include a valine to phenylalanine substitution (Val105) that  
573 would disrupt a helix in ALG3, which has been implicated in congenital disorders of glycosylation that  
574 have ocular phenotypes<sup>87</sup> (Supplementary Figure 7A). We also identified multiple glycine substitutions in  
575 TNFRSF13B in areas associated with heparan sulfate – glycosaminoglycan biosynthesis; heparan sulfate  
576 has been shown to play a role in eye pathologies<sup>88</sup> (Supplementary Figure 7B).

#### 577 **Discussion**

578 In this large scale, gene-based analysis of rare variants in refractive error, 129 associated genes were  
579 identified. Though many of the genes were associated with eye conditions or ocular development, only  
580 ten genes had previously been identified with refractive error or myopia: six with myopia including two  
581 with high myopia — *USH2A* and *GDF15*<sup>83,89</sup> — and ten with refractive error. Pathway analysis revealed  
582 that 59 of these genes were involved in cell cycle, organ morphology, and embryonic development and  
583 21 of these genes had upstream regulators that were directly involved in retinal development or eye  
584 morphogenesis. Given the substantial level of missing heritability still present within the refractive error,  
585 it is likely that at least some of this heritability is explained by rare variants within these genes. The fact  
586 that the significance of these genes and the explained variance of refractive error due to these genes did  
587 not significantly change after inclusion of GRS in the analysis, suggests that these association signals are  
588 independent from the effects of known common refractive error risk variants.

589 This is the first large scale meta-analysis using gene-based tests for rare variants in refractive error,  
590 which was undertaken to identify rare variants that may be partially responsible for missing heritability,  
591 particularly within the CREAM data set<sup>21</sup>. The CREAM data set is well-suited for this type of rare variant  
592 analysis. First, we were able to combine many smaller cohorts into two mega-analyses – IECC ( $N =$

593 11,505) and EACC (N = 4,867). These meta-analyses greatly boosted power to detect variants with a  
594  $MAF \leq 0.01$  and allowed more rare variants to be combined into a single, gene-based marker. In  
595 addition, we had three cohorts > 1000 subjects to observe replication and perform the combined meta-  
596 analyses. Genes identified in this study were done so across a very large pool of subjects, lowering the  
597 potential for type I error.

598 The multiethnic composition of this dataset also allowed for observation both across and within  
599 ethnicities. We have delineated how rare variants in some genes were found only in Indo-Europeans and  
600 others in Eastern Asians, as well as some that cut across the ethnic divide. Thus, we were able to identify  
601 risk genes that might contain rare variants that affect SER within a particular population (such as  
602 *ST6GALNAC5* in IECC), or more universally, like *PDCD6IP*.

603 *PER3*, *PDCD6IP*, *MAPT*, *CHST6*, *P4HTM*, *USH2A*, and *GRHL2* are good candidate genes, all known to be  
604 associated with ocular abnormalities. *PER3* is a circadian rhythm gene; circadian rhythm is associated  
605 with refractive error<sup>22</sup>. *PDCD6IP* and *MAPT* are both expressed in the retina while *CHST6*, and *GRHL2* are  
606 both involved in corneal dystrophy<sup>78,90</sup>. *P4HTM* affects eye morphology in mice knockouts<sup>84</sup>; it is also  
607 notable for being replicated in the UKBB analysis. *USH2A* is expressed in the retina and is a known RP  
608 gene<sup>81,82</sup>.

609 Five of these prioritized genes were found to be regulated by the cytokine *MIF*, which has been shown  
610 to regulate zebrafish eye development<sup>84</sup> and have protective effects for photoreceptors<sup>86</sup>. More work on  
611 the *MIF* network with respect to refractive error is needed. We were further able to identify potential  
612 causal variants in these prioritized genes and, using structural analysis, were even able to determine the  
613 effect on protein stability.

614 *STON1*, *C5AR1*, and *WDFY3* were all replicated in UKBB. *C5AR1* is expressed in retinal Müller cells, which  
615 are known to play a role in retinal disease<sup>91</sup>. *STON1* is associated with AMD<sup>92</sup> while *WDFY3* is associated  
616 with inherited retinal dystrophies<sup>93</sup>. Other potential interesting candidates include *GDF15*, which was a  
617 top significant gene across all four meta-analyses, and has been found to be significantly overexpressed  
618 in highly myopic eyes<sup>89</sup> and patients with vitreoretinal disorders<sup>94</sup> and may also be a potential molecular  
619 marker of neurodegeneration in glaucoma<sup>95</sup>, and *MRPS27*. This gene was genome-wide significant in the  
620 meta-analysis and in two individual cohorts, REHS and EPIC-Norfolk. While *MRPS27* is not known to be  
621 associated with eye disease, a common variant in this gene was found to be genome-wide significant in  
622 the GWAS meta-analysis of refractive error conducted by Hysi et al.<sup>22</sup>. Other candidate genes with  
623 known links to eye disease/functions include *HCAR1* with glaucoma<sup>96,97</sup> and *EPB41L2* with a potential  
624 role in phototransduction<sup>98</sup>.

625 One final interesting set of genes was those that were genome-wide significant within a single cohort.  
626 This implies that there may be rare risk variants unique to a certain population that are fixed in other  
627 populations. This includes *ST6GALNAC5*, which was genome-wide significant in IECC in both EMMAX-VT  
628 and ACAT ( $P = 5.84 \times 10^{-7}$ ,  $9.03 \times 10^{-10}$ ). This gene catalyzes the transfer of sialic acid; polysialic acid has  
629 been shown to prevent vascular damage in retina<sup>99</sup> and to stimulate the generation of new rods in the  
630 retinas of developing zebrafish<sup>100</sup>. Other interesting significant genes unique to a single cohort included  
631 *SERTAD3* in EACC, which is overexpressed in retinoblastoma<sup>101</sup> and *KLF1* in EPIC-Norfolk, which may be  
632 expressed in the eye<sup>102</sup>. We also note that gene-based analyses for refractive error had been previously  
633 performed in BDES<sup>103</sup>. Of the five significant genes from that analysis, two were replicated at  $P \leq 0.05$  —

634 *PTCHD2* and *CRISP3*. *PTCHD2* is located near the known myopia locus *MYP14* on 1p36.22<sup>69,104</sup> and *CRISP3*  
635 is expressed in the retina<sup>103,105</sup>.

636 This study used multiple tests (EMMAX-VT, EMMAX-CMC and ACAT) to identify significant genes and  
637 looked at overlap to find more robust signals. By using multiple tests that differ slightly in design, we  
638 were able to cast a wider net in our search. The ACAT test was particularly useful for identifying  
639 potential causal variants within a candidate gene, as it allowed us to observe which variants had  
640 significant single variant p-values. This enabled us to zero in on potential causal variants in genes like  
641 *PDCD6IP* and *PER3*, though we note that highlighting any potential causal variants are speculative at this  
642 point. We also felt it prudent to not give more weight to the result of one test over another and instead  
643 take the largest number of unique, significant genes since this was a discovery study, though we did try  
644 to give more weight to the genes that were identified by all three tests, such as *PDCD6IP*.

645 We note that the three tests did not always agree, though the two burden-style tests agreed more often  
646 than ACAT. This is not surprising given the different nature of the tests. Both EMMAX-VT and EMMAX-  
647 CMC were burden-style tests that create a new, gene-based marker on which the p-value is calculated.  
648 The ACAT test was an aggregation-style test created from single variant p-values that does not create a  
649 new gene-based marker<sup>35</sup>. This is a critical distinction; it means that the markers analyzed in the burden-  
650 style tests and the ACAT tests are different. The ACAT analyses may have been slightly underpowered  
651 with respect to the burden-style tests, as we used a minimum allele count of three in our analyses. For  
652 EMMAX-VT and EMMAX-CMC this was calculated across all variants within a gene and for ACAT at each  
653 individual variant, which resulted in certain variants being removed from the ACAT analysis that were  
654 present in the burden style analyses. Therefore, genes present in all three analyses indicate a more  
655 robust association with refractive error.

656 Since this is an exome microarray study, there were still large portions of the genome that would not  
657 have been covered in this work. Thus, there are almost certainly additional rare risk variants for  
658 refractive error in these cohorts that were not genotyped in this study. The goal of this discovery study  
659 was to provide an initial starting point for further analysis; we plan whole genome sequencing on high-  
660 risk individuals identified by this study. These non-genotyped variants could explain why we did not see  
661 replication with previous refractive error GWAS findings<sup>21,22</sup>. Some of the genes identified in the  
662 common variant GWAS may have included rare risk variants that were specific to a particular population  
663 that was not used in this study.

664 Another challenge is that due to the gene-based nature of this work, it is critical to remember that the  
665 gene-based markers across the cohorts are often made up of different variants. This means that the  
666 gene-based marker for gene A in IECC might be made up of three variants, and in REHS might be made  
667 up of seven variants, two of which are shared across the two cohorts. This means that it was possible  
668 that some cohorts may have had association tests that were less significant because of inclusion of non-  
669 significant rare variants that did not appear in other cohorts.

670 We also note that this was an exploratory analysis to determine candidate genes, and one of our goals  
671 was to cast a wide net to capture potential candidates. Therefore, we chose a more liberal replication  
672 significance threshold, which may allow for potential type I errors but would also ensure that a good  
673 candidate gene would not be missed or because functional rare variants did not appear in that cohort.

674 We also note that while we did utilize eye expression data in this study, we were limited to expression  
675 from retinal tissue only. We are actively seeking expression data from additional eye tissue, particularly  
676 corneal and scleral tissue, to further prioritize these genes.

677 This work identified 129 genome-wide significant genes for refractive error using the gene-based rare  
678 variant approach. Most of these genes are novel for association with refractive error but many have  
679 associations with other ocular abnormalities. This is the largest gene-based study of rare variants  
680 performed on refractive error. The fact that we found over 100 significant genes shows that rare  
681 variants ( $MAF \leq 0.01$ ) do account for some of the missing refractive error heritability not identified in  
682 the common variant GWAS. We were able to prioritize seven of these genes as our best candidate genes  
683 for causality based on biological function – *PDCD6IP*, *MAPT*, *CHST6*, *GRHL2*, *USH2A*, *P4HTM*, and *PER3* –  
684 as well as *GDF15* and *MRPS27* based on the strength of association. Validation studies, including  
685 replication within additional cohorts, are planned to identify the best candidates for functional studies  
686 to unravel the pathophysiology of refractive error and myopia. We also plan further analysis with the  
687 conversion of our quantitative refractive error phenotype to binary phenotypes to test for association  
688 with myopia, hyperopia, and astigmatism.

## 689 **Acknowledgments**

690 The authors gratefully acknowledge Sana Wajid of the Bioinformatics Core of the University of  
691 Pennsylvania for her quality control work on these data. This work was funded in part by the Intramural  
692 Research Program of the National Human Genome Research Institute, National Institutes of Health. The  
693 acknowledgments for each individual study cohort are given alphabetically by study below. APK is  
694 supported by a UKRI Future Leaders Fellowship. Molecular graphics and analyses were performed with  
695 UCSF ChimeraX, developed by the Resource for Biocomputing, Visualization, and Informatics at the  
696 University of California, San Francisco, with support from National Institutes of Health R01-GM129325  
697 and the Office of Cyber Infrastructure and Computational Biology, National Institute of Allergy and  
698 Infectious Diseases

699 *AREDS*: AREDS was supported by the National Eye Institute (grants R01EY16482, R21EY015145, and  
700 P30EY11373) and by Research to Prevent Blindness and the Ohio Lions Eye Research Foundation.  
701 AREDS was also supported by contracts from National Eye Institute/National Institutes of Health,  
702 Bethesda, MD, with additional support from Bausch & Lomb Inc, Rochester, NY. The genotyping costs  
703 were supported by the National Eye Institute (R01EY020483 to D.S.) and some of the analyses were  
704 supported by the Intramural Research Program of the National Human Genome Research Institute,  
705 National Institutes of Health, USA. AREDS acknowledges Frederick Ferris, National Eye Institute,  
706 National Institutes of Health, Bethesda, MD; and the Center for Inherited Disease Research, Baltimore,  
707 MD where SNP genotyping was carried out. The investigators gratefully acknowledge the advice and  
708 guidance of Hemin Chin of the National Eye Institute.

709 *BDES*: BDES was supported by the National Eye Institute of the National Institutes of Health under award  
710 numbers EY06594 (R. Klein and B. E. K. Klein), EY10605 (B. E. K. Klein) and R01EY021531 (A.P.K and P.D.)  
711 and some of the analyses were supported by the Intramural Research Program of the National Human  
712 Genome Research Institute, National Institutes of Health, USA.

714 *Croatia-Korcula*: The Croatia-Korcula study was funded by the Medical Research Council (UK) "QTL in  
715 health and disease" programme core grants, currently MC\_UU\_00007/10, as well as grants from the

716 Republic of Croatia Ministry of Science, Education and Sports (108-1080315-0302; 216-1080315-0302)  
717 and the Croatian Science Foundation (8875). The study acknowledge Dr. Biljana Andrijević Derk,  
718 Valentina Lacmanović Lončar, Krešimir Mandić, Antonija Mandić, Ivan Škegro, Jasna Pavičić Astaloš,  
719 Ivana Merc, Miljenka Martinović, Petra Kralj, Tamara Knežević and Katja Barać-Juretić as well as the  
720 recruitment team from the Croatian Centre for Global Health, University of Split and the Institute of  
721 Anthropological Research in Zagreb for the ophthalmological data collection; the Wellcome Trust Clinical  
722 facility (Edinburgh, United Kingdom) for Exome array genotyping.

723  
724 *EGCUT*: EGCUT was supported by the European Union H2020 grant 692145, Est.RC grant IUT20-60 and  
725 the European Regional Development Fund, in the frame of Centre of Excellence in Genomics and  
726 Estonian Research Infrastructure's Roadmap and the University of Tartu (SP1GVARENG). This research  
727 was supported by NIH grant 5R01 DK07 57 87 -13, under subward-agreement GENFDOOO1B52751; the  
728 European Union through Horizon 2020 research and innovation programme under grant 633589 and the  
729 European Regional Development Fund (Project No. 2014-2020.4.01.16-0125). This research was also  
730 supported by the European Union through the European Regional Development Fund (Project No. 2014-  
731 2020.4.01.16-0125) and the Estonian Research Council grant PUT (PRG687) European Union H2020  
732 grant 654248 (Corbel). EGCUT acknowledges the High Performance Computing Center of the University  
733 of Tartu.

734 *EPIC-Norfolk*: The EPIC-Norfolk study (DOI 10.22025/2019.10.105.00004) has received funding from the  
735 Medical Research Council (MR/N003284/1 and MC-UU\_12015/1) and Cancer Research UK  
736 (C864/A14136). The genetics work in the EPIC-Norfolk study was funded by the Medical Research  
737 Council (MC\_PC\_13048). We are grateful to all the participants who have been part of the project and to  
738 the many members of the study teams at the University of Cambridge who have enabled this research.

739 *FITSA*: FITSA was supported by ENGAGE (FP7-HEALTH-F4-2007, 201413);  
740 European Union through the GENOMEUTWIN project (QLG2-CT-2002-01254); the Academy of  
741 Finland Center of Excellence in Complex Disease Genetics (213506, 129680); the Academy of Finland  
742 Ageing Programme; and the Finnish Ministry of Culture and Education and University of Jyväskylä. FITSA  
743 acknowledges the contributions of Emmi Tikkanen, Samuli Ripatti, Markku Kauppinen, Taina Rantanen  
744 and Jaakko Kaprio.

745 *Ogliastra*: The Ogliastra Study gratefully acknowledges the population of Ogliastra, Sardinia, Italy. The  
746 Ogliastra study was funded by a grant from the Italian Ministry of Education, University and Research  
747 (MIUR) n°: 5571/DSPAR/2002.

748  
749 *RSI, ERF*: The Rotterdam Study and ERF were supported by European Research Council (ERC) under the  
750 European Union's Horizon 2020 research and innovation programme (grant 648268), Netherlands  
751 Organisation for Scientific Research (NWO, grant 91815655 to CCWK and NWO Veni 91617076 to VJMV),  
752 Ammodo Award (to CCWK), Erasmus Medical Center and Erasmus University, Rotterdam, The  
753 Netherlands; Netherlands Organization for Health Research and Development (ZonMw); the Research  
754 Institute for Diseases in the Elderly; the Ministry of Education, Culture and Science; the Ministry for  
755 Health, Welfare and Sports; the European Commission (DG XII); the Municipality of Rotterdam; the  
756 Netherlands Genomics Initiative/NWO; Center for Medical Systems Biology of NGI; Jacoba Breen Fonds,  
757 Topcon Europe; Ada Hooghart, Corina Brussee, Riet Bernaerts-Biskop, Amal Hamimida, Patricia van  
758 Hilten, Pascal Arp, Jeanette Vergeer, Sander Bervoets. The generation and management of the Illumina

759 exome chip v1.0 array data for the Rotterdam Study (RS-I) was executed by the Human Genotyping  
760 Facility of the Genetic Laboratory of the Department of Internal Medicine, Erasmus MC, Rotterdam, The  
761 Netherlands. The Exome chip array data set was funded by the Genetic Laboratory of the Department of  
762 Internal Medicine, Erasmus MC, from the Netherlands Genomics Initiative (NGI)/Netherlands  
763 Organisation for Scientific Research (NWO)-sponsored Netherlands Consortium for Healthy Aging  
764 (NCHA; project nr. 050-060-810); the Netherlands Organization for Scientific Research (NWO; project  
765 number 184021007) and by the Rainbow Project (RP10; Netherlands Exome Chip Project) of the  
766 Biobanking and Biomolecular Research Infrastructure Netherlands (BBMRI-NL; [www.bbmri.nl](http://www.bbmri.nl)). We  
767 thank Ms. Mila Jhamai, Ms. Sarah Higgins, and Mr. Marijn Verkerk for their help in creating the exome  
768 chip database. The authors are grateful to the study participants, the staff from the Rotterdam Study  
769 and the participating general practitioners and pharmacists.

770

771 *REHS*: The core management of the Raine Study is funded by the University of Western Australia,  
772 Australia; the Telethon Institute for Child Health Research, Australia; Raine Medical Research  
773 Foundation, Australia; Women's and Infant's Research Foundation, Australia; Curtin University,  
774 Australia; Murdoch University, Australia; Edith Cowan University, Australia; and the University of Notre  
775 Dame, Australia. The Generation-2 20-year follow-up of the Raine Study was funded by the National  
776 Health and Medical Research Council (NHMRC), Australia: project grant no.: 1 021 105. The Generation-  
777 2 28-year follow-up of the Raine Study was funded by the NHMRC, Australia: project grants 1 121 979  
778 and 1 126 494

779 *SCES, SiMES, SINDI*: The Singapore studies (SCES, SiMES, SINDI) were supported by the National Medical  
780 Research Council, Singapore (NMRC 0796/2003, NMRC 1176/2008, STaR/0003/2008; CG/SERI/2010),  
781 Biomedical Research Council, Singapore (06/1/21/19/466, 09/1/35/19/616 and 08/1/35/19/550). The  
782 Singapore Tissue Network and the Genome Institute of Singapore, Agency for Science, Technology and  
783 Research, Singapore provided services.

784 *TwinsUK*: TwinsUK received funding from the Wellcome Trust; the European Union MyEuropa Marie  
785 Curie Research Training Network; Guide Dogs for the Blind Association; the European 18 Community's  
786 FP7 (HEALTHF22008201865GEFOS); ENGAGE (HEALTHF42007201413); the FP-5 GenomEUtwin Project  
787 (QLG2CT200201254); US National Institutes of Health/National Eye Institute (1RO1EY018246); NIH  
788 Center for Inherited Disease Research; the National Institute for Health Research comprehensive  
789 Biomedical Research Centre award to Guy's and St. Thomas' National Health Service Foundation Trust  
790 partnering with King's College London. P.G.H. is the recipient of a Fight for Sight ECI award. We  
791 acknowledge the contribution of Drs Toby Andrew, Margarida Lopes, Samantha Fahy and Diana  
792 Kozareva.

### 793 **Data Availability**

794 The data that support the findings of this study are not publicly available due to information that could  
795 compromise research participant privacy and/or consent. European Union data privacy rulings currently  
796 forbid sharing of genomic data outside the EU and several of the participating studies have additional  
797 restrictions to protect the privacy of the study participants. Deidentified data were used here under data  
798 use agreements with each participating study. Data may be available by request from the individual  
799 participating studies if all regulatory conditions are met.

800

### 801 **Code Availability**

802 The R scripts used to run the EPACTS software for the association study are available upon request from  
803 the first authors or corresponding author.

#### 1047 **Figure Legends**

1048 **Figure 1: P-values of the multiethnic meta-analysis.** The gene-based p-values of the meta-analysis  
1049 association study combining all five cohorts (N=26,946) using the A) EMMAX-VT test, B) EMMAX-CMC  
1050 test, and C) ACAT. The line represents the genome-wide significant threshold of  $1 \times 10^{-5}$ .

1051 **Figure 2: Overlap between three tests in the multiethnic meta-analysis.** A Venn diagram showing the  
1052 overlap and unique significant genes in the multiethnic meta-analysis using the three different tests:  
1053 EMMAX-VT (green), EMMAX-CMC (red), and ACAT (blue).

1054 **Figure 3: P-values of the Indo-European meta-analysis.** The gene-based p-values of the meta-analysis  
1055 association study (N=22,079) combining the four Indo-European derived cohorts using the A) EMMAX-  
1056 VT test, B) EMMAX-CMC test, and C) ACAT. The line represents the genome-wide significant threshold of  
1057  $1 \times 10^{-5}$ .

1058 **Figure 4: Overlap between three tests in the Indo-European meta-analysis.** A Venn diagram showing  
1059 the overlap and unique significant genes in the Indo-European cohorts meta-analysis using the three  
1060 different tests: EMMAX-VT (green), EMMAX-CMC (red), and ACAT (blue).

1061 **Figure 5: P-values of the analysis using the Eastern Asian EACC only.** The gene-based p-values of the  
1062 EACC association analysis (N=4,867) using the A) EMMAX-VT test, B) EMMAX-CMC test, and C) ACAT.  
1063 The line represents the genome-wide significant threshold of  $1 \times 10^{-5}$ .

1064 **Figure 6: Overlap between three tests in the Eastern Asian EACC analysis.** A Venn diagram showing the  
1065 overlap and unique significant genes in the EACC analysis using the three different tests: EMMAX-VT  
1066 (green), EMMAX-CMC (red), and ACAT (blue).

1067 **Figure 7: Prioritization of top genes from all 129 genome-wide significant genes.** The top genes ranked  
1068 by our prioritization schema. The figure contains the chromosome, basepair position, gene name, as  
1069 well as the meta-analysis p-value and the individual cohort p-values for each gene. It also contains which  
1070 test the given significant meta-analysis p-value refers to, and how many times the gene replicated in our  
1071 internal analyses. Finally, it contains information regarding gene expression, whether the gene has a  
1072 known ocular phenotype in mice or humans, overlap with the GWAS performed by Hysi et al., and the  
1073 final overall prioritization score.

Legend: The summary statistics from our prioritized genes. The p-values for the CMC, VT, and ACAT analyses and betas for the CMC analyses for the meta-analysis and the five individual cohorts. Note that for the CMC meta-analysis, no beta is provided because Fisher's method does not provide an effect size.
