### Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

**Abstract**

Carbon monoxide (CO) is the second most abundant gas-phase molecule after molecular hydrogen ( $H_2$ ) of the Interstellar Medium (ISM). In Molecular Clouds (MCs), an important component of the ISM, it adsorbs at the surface of core grains, usually made of Mg/Fe silicates, and originates Complex Organic Molecules (COMs) through the catalytic power of active sites at the grain surfaces. To understand the atomistic, energetic and spectroscopic details of the CO adsorption on core grains, we resorted to Density Functional Theory based on the hybrid B3LYP-D\* functional inclusive of dispersion contribution. We modeled the complexity of interstellar silicate grains by studying adsorption events on a large set of infinite extended surfaces cut out from the bulk  $Mg_2SiO_4$  forsterite, the Mg end-member of olivines ( $Mg_{2x}Fe_{2-2x}SiO_4$ ), also a very common mineral on Earth crust. Energetic and structural features indicate that CO get exclusively physisorbed, with binding energy values in the 23-68  $\text{kJ mol}^{-1}$  range. Detailed analysis of data revealed that dispersive interactions are relevant together with the important electrostatic contribution due to the quadrupolar nature of the CO molecule. We performed a full thermodynamic treatment of the CO adsorption at the very low temperature typical of the ISM as well as a full spectroscopic characterization of the CO stretching frequency, which we prove to be extremely sensitive to the local nature of the surface-active site of adsorption.

We also performed a detailed kinetic analysis of CO desorption from the surface models at different temperatures characterizing the colder regions of the ISM. Our computed data could be incorporated in the various astrochemical models of interstellar grains developed so far and thus contribute to improve the description of the complex chemical network occurring at their surfaces.

Astrochemistry, Molecular Clouds, dust core grains, forsterite surfaces, CO adsorption, B3LYP-D\*

## 1. Introduction

The observation of the Interstellar Medium (ISM) by means of rotational spectroscopic techniques was performed since the first half of the XX century, and has revealed, according to the Cologne database,<sup>1</sup> the presence of more than 200 molecular species in the Molecular Clouds (MCs).<sup>2,3</sup> These observations suggested the occurrence of different chemical processes with prebiotic implications, which are ultimately connected with the emergence of life on Earth (and maybe on other exogenous planets) since MCs are the cradle where star-forming processes occur. Moreover, the Solar System not only includes the presence of comets, asteroids and Kuiper belt-objects, but also suffers from a dust flux coming from the remote ISM. This dust is continuously falling on Earth with a density of about  $10^{-6} \text{ m}^{-3}$ .<sup>4</sup> Specifically, one hypothesis is that amino acids precursors, or even amino acids themselves, can form in MCs under suitable conditions. As an example, aminoacetonitrile  $\text{H}_2\text{NCH}_2\text{CN}$ , the precursor of glycine, was identified in Sgr B2, a giant MC localized at the center of the Milky Way.<sup>5</sup>

The IR observations of MCs have also suggested the presence of a small fraction of solid, dust-like material whose exact composition is still a current matter of debate.

IR telescope observations support the presence of solid materials in MCs. The  $9.7 \mu\text{m}$  and  $18 \mu\text{m}$  absorption bands are particularly important as they are associated with the Si-O stretching and O-Si-O bending modes, suggesting the presence of silicates, mainly olivines  $\text{Mg}_{2x}\text{Fe}_{2-2x}\text{SiO}_4$ .<sup>6</sup> The broadness of these two features leads to hypothesize that the structure of such grains is dominated by an amorphous phase, although it is also speculated that  $\sim 5\%$  of the grain population is crystalline, and in other environments (*e.g.*, circumstellar and protostellar disks, comets and interplanetary medium) even greater.<sup>7,8</sup> Moreover, crystalline silicates are expected to be larger in size than amorphous ones and could have formed through coagulation of smaller particles.<sup>8</sup> In MCs, these two class of refractory materials are covered in ice mantles which are built up by the freeze-out of gas-phase species, and also by the *in-situ* formation of molecules, on the cold dust grain surfaces. The composition of the ices can be elucidated by their infrared spectroscopic features.<sup>9</sup> In

1  
2  
3 general, H<sub>2</sub>O is the most abundant constituent of the mantles, which is clearly featured by its 3.0  
4  $\mu\text{m}$  and 6.00  $\mu\text{m}$  bands associated with the O-H stretching and H-O-H bending modes. Nonetheless,  
5  
6  
7 mantles also contain other species, and hence that they are also usually referred to as “dirty ices”;  
8  
9  
10 *i.e.*, CO (4.67  $\mu\text{m}$ ), CO<sub>2</sub> (4.27 and 15.2  $\mu\text{m}$ ), CH<sub>3</sub>OH (3.54 and 9.75  $\mu\text{m}$ ), NH<sub>3</sub> (2.97  $\mu\text{m}$ ) CH<sub>4</sub> (7.68  
11  
12  $\mu\text{m}$ ), H<sub>2</sub>CO (5.81  $\mu\text{m}$ ).<sup>10</sup>

13  
14 Since H is the most abundant species in the ISM, the actual composition of a particular ice mantle  
15  
16 depends on the H/H<sub>2</sub> ratio where it is formed. In regions where this ratio is greater than 1, reactive  
17  
18 species such as O, N and C are readily hydrogenated thus forming hydride-rich ices (*i.e.*, H<sub>2</sub>O, NH<sub>3</sub>  
19  
20 and CH<sub>4</sub>). In contrast, if the H/H<sub>2</sub> is significantly less than 1, the reactive species are free to interact  
21  
22 with other species forming molecules such as CO, CO<sub>2</sub> or N<sub>2</sub>. Thus, two qualitatively different types  
23  
24 of ice matter can be produced: with high or with low dipole moment species, usually referred to as  
25  
26 polar or apolar ices, respectively.<sup>11</sup> It is worth mentioning that even in the apolar ices, H<sub>2</sub>O is a  
27  
28 prominent species at least in the very first layers covering the silicate core, which are expected to be  
29  
30 composed by hydrogenated species.<sup>9,12</sup> For these apolar ices, CO is usually the second most  
31  
32 abundant solid phase species,<sup>11</sup> even if it has been reported that around some sources, solid CO  
33  
34 becomes the most abundant species (up to 85% with respect to solid H<sub>2</sub>O).<sup>9</sup> The CO IR features in  
35  
36 ices with high percentages of CO are perturbed by interaction with other apolar species (e.g., CO<sub>2</sub>)  
37  
38 and not by H<sub>2</sub>O thus suggesting the formation of apolar islands within the ice mantle.<sup>9</sup> In our  
39  
40 opinion, such great abundances (with respect to H<sub>2</sub>O) together with the fact that CO is the second  
41  
42 most abundant gas-phase species could justify a theoretical investigation of the interaction between  
43  
44 CO molecules and olivines surfaces.

45  
46  
47 Grain surfaces have also a role of paramount importance in the chemical evolution of space: they  
48  
49  
50 can act as catalysts in the formation of both simple and more evolved molecular species, including  
51  
52 the Complex Organic Molecules (COMs). For example, there is general consensus that H<sub>2</sub>, the most  
53  
54 abundant species in the Universe, can form at these surfaces and not via symmetry-prohibited,  
55  
56 direct gas-phase collision reactions.<sup>13</sup> Formation of COMs, such as carbonyl species, alcohols or  
57  
58  
59  
60

1  
2  
3 even amino acids precursors would occur by involving other simple but reactive molecules such as  
4  
5 carbon monoxide (CO), the second most abundant gas-phase species in the ISM.<sup>2</sup> Hence, a detailed  
6  
7 study of the mechanisms underlying the interaction of (covered) silicate grains and CO may  
8  
9 improve our knowledge about the chemical processes occurring in MCs.  
10

11 Laboratory experiments<sup>14-23</sup> can hardly reproduce the MCs physical features (very low temperatures  
12  
13 and atomic densities), thus Quantum-Mechanical (QM) methods represent a powerful alternative to  
14  
15 simulate chemical processes occurring in MCs. A comprehensive knowledge of olivine surface  
16  
17 energetics and morphology at the atomic level is of extreme importance to understand the true  
18  
19 nature of these processes and, more generally, all processes involving the olivine interface. Several  
20  
21 studies at different computational level have been conducted in order to investigate possible  
22  
23 formation, adsorption and desorption of small organic and inorganic molecules such as ammonia,<sup>24</sup>  
24  
25 glycine,<sup>24</sup> carbon dioxide,<sup>25</sup> hydrogen,<sup>13,26-31</sup> water.<sup>24,25,32-40</sup> Only a few of them have dealt with the  
26  
27 problem of olivine's morphology<sup>41-46</sup> together with a complete QM level of treatment.<sup>13,43-46</sup>  
28  
29 Furthermore, to the best of our knowledge, no theoretical works dealing with the adsorption of CO  
30  
31 on olivine surfaces can be found in the literature.  
32  
33  
34  
35

36 For these reasons, in this work, we have modeled the adsorption of CO on the end-member of  
37  
38 olivine, *i.e.* crystalline forsterite (Mg<sub>2</sub>SiO<sub>4</sub>) surfaces by means of the Density Functional Theory  
39  
40 (DFT), aiming to contribute to the understanding of interstellar gas-grain phenomena by providing a  
41  
42 reliable theoretical background. We assume a crystalline nature of the interstellar grain core, well  
43  
44 aware that the dominant phase is amorphous. Obviously, when compared to the unknown nature of  
45  
46 amorphous silicate grain structure, crystalline models ensure a well-defined structure derived from  
47  
48 the bulk silicate. We hope that this work can be useful to elucidate processes occurring at silicate  
49  
50 surfaces in the very harsh condition characterizing the various regions of the ISM. Important  
51  
52 progress in the modeling of amorphous grains, albeit of very small size, is the work leaded by S.  
53  
54 Bromley.<sup>47</sup>

## 2. Computational Details

We performed all calculations with a developmental version of the periodic computational code CRYSTAL14<sup>48</sup> and we only report the most relevant details leaving the more specific ones in the Supporting Information (SI). We used the hybrid B3LYP Hamiltonian,<sup>49-51</sup> already shown to provide accurate results for the structural and dynamical properties of olivine end-members.<sup>52-55</sup> To account for dispersion forces, in this work we used the D\* version, which is a modified Grimme's D2 version,<sup>56-58</sup> optimized for the B3LYP functional in molecular crystals by Civalleri et al.<sup>59</sup> CRYSTAL adopts Gaussian based functions and we used the same Gaussian-type basis set applied by Bruno et al.<sup>45</sup> for forsterite bulk and slabs, while CO was dressed by the Alhrichs-TZV polarized basis sets (details in SI).<sup>60</sup>

We adopted default values for the energetic thresholds controlling the accuracy in the evaluation of the Coulomb and exchange integrals. We used an extra-large grid to ensure a satisfactory accuracy in the numerically integrated electron charge density, as previously stated by Bruno et al.<sup>45</sup> and enough  $k$  sampling points to sample the Brillouin zone to ensure a good energy convergence (see SI).

Geometry optimizations of bulk and slabs adducts (forsterite surfaces + CO molecules) were performed following the Broyden-Fletcher-Goldfarb-Shanno (BFGS) algorithm<sup>61-64</sup> and allowing only the atomic positions to relax (cells parameters were kept fixed to bulk values reported by Bruno).<sup>45</sup> Symmetry was enforced during the bulk optimization only.

To assess the relative stability of the seven surface models, the surface energies  $E_S$  were computed as

$$E_S = \frac{E_{slab} - 4E_{bulk}}{2A} \quad \text{Eq. 1}$$

where  $E_{slab}$  and  $E_{bulk}$  are the DFT unit cell total energies. For a more detailed discussion on how to compute  $E_S$ , the interested reader can refer to a previous work on surface modelling of bioceramics.<sup>65</sup> The factor 4 accounts for the stoichiometric 4:1 ratio between slab and bulk.

For the optimized adduct structures, we computed the binding energies per adsorbed CO (BE), including dispersion and corrected for the Basis Set Superposition Error (BSSE)<sup>66,67</sup> through the “Counterpoise” method (CP),<sup>68</sup> as detailed in the SI.

On the optimized adduct structures, we restrict the calculation of the harmonic IR spectrum in  $\Gamma$  point<sup>69,70</sup> to the CO molecule considered as a fragment (the surface/CO intermolecular modes are included) by diagonalizing the mass-weighted Hessian matrix.<sup>69</sup> This strategy has been validated by our research group in the past and showed to be satisfactory.<sup>71,72</sup> The IR intensity of each normal mode of vibration was computed using the Berry phase approach.<sup>73</sup>

We scaled all frequencies values by the following scaling factor  $s_{fac}$ , derived by comparing the B3LYP harmonic frequency value for the isolated CO with the experimental one for CO in gas phase:

$$s_{fac} = \frac{\bar{\nu}_{exp} (free\ CO)}{\bar{\nu}_{theo} (free\ CO)} = \frac{2143\text{ cm}^{-1}}{2201\text{ cm}^{-1}} = 0.9736 \quad \text{Eq. 2}$$

This partially recovers the systematic errors associated with B3LYP method and corrects for anharmonicity, improving the comparison with experiment. For each optimized structure  $i$ , we computed the IR spectrum  $S_i(\bar{\nu})$  in the CO stretching region as a linear combination of Gaussian functions  $G(\bar{\nu} - \bar{\nu}_j)$ , each one centered at the  $j$ -th CO B3LYP scaled frequency value  $\bar{\nu}_j$ . We arbitrarily chose a value of  $15\text{ cm}^{-1}$  as Full Width at Half-Maximum (FWHM). Finally, we weighted each band  $j$  by the corresponding IR intensity ( $I_j$ ):

$$S_i(\bar{\nu}) = \sum_j I_j G(\bar{\nu} - \bar{\nu}_j) \quad \text{Eq. 3}$$

The frequencies computed for the CO fragment allowed computing the desorption enthalpies variations at 0 K, through the standard statistical thermodynamics relation:

$$\Delta_{des}H(0) = -\Delta_{ads}H(0) = BE - \Delta ZPE \quad \text{Eq. 4}$$

where  $\Delta ZPE$  is the Zero-Point Energy correction. We neglect the  $PV$  and the thermal factor terms,<sup>13</sup> which, at the typical pressure characterizing MCs, are completely negligible.<sup>74</sup> Therefore, Gibbs free energies coincide with Helmholtz free energies  $\Delta_{ads}A$

$$\Delta_{ads}A(T) = -BE + \Delta ZPE + \Delta E(T) - T\Delta S(T) \quad \text{Eq. 5}$$

We outline that  $\Delta ZPE$ ,  $\Delta E(T)$  and  $\Delta S(T)$  terms are evaluated only for the adsorbed CO molecules (see *Surface free energies and adsorption free energies (Eq. 7 and 8)* section of the SI for a complete justification).

We used the computed binding energies to evaluate desorption times ( $t_{des}$ ) using Eyring equation.

Thus, desorption times resulted as:

$$t_{des} = \frac{1}{k_D} = \frac{h}{k_B T} e^{-\Delta_{ads}A/RT} \quad \text{Eq. 6}$$

To evaluate the stability of the surfaces in presence of adsorbed carbon monoxide, we computed the surface free energies  $G_S$  according to the following expression:

$$G_S(T, P, \sigma) = E_S + \Delta \bar{G}(T, P^\theta, \sigma)_{CO} - \sigma \left[ BE + RT \ln \left( \frac{P}{P^\theta} \right) \right] \quad \text{Eq. 7}$$

which is derived from first principle thermodynamics.<sup>75-85</sup>  $E_S$  is the surface energy computed according to Eq. 1, BE is the dispersion-BSE-corrected binding energy per adsorbed molecule.  $T, P$  and  $P^\theta$  are the absolute temperature, the partial pressure of CO and the standard pressure (= 101 325 Pa).  $\sigma$  is the surface density, *i.e.* the number  $n^\dagger = n/2$  of adsorbed CO molecules per unit cell divided by the unit area  $A$  of the slab ( $n$  total number of adsorbed CO molecules on both ends of the slab model). In  $\Delta \bar{G}(T, P^\theta, \sigma)_{CO} = \Delta G(T, P^\theta, n)_{CO}/2A$ ,  $\Delta G(T, P^\theta, n)_{CO}$  is the Gibbs's free energy correction for gaseous CO computed from statistical thermodynamics relations.

From Eq. 7, Gibbs's free energy of CO adsorption becomes:

$$\Delta_{ads}G(T, P, n) = \Delta G(T, P^\theta, n)_{CO} - n \left[ BE + RT \ln \left( \frac{P}{P^\theta} \right) \right] \quad \text{Eq. 8}$$

Both Eq. 7 and 8 are based on the assumption of thermodynamic equilibrium among phases.<sup>79-82</sup>

For a detailed discussion, see the SI.

### 3. Results and discussion

#### 3.1 Forsterite surface models characterization

To start with, we borrowed both the forsterite bulk and surface models from Bruno et al.<sup>45</sup> previous work at B3LYP (without Grimme's correction for dispersive interactions) level of theory of the most natural occurring forsterite surfaces, *i.e.* (010), (120), (101), (001), (111), (021) and (110). We re-optimized at B3LYP-D\* level only the atomic positions keeping the cell parameters computed by Bruno et al. Results are summarized in Table 1, together with the experimental data<sup>86</sup> and computed ones obtained by Escamilla-Roa at PBE level.<sup>24</sup>

**Table 1.** Experimental and computed lattice parameters (Å) for forsterite bulk. The present work adopts the same cell parameters of Bruno et al. work.<sup>45</sup> Percentage variations with respect to experimental values in parentheses.

Parameter	Experimental <sup>#</sup>	Escamilla-Roa <sup>§</sup>	Bruno <sup>§</sup> /This work (%Δ)
<i>a</i>	4.7490	4.81(1.3%)	4.7892 (0.8%)
<i>b</i>	10.1985	10.35(1.5%)	10.2539 (0.5%)
<i>c</i>	5.9792	6.06(1.4%)	6.0092 (0.5%)

<sup>#</sup>: Bostom.<sup>86</sup>

<sup>§</sup>: Escamilla-Roa et al.<sup>24</sup>

<sup>§</sup>: Bruno et al.<sup>45</sup>

The models representing the seven surfaces (slab models) have resulted by properly cutting the optimized bulk structure, following the slab model approach, *i.e.* without generating a perpendicular dipolar moment,<sup>87</sup> or breaking the unity of the SiO<sub>4</sub> moiety, in agreement with previous computational works showing forsterite as an ionic material where the SiO<sub>4</sub> groups act as single anion entity.<sup>24,32–36,39,88–90</sup> For a detailed discussion of how slabs models have been generated, see the original Bruno's work.<sup>45</sup> With local Gaussian basis set, there is no need to replicate the slab along the *c* axis, as mandatory when adopting plane waves basis set. In this work we followed the same computational scheme by Bruno and coworkers, by further adding the Grimme's corrections for dispersive interactions,<sup>56–58</sup> as detailed in the Computational section. In practice, from the optimized slab structures, we computed the surface energies, the morphological relevance index (MRI, *i.e.* the ratio, expressed as percentage, between the unit area of a single surface and the total

1  
2  
3 area of the crystal) and, through the Wulff theorem,<sup>91</sup> the equilibrium shape (ES) of the crystal a 0  
4  
5 K (Table 2 and Figure 2).  
6

7 Figure 1 shows the structural features of forsterite bulk and slabs. Forsterite ( $\text{Mg}_2\text{SiO}_4$ ), the Mg  
8  
9 end-member of the olivines isomorphous solid solution ( $\text{Mg,Fe}_2\text{SiO}_4$ ), belongs to *Pbnm* space group  
10  
11 (orthorhombic,  $Z=4$ ,  $a \neq b \neq c$ ,  $\alpha = \beta = \gamma = 90.0^\circ$ ). Its bulk structure is composed of a distorted  
12  
13 hexagonally close-packed array of oxygen with 1/8 of the tetrahedral sites occupied by  $\text{Si}^{4+}$  ( $\text{SiO}_4$   
14  
15 units) and 1/2 of the octahedral sites occupied by divalent cations ( $\text{Mg}^{2+}$ ) usually denoted as M1 and  
16  
17 M2 ( $\text{MgO}_6$  units). Of the two octahedral sites, the M1 site, which is more distorted and compact  
18  
19 than M2 one, forms edge-sharing chains parallel to the *c* axis. The adsorption surface sites for all  
20  
21 the seven slab models are either  $\text{Mg}^{2+}$  cations or oxygen atoms belonging to external  $\text{SiO}_4$  groups.  
22  
23 We labeled each site in alphabetic order following its *z*-coordinate value, from the most (highest *z*-  
24  
25 coordinate) to the least (lowest *z*-coordinated) exposed (see Figure 1), in which the *z*-coordinate  
26  
27 refers to the Cartesian axis perpendicular to the cut plane.  
28  
29  
30

31 The seven surfaces are characterized by very different structural features (Table 2) and  
32  
33 morphologies: some surfaces, such as the (010) and the (001) ones, show very compact structures  
34  
35 with only a few exposed sites and very little surface area values, while others such as the (120), the  
36  
37 (101), and the (111) ones present irregular morphologies, thus exposing several adsorption sites.  
38  
39 Finally, the last two surfaces, (021) and (110), are characterized by very low-coordinated sites (Mg  
40  
41 A for the first one and Mg A and Mg B for the second one) explaining their high surface energies  
42  
43 (Table 2). The considered slab models did not exhibit defects, such as steps, corners, and vacancies.  
44  
45 Nevertheless, as reported by King et al.<sup>36</sup> for the water case, the energetics adsorption process is not  
46  
47 influenced by such defects, but, rather, by the presence of exposed and low-coordinated Mg cations.  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

**Figure 1.** Forsterite bulk (top-left corner, unit cell borders in blue) and side views of the seven slab models. M1 and M2 indicate the Mg octahedral sites. The figure only shows few atomic layers, for sake of clarity. Mg cations available for adsorption are labeled in alphabetic order according to their  $z$ -coordinated. For the (120) and (110) surfaces, Mg D/E and Mg A/B are indicated as “D,E” and “A,B”, respectively, since they are eclipsed in this representation.

The surface energy values  $E_S$  (at 0 K) according to Eq. 1 (Table 2) allow sorting the seven surfaces by their relative stability: the higher the surface energy, the less stable is the surface. Table 2 highlights the role of dispersion interaction on the  $E_S$  values by comparing the B3LYP-D\* data with the ones computed at B3LYP//B3LYP-D\* (in parentheses), *i.e.* by single point energy evaluation at B3LYP on the B3LYP-D\* optimized geometries. This comparison gives a measure of the role of dispersion on the final  $E_S$  values. The stability order, at B3LYP//B3LYP-D\*, is:

$$(010) < (120) < (101) < (001) < (111) < (021) < (110)$$

with the (010) being the most stable one. Data at B3LYP-D\* follow the same order of stability, which also coincides with that computed by Bruno et al. (Table 2). To compute the MRI values and

the resulting equilibrium crystal morphology at 0 K (Figure 2) we used the  $E_S$  values from B3LYP-D\*.

**Table 2.** Structural and energetic features for the seven slab models. Cell parameters,  $a$ ,  $b$  and  $\gamma$  ( $\text{\AA}$ , degrees),  $A$  ( $\text{\AA}^2$ ) surface unit cell area,  $E_S$  ( $\text{J m}^{-2}$ ) surface energy from Eq. 1 (values at B3LYP//B3LYP-D\* in parentheses) and Morphological Relevance Index (MRI, see text for details).  $\% \Delta$  is the percentage variations between Bruno's and the present B3LYP//B3LYP-D\* values. The MRI for the present work is for  $E_S$  at B3LYP-D\*

$(hkl)$	Cell parameters				$E_S$			MRI	
	$a$	$b$	$\gamma$	$A$	This work	Bruno <sup>§</sup>	$\% \Delta$	This work	Bruno <sup>§</sup>
(010)	4.795	6.043	90.0	28.98	1.44 (1.23)	1.22	0.8	23.8	21.7
(120)	6.009	13.932	90.4	83.71	1.68 (1.37)	1.36	0.7	29.7	37.0
(101)	7.745	10.253	90.1	79.41	1.96 (1.62)	1.78	-9.0	20.7	12.2
(001)	4.806	10.149	91.0	48.76	1.98 (1.72)	1.78	-3.4	19.8	15.8

§: Ref.<sup>45</sup>

The B3LYP//B3LYP-D\*  $E_S$  percentage variations from the present work compared to that by Bruno et al.<sup>45</sup> are relatively small for all cases but for (101) and (001) surfaces, probably due to large structural rearrangements occurring during the optimization when dispersion is included. When dispersion is fully accounted for at B3LYP-D\* level the corresponding MRI values are significantly different from that by Bruno et al.<sup>45</sup> Nevertheless, the final equilibrium shape morphologies only show relevant change in surface extension for the (101) and (111) facets, the ones whose  $E_S$  is affected most by the inclusion of dispersion (Figure 2).

9  
10 To characterize the forsterite surfaces with respect to CO interaction, we also computed the  
11 electrostatic potential maps (ESPMs) superimposed to the ground state electron density (Figure 3).  
12  
13 For transition metals, the CO/surface interaction is dominated by chemical effects ( $\pi$ -back-  
14 donation),<sup>93-95</sup> while for ionic systems, like the present case, where chemical effects are very small,  
15 electrostatic complementarity between CO and the adsorbing surface docks CO at the different  
16 sites.<sup>96,97</sup> Figure 3 clearly shows the quadrupolar nature of CO, which is dominant over its small  
17 dipole moment, with a deeper negative value around C atom compared to oxygen, in agreement  
18 with previous findings.<sup>98</sup> Within B3LYP-D\* approach, the CO dipole has the right alignment  
19 ( $C(\delta^-) \rightarrow O(\delta^+)$ ) with magnitude of 0.094 D, slightly smaller than the experimental value of 0.122  
20 D.<sup>99</sup> Figure 3 also displays deep positive and negative regions over the Mg and the SiO<sub>4</sub> ions, for  
21 two representative forsterite surfaces. Clearly, the complexity of the surface ESPMs, the  
22 quadrupolar nature of the CO, together with the role played by the dispersion interactions - not  
23 accounted for by the ESPMs - hinder an easy prediction of the final CO/surface configuration  
24 without actually running the full calculation. Nevertheless, guided by the principle of electrostatic  
25 complementarity, we started with up to 37 different CO/surface cases for all seven forsterite  
26 surfaces. For each case, full geometry optimization at B3LYP-D\* reveal the subtle structural and  
27 energetic details of this kind of interaction.

Unit cell top views of the (111) surface superimposed on the ESP map: Mg sites are labeled in alphabetic order from the most (A) to the least exposed (E).

### 3.2 CO adsorption on forsterite surfaces

We started by adsorbing CO molecules at about 2.2 Å from the exposed Mg ions at both the upper/lower surfaces. For all the surfaces, we first considered the lowest CO coverage, by adsorbing a single CO molecule on each Mg available ion, to probe them separately. We then considered the highest CO coverage by adsorbing the CO molecule on all available exposed Mg ions at the same time. For the (120), (101), (001) and (111) surfaces we also tested intermediate coverages. We label all simulated structures according to the Mg ions where CO molecules have been initially located.

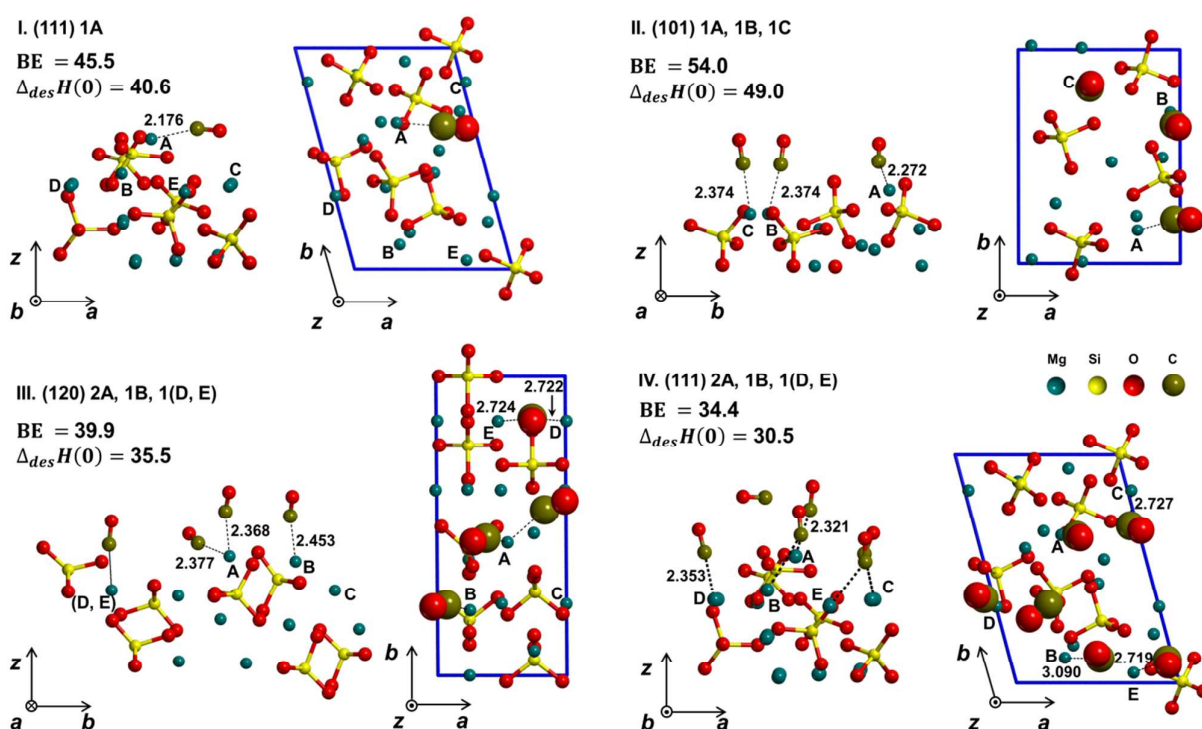

For the optimized structures, we computed the average binding energies, BE, *i.e.* the binding energy *per* adsorbed CO molecule and the enthalpies of desorption at 0 K,  $\Delta_{des}H(0)$ . The computed BE values include deformation, lateral interactions between adsorbed CO molecules<sup>100</sup> and also the Counterpoise correction<sup>68</sup> to cure the basis set superposition error.<sup>66,67</sup> Table 3 resumes the binding energy and enthalpy variation values (Eq. 4) for all the considered cases.

Figure 4 shows, as an example, four significant cases corresponding to the optimum structures of

mono-, intermediate- and maximum CO coverage (see SI for the whole set of cases). In all four cases, the Mg-C distances (from 2.1 to 2.8 Å) and the energetic features (some tens of  $\text{kJ mol}^{-1}$ ) revealed a weak CO/forsterite interaction, entirely dominated by non-chemical interactions.

Figure 4.I shows that CO molecules do not lie perpendicular to the forsterite surfaces, as in a classical cation/dipole interaction. For the “(111) 1A” case, CO molecules lie almost flat to the surface due to the role played by the complex CO quadrupolar/surface ESP interaction and dispersion interaction.

**Figure 4.** Optimized structures for the CO adsorption on three selected forsterite surfaces corresponding to mono (I), intermediate (II) and maximum (III and IV) CO coverages. IV. Maximum coverage for the (111) surface: one of the two molecules initially placed close to Mg A lies parallel to the surface (no Mg-C interactions). Left part: side views, right part: top views. Mg-C distances in Å, BE and  $\Delta_{des}H(0)$  in  $\text{kJ mol}^{-1}$ . In top views, CO molecules as van der Waals spheres.

For the “(101) 1A, 1B, 1C” case (intermediate coverage), the CO molecules adsorbed on Mg B and C lie almost perpendicular to the surfaces, suggesting that in such cases the dipole-charge interactions dominate. This complex structural scenario will affect the CO stretching frequency in a rather subtle way (see next section).

Along the route of increasing the CO coverage, we adsorbed two CO molecules on the most exposed site of the (120), (101), (001) and (111) surface. In all cases, the two CO molecules repelled themselves. Nevertheless, for the (120), (101) and (001) surfaces, the interaction with the cation overcomes the repulsion, resulting in structures exhibiting two adsorbed CO molecules *per* Mg cation (example: Figure 4.III). For the (120) and the (110) surfaces, the closeness of the two Mg sites (Mg D and E and Mg A and B - respectively - Figure 1 and 4.III but also Figures S3, S8, S11, S16 of the SI) gives one CO molecule to be bi-coordinated.

**Table 3.** Structural and energetic features of CO adsorbed on forsterite surfaces. Binding energies – corrected for the BSSE – inclusive (BE disp) and non-inclusive (BE no-disp) of Grimme’s correction, desorption enthalpy variations  $\Delta_{des}H(0)$ , lateral interaction energies  $E_L$  among CO molecules, BSSE and dispersion (disp) contributions to BEs disp values in  $\text{kJ mol}^{-1}$ ; average Mg-C distances  $\langle d_{\text{Mg-C}} \rangle$  in Å. All energy quantities ( $3^{\text{rd}}$ – $8^{\text{th}}$  columns) are *per* adsorbed CO molecule. Averages, standard deviations (Std. dev.), minimum and maximum values for each quantity are also reported.

\*: average only for molecules effectively adsorbed on Mg sites, see Figure 4.IV.

Data resumed in Table 3 confirmed the weak nature of CO adsorption on forsterite surfaces. Mg-C bond distance ranges from 2.176 (“(111) 1A” case) to 2.843 (“(111) 2A, 1B, 1C, 1D, 1E” case) Å, with  $2.4 \pm 0.1$  Å resulting by averaging all values of the last column. The only outlier is for the “(111) 2A, 1B, 1C, 1D, 1E” case in which  $\langle d_{\text{Mg-C}} \rangle = 2.843$  Å: it is worth noting that this is not due to the contribution of the extra CO molecule initially adsorbed on Mg A and lying flat on previously adsorbed CO molecules (Figure 4.IV).

By comparing related cases in Table 3, it is easy to compute the contribution to the binding energy for a specific single adsorption process. For example, the net BE of the “lying flat” CO molecule of the “(111) 2A, 1B, 1C, 1D, 1E” case can be computed as  $6 \cdot \text{BE} [(111) 2A, 1B, 1C, 1D, 1E] - 5 \cdot \text{BE} [(111) 1A, 1B, 1C, 1D, 1E]$  giving a value of  $14.4 \text{ kJ mol}^{-1}$ . This value may be representative to understand the formation of a CO ice.

BE-disp values range from 23.3 (“(001) 2A, 2B” case) to 68.1 (“(101) 1A” case)  $\text{kJ mol}^{-1}$ , showing exclusively physisorption of CO on the forsterite surfaces.

BSSE and dispersion interactions play fundamental and opposite roles. The former affects the BE-disp values by 56% on average, a value close to that resulting from the adsorption of drugs on amorphous silica.<sup>101</sup> Dispersion contribution to the BE-disp is also large (50% on average of the BE-disp) and, unlike BSSE, is a physically related quantity. For the “(001) 2A, 2B” or the “(111) 1C” cases, they entirely dominate the interaction between CO and forsterite surfaces.

1  
2  
3 In the penultimate column of Table 3 we also report the CO lateral interactions  $E_L$  simply computed  
4 as the energy differences between the B3LYP-D\* energy of the corresponding periodic layers of  
5 adsorbed CO for each specific case with respect to the same number of isolated CO molecules (see  
6 the SI for the details). The sign convention is the same as for the BEs, *i.e.* negative values means  
7 repulsive interactions. All values, except the “(001) 2A, 2B” case, are very small and negligible  
8 with respect to BEs, showing that the BE for a specific site is not influenced by the CO adsorbed on  
9 a nearby site (site-site independence). The relatively high value of  $E_L$  ( $-4.7 \text{ kJ mol}^{-1}$ ), for “(001) 2A,  
10 2B” case is due to the repulsive interaction between the two CO molecules co-adsorbed on the same  
11 Mg B site (compare with the “(001) 2A, 1B” ( $0.3 \text{ kJ mol}^{-1}$  case, see Figure S13).

12 We did not find any significant correlation between the binding energy, or the enthalpy variations,  
13 and the Mg-C distance.

14 We did not consider the adsorption of CO oxygen-down. This is known to occur, for instance, in  
15 acidic and cation exchanged zeolites<sup>102,103</sup> while it has never been observed for CO adsorption on  
16 extended ionic surfaces. To further check that this is the case also here, we computed the BE for the  
17 O-down adsorption for some cases, for instance, the “(120) 1C case”: a value of  $17.5 \text{ kJ mol}^{-1}$   
18 resulted, to be contrasted with the C-down value of  $35.5 \text{ kJ mol}^{-1}$ . This large difference in BE  
19 ensure that the O-down population is entirely negligible at the temperature of interest and does not  
20 play a relevant role in the features of the forsterite/CO adsorption.

### 21 3.3 CO desorption times

22 Since the first observations of the ISM in the IR region were carried out, different astrophysical  
23 models for dust grains have been proposed.<sup>7,104–110</sup> Several parameters characterize the models,  
24 whose values derive either from direct observations (when possible) or from “terrestrial  
25 techniques”, such as laboratory experiments and computer modelling. Examples are the residence  
26 times of adsorbed species (molecules, ices but also of layers of carbonaceous material<sup>110</sup>) on the  
27 surface of grains at a given temperature and pressure.

1  
2  
3 Along that line, the present computed data can be used to predict the desorption kinetics of CO from  
4  
5 forsterite grains through the Eyring equation for the kinetic desorption constant  $k_D$ .

6  
7 Since CO adsorbs barrier less, as no chemical bond making/breaking occurs at the forsterite  
8  
9 surfaces, the Gibbs free activation energy of desorption  $\Delta_{des}G^\ddagger$  coincides with the negative of the  
10  
11 Gibbs free energy of adsorption  $\Delta_{des}G = -\Delta_{ads}G \equiv \Delta_{des}G^\ddagger$ . However, in our case,  $\Delta_{des}G$  values  
12  
13 coincide in turn with  $\Delta_{des}A$  values computed according to Eq. 5 at a given temperature. With these  
14  
15 assumptions, desorption times  $t_{des}$  from Eq. 6 are normalized to 10 Myr, assumed as the typical  
16  
17 lifetime of MCs.<sup>111</sup> Figure 5 shows the  $\log(t_{des}/10 \text{ Myr})$  vs  $T^{-1}$  trend in the 0÷100 K range for the  
18  
19 mono-most-bound case of each surface. At the low temperatures characterizing cooler clouds,  
20  
21 desorption times are much greater than the times typically required for MCs evolution (this  
22  
23 evolution times are represented by the straight lines in the inset box of Figure 5) and becomes  
24  
25 comparable only at temperature of about 75-100 K. For the complete data set, see Table S1.

57  
58  
59  
60

**Figure 5** CO desorption times ( $t_{des}$ ) for the mono-most-bound cases of each surface as a function of temperature ( $T$ ). Times are normalized with respect to 10 Myr – the typical lifetime of a MC – and reported in logarithmic scale for convenience. The values in square brackets represent the different temperatures to which desorption times have been computed according to Eq. 6. Straight lines in the inset box represent time intervals for the MCs evolution: gravitational collapse time ( $10^5 \div 10^6$  yr, dashed lines)<sup>111</sup> and lifetime ( $10^7$  yr, dotted line).<sup>112–115</sup>

A long residence time increases the probability of molecular encounters at the surfaces, more likely through the Eley-Rideal mechanisms, providing the base for the formation of COMs. At higher  $T$ , desorption/re-adsorption processes becomes feasible so that the Langmuir-Hinshelwood mechanism accounts for CO reactions. Clearly, the present data can be profitably used in models assuming the dynamical evolution of clouds.<sup>109,110</sup>

### 3.4 Vibrational frequencies of CO molecules

When dealing with adsorbed CO molecules, a key quantity is their stretching frequency shift values with respect to the free CO one. Positive, or hypsochromic, shifts are referred as “blue shift”, while

1  
2  
3 negative, or bathochromic, ones as “red shift”. Blue shift implies a CO bond shortening with a  
4  
5 corresponding increase in the bond force constant and vibrational frequency. The reverse happens  
6  
7 for red-shifted cases.<sup>116</sup> The relevance of the CO vibrational shift is to probe the electric field and  
8  
9 the chemical features of the adsorbing surface sites. In transitional metals with electronic  
10  
11 configuration different from  $d^0$ , the main contribution to the interaction energy for the metal-CO  
12  
13 system is due to the  $\pi$ -backdonation from  $d$  orbitals of the metal to the antibonding  $2\pi^*$  LUMO of  
14  
15 the CO. Thus, the anti-bonding levels of CO become more populated, weakening the C-O bond. On  
16  
17 the other hand, the  $\sigma$ -donation from the non-bonding  $5\sigma$  HOMO produces a reinforcement of the C-  
18  
19 O bond although of minor entity.<sup>93-95,116</sup> For non- $d/d^0$  metals (as the case of  $Mg^{2+}$ ), backdonation is  
20  
21 prevented so the only possible interaction is the  $\sigma$ -donation from the CO-HOMO to the metal  $s/p$ -  
22  
23 orbital. Due to the weak anti bonding nature of the  $5\sigma$  HOMO, the C-O bond is reinforced and  
24  
25 vibrational blue shifts resulted. However, this “classical” point of view has been questioned since it  
26  
27 does not produce sufficiently high interactions energies and large blue shifts. Thus, it has been  
28  
29 suggested that a large part of the interaction between CO and non- $d/d^0$  metals would then be played  
30  
31 by pure electrostatic effects.<sup>96,97,116</sup> More specifically, the electric field originated by the metal  
32  
33 cation would produce a polarization of both  $\sigma$  and  $\pi$  CO bonding orbitals along the  $O \rightarrow C$  direction,  
34  
35 enhancing the covalent character and the strength of the CO bond.<sup>98</sup>  
36  
37  
38  
39

40 For  $d^{10}$  metals, back-donation is also expect to occur but in some cases, as in  $Zn^{2+}$  zeolites, they  
41  
42 seem to behave like non- $d/d^0$  metals.<sup>117</sup>  
43  
44

45 For Ca(II), Na(I), Zn(II), Ag(I) and Cu(I) exchanged zeolites, Bolis and coworkers reported the  
46  
47 existence of a liner correlation between experimental  $\Delta\bar{\nu}$  and the values of desorption enthalpies in  
48  
49 the CO zero coverage limit.<sup>117,118</sup> They showed that any deviation from the linear behavior reveals  
50  
51 the incoming effect due to increasing charge transfer and back-donation towards CO. Despite the  
52  
53 highly ionic nature of the forsterite surfaces, we did not observe a straight linear correlation  
54  
55 between the computed desorption enthalpies (or, equivalently the BEs) and the CO vibrational  
56  
57 shifts, but only a broad trend (data not shown). Furthermore, for some cases we computed red-  
58  
59  
60

1  
2  
3 shifted values. These cases represent a small percentage of the total (7 negative shifts out of a total  
4 of 73, see Figure 6.II and Table S2). The missing expected linear correlation between energetic and  
5 spectroscopic features reveals a more complex interaction for the present case with respect to the  
6  
7  
8 systems considered by Bolis et al,<sup>117,118</sup> in which the surrounding of the adsorbing cation was much  
9  
10 more regular than in forsterite surfaces. The complexity of the surface sites in the present case (*vide*  
11  
12 *supra*) and the important role of dispersion interaction deviate from the simpler ion/dipole model  
13  
14 for the systems accounted for by the Bolis et al.<sup>117,118</sup> Nevertheless, we have found a very good  
15  
16 linear correlation between  $\Delta\bar{\nu}$  shifts and C-O distances ( $d_{CO}$ ), as predicted by the Blyholder  
17  
18 model<sup>116</sup> (Figure 6.I). This linear relation is useful for quickly evaluating the CO vibrational shift  
19  
20 without performing an expensive frequency calculation, by only using its CO bond length.  
21  
22

23  
24 To the best of our knowledge, while bathochromic shifts have been reported for CO adsorbed in  
25  
26 cation-exchanged zeolites,<sup>102,103</sup> no experimental evidence of that has ever been reported for CO  
27  
28 adsorbed on extended ionic surfaces in the CO low coverage regime. For the zeolite case, the CO  
29  
30 bathochromic shifts were proved to be due to CO adsorbed oxygen-down at the cations, which is in  
31  
32 thermodynamic equilibrium with the most stable C-down isomer, even if with a much reduced  
33  
34 population (*vide supra*).  
35  
36

37  
38 In our set, the “(111) 2A, 1B, 1C, 1D” case ( $\Delta\bar{\nu} = -2 \text{ cm}^{-1}$ ) may be rationalized because of the high  
39  
40 CO coverage, in which the second CO molecule initially adsorbed on Mg A lies in a configuration  
41  
42 almost flat without evidence of C-Mg interaction (Figure 4.IV).  
43  
44

45  
46 Four out of the six remaining bathochromic shifts belong to cases of multi-loading CO coverage, in  
47  
48 which lateral interactions among adsorbed CO molecules may cause negative CO frequency shifts  
49  
50 through in space coupling. The remaining two cases, “(101) 1B” and “(110) 1C”, are CO mono-  
51  
52 loading ones, in which the dominant quadrupolar nature of CO comes into play to account for the  
53  
54 bathochromic shifted values.

3  
4  
5  
6 As pointed out by the structures reported in Figures 3.II and 3.III (but also in Figures S2-S8 of the  
7  
8 SI), forsterite surfaces are really complex from an electrostatic point of view. Therefore, the  
9  
10 interaction between CO and exposed Mg sites cannot be interpreted through a simple dipole-charge  
11  
12 model, as interactions involving the negative O atoms of the exposed SiO<sub>4</sub> units with the positive  
13  
14 belt of the CO quadrupole may play a fundamental role.  
15  
16

### 17 18 *3.5 Interplay between electrostatic and dispersive interactions* 19

20 Interplay between electrostatic and dispersion interactions, evaluated by the Grimme's correction,  
21  
22 may affect the final structures in several ways. To elucidate the role of both aspects, we re-  
23  
24 optimized at B3LYP level (no dispersion included): i) all the most bound cases for all the seven  
25  
26 surfaces; ii) the two mono-coverage cases affected by red-shifted frequencies, "(101) 1B" and  
27  
28 "(110) 1C", respectively. For the sake of brevity, we show results referring only to two  
29  
30 representative cases, the "(010) 1A" and the "(101) 1B" (Figure 7). All the other tested cases are  
31  
32 available in the SI.

60

**Figure 7.** Optimized structures with (left) and without (right) Grimme's correction for two representative cases. Distances in Å, energies in  $\text{kJ mol}^{-1}$  and CO frequency shifts in  $\text{cm}^{-1}$ .

As expected, at B3LYP level, all the distances increase with respect to B3LYP-D\* case, due to the missing attractive term. For the “(010) 1A” case (and similarly related ones, see SI), due to the symmetry constraints forcing CO to stay aligned on top of Mg ion (Figure 7, top), no difference in the CO frequency shifts resulted, despite the general shrinking of the intermolecular distances. When moving to the “(101) 1B” case, the differences between the two geometries are more subtle: dispersion is dramatically enlarging the value of the surface  $\text{Mg}\cdots\text{O}\cdots\text{Si}$  angle which, in turn, affects the way in which CO becomes adsorbed. Comparison of the optimized B3LYP with the corresponding B3LYP-D\* structure (see structures at the bottom of Figure 7) shows how dispersion brings CO closer to the negatively charged oxygen atom belonging to the most exposed  $\text{SiO}_4$  tetrahedron. This interaction is attractive, when considering the quadrupolar electrostatic nature of the CO molecule (see Figure 3.I). Nevertheless, the mechanism behind the charge flux rearrangement of CO for this case is such that a bathochromic shift of the CO stretching frequency occurs. Interestingly, Figure 6.III shows a trend between the negative shift  $\Delta\bar{\nu}$  values and the distances between the centers of mass of CO molecules and the closest oxygen atom of a  $\text{SiO}_4$  unit.

1  
2  
3 This relation hold true for – “(101) 1B”, “(101) 1A, 1B, 1C”, “(101) 1A, 1B, 1C, 1D, 1E” and  
4  
5 “(110) 1C” – cases, in which a single bathochromic shift occurs for a single CO molecule (see  
6  
7 Table S2 of the SI). For the “(001) 2A, 2B” cases, where three CO molecules are involved in two  
8  
9 modes characterized by bathochromic shifts, the distance between the CO center of mass and the  
10  
11 closest oxygen atom of the SiO<sub>4</sub> moiety cannot be worked out. As the number of cases is very  
12  
13 limited, we do not claim a statistical robustness for the graph in Figure 6.III. Nevertheless, we  
14  
15 believe it contains a physically sensible message, *i.e.* “the shorter the distance between the centers  
16  
17 of mass of CO to the nearby surface oxygen, the larger is the bathochromic shift suffered by CO”.

18  
19  
20 This complex behavior is probably the reason why the whole set of energetic data and vibrational  
21  
22 ones do not rest on a linear correlation, as found through experiments by Bolis *et al.*<sup>117</sup> for CO  
23  
24 adsorbed in cation-exchanged zeolites. Nevertheless, Figure 6.IV, shows that, for the most bound  
25  
26 cases of the most representative surfaces, a good correlation holds true.

27  
28  
29 Figure 6.V summarizes the overall simulated IR spectra in the CO stretching region corresponding  
30  
31 to the lowest/highest CO coverage. Experimentally, the most interesting case is for the zero-limit  
32  
33 CO coverage,<sup>117</sup> which correspond to the “min” spectrum. Each spectrum results by a linear  
34  
35 weighted sum of the CO stretching frequency value for all considered cases within the “min/max”  
36  
37 coverage regimes. The weights of the sum are the Boltzmann’s factor  $\exp(-\Delta(\text{BE})/RT)$  computed  
38  
39 at  $T = 100$  K using the difference  $\Delta(\text{BE})$  in CO relative binding energy. MRI values of Table 2 also  
40  
41 multiply each weight, to account for the spatial extension of each surface. The adopted temperature  
42  
43 is close to that of liquid nitrogen to mimic most experimental conditions. The spectrum  
44  
45 corresponding to the “min” coverage only shows components higher than 2143 cm<sup>-1</sup> (free CO), in  
46  
47 line with the expected hypsochromic shift observed from the vast majority of experiments dealing  
48  
49 with CO on extended oxide surfaces. The main contribution to this spectrum derives from the CO  
50  
51 mono-most-bound cases for each surface. At maximum coverage (“max”), the spectrum suffers a  
52  
53 shift toward lower wave numbers, due to the bathochromic contributions to the CO frequency  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 deriving from multi-loading cases (*vide supra*) for which both BE and  $\Delta\bar{v}$  values are lower with  
4  
5 respect the mono loading cases.  
6  
7

### 8 3.6 Thermodynamic analysis 9

10 For each of the 37 considered cases, we computed the surface free energies  $G_S(T, P, \sigma)$  and the  
11 related adsorption free energies  $\Delta_{ads}G(T, P, n)$  according to Eq. 7 and 8, at the pressure value of  
12  $10^{-16}$  Pa which is indicative of the physical conditions characterizing MCS.<sup>74</sup> The stability diagrams  
13 ( $G_S$  vs  $T$  trend) are shown in the top-left part of Figure 8 for all CO adsorption cases of the (120)  
14 surface. The diagrams show the thermodynamically favored structures for which  $G_S < E_S$  at a given  
15 temperature. Since the adsorption is a true physisorption (*vide supra*), the most stable structures (at  
16 a given  $T$ ) are the ones expected to exist; therefore these diagrams can be interpreted also as phase  
17 diagrams. For the sake of brevity, we do not show data referring to all the other surfaces as their  
18 calculation is straightforward.  
19

23  
24  
25  
26  
27  
28  
29

30 As you can see from the left of Figure 8, the case of highest CO coverage, “(120) 2A 1B 1(D,E)”, is  
31 the most stable up to 50 K, since it has the lowest values of  $G_S$ . Beyond this point, there is a  
32 crossing (green-dashed line) for the adsorption of two CO per unit cell, “(120) 1A 1C”, which is the  
33 most stable one only up to about 60 K. Over 60 K, the mono CO covered “(120) 1A” case, the most  
34 bound one at 0 K and 0 Pa (see Table 3), becomes the most stable one.

59  
60

**Figure 8.** Top-left: stability diagrams for all CO adsorbed cases of the (120) surface. Pressure is equal to  $10^{-16}$  Pa. Horizontal black line corresponds to the  $G_S = E_S$  condition. Different CO coverages as lines: solid ( $n^\dagger = 1$ ), dashed ( $n^\dagger = 2$ ), dot-dashed ( $n^\dagger = 3$ ), short-dotted ( $n^\dagger = 4$ ). Top-right: variations of adsorption Gibbs free energy for some single-adsorption processes occurring at the (120) surface (see text) as a function of temperature. Pressure is equal to  $10^{-16}$  Pa. Different processes as lines: (120) + CO  $\rightarrow$  “(120) 1A” (solid, MONO), CO + “(120) 1A”  $\rightarrow$  “(120) 1A 1B” (dashed, BI), CO + “(120) 1A 1B”  $\rightarrow$  “(120) 1A 1B 1(D,E)” (dot-dashed, TRI), CO + “(120) 1A 1B 1(D,E)”  $\rightarrow$  “(120) 2A 1B 1(D,E)” (short-dotted, TETRA). Bottom: schematic representation of all Gibbs free energy variations involved in the formation of the most-covered case for the (120) surface, the “(120) 2A, 1B, 1C” one (at  $10^{-16}$  Pa and 10 K) as a sequence of single-adsorption processes. Numbers beside vertical lines represent the variations of adsorption Gibbs free energy for each step in  $\text{kJ mol}^{-1}$ . For all the involved structures, we show a detail of the side views (see also Figure S10 and S11).

Exploiting Eq. 8 we also computed the adsorption Gibbs free energies  $\Delta_{ads}G(T, P, n)$  for each of the 37 simulated cases at  $10^{-16}$  Pa. However, again we show only data referring to the (120) surface. Top-right corner of Figure 8 reports the variations in adsorption Gibbs free energies for some single CO molecule adsorption processes, *i.e.*  $\Delta(\Delta_{ads}G) = \Delta_{ads}G(T, P, n + 1) - \Delta_{ads}G(T, P, n)$  as a function of temperature. For the sake of clarity, we report only those processes involved in the formation of the most covered case, the “(120) 2A, 1B, 1(D,E)” one (for a more complete picture, see Figure S26). For the whole  $G_S(T, P, \sigma)$  and  $\Delta_{ads}G(T, P, n)$  data set, see Table S3). Specifically, the considered processes are:

Selecting one temperature, the total Gibbs free energy of adsorption for the step-by-step formation of the “(120) 2A, 1B, 1(D,E)” case can be easily computed. For example, in the bottom part of Figure 8, we report all the energetics steps at 10 K. At this low  $T$  (and  $P$ ) all formation steps are thermodynamic favored. At temperatures higher than 65 K only the MONO process (formation of the mono-covered case) is thermodynamic favored.

However, we would like to stress that thermodynamic arguments are based on the assumption of equilibrium between gas and solid phase<sup>79,80</sup> (see SI - Computational details - *Surface free energies and adsorption free energies (Eq. 7 and 8)*) which may not be easily fulfilled in the harsh physical conditions of the ISM, despite the very long lifetimes of MCs.

## Conclusions

We investigated at a B3LYP-D\*<sup>49-51,59</sup> level of theory (inclusive of dispersion contribution to the interaction energy) the adsorption of carbon monoxide (CO) on seven different surfaces of forsterite ( $\text{Mg}_2\text{SiO}_4$ ), the Mg end-member of olivines, one of the main component of the interstellar core dust

1  
2  
3 grains in Molecular Clouds (MCs).<sup>2,119–121</sup> CO is the second most abundant gas-phase molecular  
4  
5 species discovered in MCs, after H<sub>2</sub>.<sup>2</sup> For these reasons, elucidating the details of the CO interaction  
6  
7 may be important from an astrochemical point of view. We focused on the (001), (010), (101),  
8  
9 (110), (111), (120) and (021) surfaces within the slab approach, following the work of Bruno *et al.*  
10  
11 adopting the same extended Gaussian basis set.<sup>45,46</sup> For the seven surfaces we provide: i) the  
12  
13 optimized structures; ii) the surface energies; iii) the Wulff's polyhedron; iv) the electrostatic  
14  
15 potential maps. The most relevant conclusion from structural and electrostatic features is that  
16  
17 forsterite surfaces have complex morphologies, which do not allow to adopt the simple charge-  
18  
19 dipole model to elucidate the CO/surface interactions.<sup>116,117</sup> That simplified model was commonly  
20  
21 used in the literature, to interpret the experiments and simulation for CO adsorbed on regular oxide  
22  
23 surfaces (NaCl, MgO, etc.) or in cation-exchanged zeolites. We revealed the role of the large CO  
24  
25 quadrupole moment coupled with the subtle geometrical changes in the surface structure induced by  
26  
27 the dispersion components of the energy to rationalize both energetic of adsorption and CO  
28  
29 stretching frequency variations with respect to free CO. We found that CO only physisorbs (no  
30  
31 bond making/breaking with the forsterite surface atoms) on exposed Mg cations of surface  
32  
33 forsterite, with desorption enthalpy variations at 0 K per CO molecule in the 18-63 kJ mol<sup>-1</sup> range,  
34  
35 depending on the surface and CO coverage. We revealed that dispersion interaction plays a  
36  
37 fundamental role, accounting, as average, for the 50% of the total energy of interaction. Lateral  
38  
39 interaction between adsorbed CO is also negligible. For all the optimized structures, we have  
40  
41 computed the CO stretching frequencies and the related IR spectra. We did not find a robust linear  
42  
43 correlation between CO interaction energy and the corresponding CO frequency shift with respect  
44  
45 to the gas phase, as usually reported for CO adsorbed in simpler oxides or cation-exchanged  
46  
47 zeolites, in the zero-coverage limit.<sup>117</sup> We discovered that dispersion interactions have a key role in  
48  
49 deforming the surface local environment on which the adsorbed CO molecule resides for some of  
50  
51 the considered surfaces. This, in turn, has a dramatic effect on the CO frequency shift with respect  
52  
53 to the gas-phase molecule, due to subtle interaction between the CO quadrupole moment and the  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 negative oxygen belonging to the nearest surface SiO<sub>4</sub> moiety. For these reasons, we computed 7  
4  
5 different adsorption cases, up to a total of 73, in which bathochromic CO frequency shifts occur. Of  
6  
7 these seven negative shifts, five refer to multi-loading cases (four to maximum coverage cases),  
8  
9 thus lateral repulsion between adsorbed molecules may explain these negative shifts, and only two  
10  
11 to mono-covered cases. Although we did not observe a correlation between adsorption energy and  
12  
13 CO frequency shifts for the above reasons, we found a good linear relation between the CO bond  
14  
15 lengths and the corresponding frequency shifts: this may serve to guess the CO frequency from its  
16  
17 geometry only, without resorting to the expensive frequency calculations. We simulated the overall  
18  
19 IR spectrum of the adsorbed CO as a function of CO coverage, which may be useful to interpret  
20  
21 experimental data coming from both the laboratory and from deep space observations. The  
22  
23 thermodynamic treatment of CO adsorption, which assumes equilibrium between the gas and solid  
24  
25 phases, gives information about the most stable adsorbed phase as a function of  $T$  at a given  $P$  and  
26  
27 the considered surface, allowing to disentangle the component of the heat of adsorption in  
28  
29 temperature programmed desorption and microcalorimetric experiments. However, our  
30  
31 thermodynamic treatment is based on the assumption that an equilibrium between gas and solid  
32  
33 phase is always established even in the harsh conditions characterizing MCs, an assumption that  
34  
35 may not be operative. The present work is also relevant in for astrochemical modelling purposes, in  
36  
37 which kinetics of CO desorption may be computed using the accurate values provided by the  
38  
39 Quantum-Mechanical calculations. Thus, we simulate desorption times exploiting our computed  
40  
41 energetic features. They can be incorporated on such models accounting for dynamical evolution of  
42  
43 interstellar objects.<sup>109,110</sup> One limitation of this work is the adoption of perfect periodic forsterite  
44  
45 surfaces to model the core dust grains. We outline again that, although silicates in interstellar clouds  
46  
47 are expected to be highly amorphous (5% of crystallinity), other regions such as protostellar and  
48  
49 circumstellar disks and the interplanetary medium should be characterized by higher percentages of  
50  
51 crystalline silicates.<sup>7,8</sup> Thus, our perfectly crystalline models could well represent what happens in  
52  
53 these regions which dynamically derive from the evolution of proper clouds. In our laboratory, we  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 are already simulating nano-sized forsterite grains, therefore closer to the real grain sizes. It will be  
4  
5 challenging to compare CO adsorption feature of the extended surfaces with that resulting on the  
6  
7 nano-clusters in which the amorphous nature is more pronounced than the crystalline surfaces.  
8
