Abbreviations:

ALT: alanine aminotransferase

AST: aspartate aminotransferase

ATP: adenosine tri-phosphate

DCD: donation after circulatory death

EAD: early allograft dysfunction

ECD: extended criteria donors

GGT: gamma glutamyltransferase

HA: hepatic artery

Hb: hemoglobin

ICAM-1: intercellular adhesion molecule 1

IL-8: interleukin 8

IL-10: interleukin 10

ILP: isolated liver perfusion

IRI: ischemia/reperfusion injury

IVC: inferior vena cava

LDH: lactate dehydrogenase

LT: liver transplantation

PV: portal vein

PNF: primary nonfunction

PNP: purine nucleoside phosphorylase

pO_2: partial pressure of oxygen

TNF-α: tumor necrosis factor alpha

Abstract:

Background: Understanding ischemia reperfusion injury (IRI) is essential to further improve outcomes after liver transplantation (LT). Porcine isolated liver perfusion (ILP) is increasingly used to reproduce LT-associated IRI in a strictly controlled environment. However, whether ILP is a reliable substitute of LT was never validated.

Methods: We systematically reviewed the current experimental set-ups for ILP and parameters of interest reflecting IRI.

Results: ILP was never compared to transplantation in animals. Considerable variability exists between set-ups and comparative data are unavailable. Experience so far suggests that centrifugal pump(s) with continuous flow are preferred to reduce the risk of embolism. Hepatic outflow can be established by cannulation of the inferior vena cava or freely drained in an open bath. Whole blood at ~38°C, hematocrit $\geq$ 20%, and the presence of leukocytes to trigger inflammation is considered the optimal perfusate. A number of parameters related to the 4 liver compartments (hepatocyte, cholangiocyte, endothelium, immune cells) are available; however, their significance and relation to clinical outcomes is not well described.

Conclusions: Porcine ILP provides a reproducible model to study early IRI events. As all models it has its limitations. A standardization of the set-up would allow comparison of data and progress in the field.

Introduction

Isolated liver perfusion (ILP) is a procedure in which a liver is normothermically perfused *ex situ* with an oxygenated and nutrient-enriched perfusate. ILP has been used to investigate hepatic pathophysiology and metabolism[1,2], test drug toxicity[3] or to develop bridge-therapy for patients suffering from acute liver failure[4,5].

In the Liver Transplantation (LT) setting, ILP has been used to investigate Ischemia-Reperfusion Injury (IRI) as a substitute for LT and recently also implemented as a technology to preserve liver grafts, generally referred to as machine perfusion preservation or dynamic preservation[6]. Although ILP was initially used to replace LT in rodents[7], the last decades have seen a rise in porcine models, especially in studies investigating protective strategies by means of liver dynamic preservation. The pig seems an appropriate animal to establish ILP and LT models, since the porcine liver is anatomically and physiologically close to humans, with comparable organ dimension and similar bile composition[8,9]. The study of IRI during LT is important as IRI invariably takes place in every transplant with injuries that may vary from minimal to complete graft destruction, and may either go clinically unnoticed or present as dysfunction or absence of life-sustaining hepatic metabolic activity. Ischemia leads to the disruption of hepatocyte aerobic respiration and a cascade of cellular and metabolic disturbances[10,11]. Static cold storage, the standard preservation technique involving cooling and storing of the graft at 4-6°C, reduces but does not abolish oxygen dependent metabolism. Subsequent graft reperfusion with warm oxygenated blood triggers the formation of reactive oxygen species and sterile inflammation, amplifying ischemia-induced damages[12].

Large animal models of LT are labor intensive, technically challenging, and carry a high financial burden[13]. In contrast, ILP allows the reduction of the number of experimental animals since a recipient is not needed. Indeed, all steps preceding the transplantation of the graft can be

5

replicated during ILP and the liver reperfused mimicking the sequence of events of LT[13]. Therefore, ILP can be used to investigate the impact of (i) warm/cold ischemia, or (ii) protective strategies (ie drugs, dynamic preservation) since the reperfusion phase takes place in a controlled environment. Additionally, ILP offers the possibility to serially sample perfusate, bile, and liver tissue, monitoring various parameters to evaluate IRI. Therefore, ILP constitutes a valuable alternative for LT research in large animals, and is particularly attractive as a preclinical tool to test new approaches to protect organs from IRI.

Experience with porcine ILP is nowadays considerable; however, this model was never validated before and comparative interpretation of published studies is difficult due to a wide variation in model design, parameters of interest and endpoints. The aim of our study was (i) to review the methodology of ILP, (ii) to evaluate it as a model to replace LT experiments in animals, and (iii) to summarize the most promising parameters to evaluate IRI during ILP. We also highlight benefits and limitations of the model and discuss possible future developments.

Materials and methods

Experimental studies reporting on methodology and results of porcine ILP as a substitute for LT were considered regardless of the type of graft preservation (ie cold storage, dynamic preservation) or protective strategy investigated (SDC, Methods, http://links.lww.com/TP/B545).

Data source, search strategy and eligibility criteria

Details are given in SDC, Methods, http://links.lww.com/TP/B545.

Data extraction

Methods details the criteria for data acquisition, SDC, http://links.lww.com/TP/B545. The extracted data were summarized in a descriptive review of the methodology of ILP and possible (bio)markers of IRI.

Quality assessment

Details of the quality assessment are given in SDC, Methods, http://links.lww.com/TP/B545.

Results

The search identified 257 articles of which 32 were eligible for further full text screening. Twenty-three papers were included in the quality assessment (SDC, Results and Figure S1, http://links.lww.com/TP/B545) and 11 different set-ups were identified (Figure 1).

All set-ups performed ILP as a substitute for LT to test various approaches to prevent/reduce the severity of IRI: 17/23 papers investigated the effects of dynamic preservation, while the remaining studied different types of preservation solutions. No study included a LT group as control. All studies largely underreported various characteristics of the experimental setting, configuring an overall unclear risk of biases. Additional details are given in SDC, Results, http://links.lww.com/TP/B545.

Mimicking liver transplantation

LT involves 4 surgical phases: (i) organ procurement, including flushing, cooling, and hepatectomy, (ii) preservation, (iii) anastomosis with progressive rewarming of the graft, and (iv) reperfusion with whole blood in the recipient. Ideally, these prereperfusion steps should be reproduced during ILP. As shown in Table 1, various methods have been published, the suitability of which may depend on the specific experimental setting. Following procurement,

7

porcine grafts are generally flushed and cooled with different solutions at variable temperatures. To mimic the graft rewarming during the anastomosis, livers are slowly re-warmed to 25-37°C by submerging in warm fluid[14], or kept at room temperature for a brief period[15]. Finally, the reperfusion phase is simulated by connecting the liver to the ILP circuit with recirculation of warm oxygenated perfusate.

Table 2 summarizes details of the experimental settings used in the different models of porcine ILP reported to date. A wide variation is seen in key parameters, such as (a) circuit design, (b) perfusion pressure and flow, (c) nature of perfusate, (d) perfusate temperature, (e) oxygenation, and (f) duration of perfusion.

a. Circuit design

Both the Hepatic Artery (HA) and Portal Vein (PV) provide blood flow to the liver integrating at the sinusoids with efferent blood collected in the Inferior Vena Cava (IVC). Physiological hepatic flow in pigs is approximately 1 mL/min per gram of liver, with 75% of total blood flow delivered by the PV and 25% by the HA[16]. Any ILP circuit provides this dual inflow but models vary with respect to the type and number of pumps, closed versus open system, heater-coolers, and oxygenators used (Figure 1).

Flow during ILP is generated either by roller or by centrifugal pumps. Both exert mechanical stress with destruction of red blood cells and platelets[17–20], although this risk is lower with centrifugal pumps[21]. Which pump to choose might be determined by the anticipated ILP duration; eg for a short-lasting ILP, hemolysis and platelet destruction by roller pumps might be less relevant. Both roller and centrifugal pumps can generate laminar or pulsatile flow; although clinical experience with cardio-pulmonary bypass has not yet revealed significant advantage of pulsatile flow[22].

8

Hepatic inflow is generated by a single pump[23–28] for both portal and arterial circulation, or by 2 separate pumps[29–31]. Alternatively, portal perfusion can be achieved by gravity[23–26,32,33] (Figure 1). Typically, ILP using blood as perfusate is performed at 1 mL/min/g[16,32–34], whereas the flow rate is generally increased with acellular solution perfusates in order to achieve sufficient oxygenation[28].

The design of the hepatic outflow circuit varies between ILP settings. In most models, the IVC freely drains in the organ receptacle which functions as a reservoir (open circuit)[14,16,29,30,34–38], while in a fully closed system the IVC is cannulated and connected directly to the pump or a venous reservoir[23–26,32,39] (Figure 1). Such a fully closed system allows thorough hemodynamic monitoring including measuring IVC flow and pressure. In a closed system, the IVC wall can collapse by negative pressure generated by the pump causing congestion in the sinusoids.

b. Pressure and flow

Pressure and flow are intertwined hemodynamic parameters and adequate regulation is essential. Elevated pressure may provoke excessive shear-stress, barotrauma, and sinusoid endothelial damage, whilst low pressure might lead to sinusoidal space collapse and inhomogeneous perfusion[7,16]. Dual pressure-controlled perfusion aiming at near-to-physiological upper pressure limits (5-15 mmHg for PV, 60-130 mmHg for HA) is used by most groups (Table 2). Some use a flow-controlled perfusion[32,33] though this carries a risk of barotrauma if intrahepatic pressures rise, or heterogeneous perfusion if lower flows are generated. In the models of Cleveland and Göttingen the flow is adjusted within a physiologic range by increasing pump speed upon reaching the target pressure[16,35,37,38]. However, it is unclear if further adjustments of flow are needed since 'auto-regulation' of hepatic circulation has been described[27,43]. In the Oxford model, portal perfusion only relies on gravity and its pressure is determined by the height of the column of perfusate in the reservoir. As such, portal flow is 'auto-regulated' by the intrahepatic

9

resistance and IVC pressure[27,43], although the physiological ratio between portal and arterial flow might not be respected constantly.

Finally, a hybrid system with flow-controlled perfusion for the PV and pressure-controlled perfusion for the HA has also been described by few groups[36,40].

c. *Perfusate*

The perfusate for ILP can be either an acellular solution or a solution containing erythrocytes. However, acellular perfusates are unlikely to reproduce the full IRI cascade as leukocytes, platelets, and other soluble factors are missing. The majority of authors (12 research groups out of 16) therefore use whole blood[16,23,24,28,29,32–37,41–43] aiming to reproduce the complex cascade of events during IRI[43,44].

Porcine blood can be collected during organ procurement via cannulation of cervical or abdominal vessels or a blood donor pig can be used[16,23,24,33,35,41]. Blood is typically heparinized or mesh-filtered to prevent clotting[42]. It can be used immediately or stored in citrate, phosphate or dextrose for up to 1 week[16,23,24,34–37,41,45]. The use of heterologous blood would include the allo-immune reactivity and inflammation typically observed during IRI and LT[46]. Using large-size pigs (70-80 Kg) allows for sufficient blood collection for 2 ILP runs[16,35]. In case the total volume retrieved is insufficient for multiple perfusions, some authors reported the dilution of whole blood provided that the hematocrit is kept sufficiently high to ensure oxygen delivery. Indeed, the hematocrit is typically maintained around 20%[16,23,33–35], although lower and higher targets are reported[14,28,44].

Whole blood perfusate is usually supplemented (Table 3). To maintain physiological pH and ion balance, most groups add sodium bicarbonate and calcium chloride before starting ILP[16,23–

10

26,29,35,36,39,40,47,48). Antibiotics were added by some groups[16,28,35,47,48] to prevent bacterial contamination. Heparin is also almost universally infused to prevent clotting[23–26,28,30,31,35,37,38,47,48].

After starting ILP, most groups regard the supplementation of nutrients, such as glucose and amino-acids, critical to optimally sustain liver metabolism[16,23–26,35,36,39,40,47,48]. Insulin is added by some as it is believed essential to support the glucose metabolism[23–26,36,40].

During ILP, neural, hormonal, and metabolic feedbacks regulating the intrahepatic vascular resistance are absent. Therefore prostacyclin is infused to ensure arterial vasodilation[16,23–26,28,35,39,47,48]. A potential drawback is that prostacyclin may inhibit platelet activity and blunt IRI[49], but a minimal concentration seems needed to keep flows within acceptable ranges[48].

In the absence of the enterohepatic recirculation, a continuous infusion of bile salts can be given to counteract declining bile production typically observed after 10 hours of ILP[24–26,36,40,50]. However, during ILP of human livers for shorter periods (eg 6 hours) without bile salts infusion, bile flow was not altered[51]. Whether bile salt depletion may only become relevant during longer periods of ILP (eg ≥ 6 hrs) is not known.

To prevent acidosis or hyperkalemia during ILP, a dialysis unit was added to the circuit by some groups[31,37,38] but regarded unnecessary by others who observed a stable acid-base equilibrium and ion balance during ILP without dialysis when adequate supply of glucose, insulin, and other metabolic substrates is provided[41,45].

d. *Temperature*

Minor temperature changes may affect the process of IRI[52,53]. It is therefore imperative to use heat exchangers, usually coupled to the oxygenator, to keep the perfusate temperature within the average range of body temperature in pigs(37-39.6°C)[54].

11

e. Oxygenation

Physiological partial oxygen pressure (pO_2) in pigs ranges between 72-95 mmHg in the HA[54] and 44-58 mmHg in the PV[55]. Yet, higher pO_2 targets are commonly used in order to compensate for the low perfusate hematocrit, especially in acellular perfusates lacking oxygen carrying capacity. Hollow fiber oxygenators are typically used delivering identical pO2 for the HA and PV[14,16,34–36,45]. A lower portal pO_2 can be generated with 2 separate circuits and oxygenators[29] or by mixing oxygen-saturated arterial and desaturated IVC blood to perfuse the PV[43]. In the clinical setting there is evidence that hyper-oxygenation (>600 mmHg) might be harmful[56].

f. Duration of perfusion

The duration of perfusion has been variously reported from 1 up to 24 hours, with the exception of 1 report in which nonischemic livers underwent *ex situ* dynamic preservation for 72 hours[45].

Parameters of interest during isolate liver perfusion

Table 4 summarizes all parameters of interest related to the 4 liver compartments (hepatocytes, cholangiocytes, endothelium, immune).

Hepatocellular compartment

Hepatocellular injury:

Cytoplasmic hepatic enzymes such as *aspartate aminotransferase* (AST)*, alanine aminotransferase* (ALT) *and lactate dehydrogenase* (LDH) are released when hepatocyte damage occurs. AST, ALT and LDH levels are well-known to be related to the severity of graft injury after ischemia. Similarly, a rise in the concentration of these markers was consistently observed in all models of ILP[14,16,23,24,27–36,38–43,47,48,57].

12

Hepatocellular function:

The concentration of adenosine tri-phosphate (ATP) can be used as a measure of recovery of energy balance during IRI and ILP[36,40]. Ischemia causes the adenine nucleotide metabolism in the liver to shut down[58]. Good functioning grafts showed a faster recovery of ATP after IRI, whereas graft failure was associated with adenine nucleotide production[59].

The consumption of oxygen, the last effector for ATP synthesis, can approximate hepatic metabolism, and can be inferred using the formula of Tolboom et al[60]. Changes in oxygen consumption might be related to changes in metabolic activity, although their interpretation in the isolated setting has not been elucidated yet.

Metabolically active livers self-regulate *glucose* concentration in the perfusate[23]. Thus, a stable glucose concentration with a progressive decline of lactic acid indirectly reflects aerobic metabolism. The perfusate *pH and bicarbonate* concentration may be used as indirect markers of hepatic metabolism, although these data need to be interpreted at the net of the oxygen and carbon dioxide delivery during ILP[41].

Protein catabolism generates ammonium and bicarbonate, which buffers the acid-base equilibrium[27]. *Ammonium* and *urea* can both be added to the perfusate and its clearance monitored as a parameter of functional recovery during ILP[27]. Similarly, metabolism of both *indocyanine green*, which depends on functional hepatocyte mass, and *lidocaine*, which is metabolized in the liver via cytochrome P450, is used to assess overall hepatic function[47,61].

Factor V, a pro-coagulant protein produced by hepatocytes, is clinically known as a sensitive marker of synthetic function. Factor V can be monitored in the perfusate during ILP, keeping into account that pigs can produce 5-fold the amount of Factor V produced by humans[62].

The production of *bile* is directly related to hepatocyte viability, metabolism and synthesis[42,45] and can be monitored during ILP by cannulation of the bile duct[45].

13

Histology:

A uniformly accepted histological scoring system to evaluate IRI severity is currently unavailable. The Oxford group designed a semi-quantitative score considering the degree of sinusoidal dilatation and congestion, hepatocellular vacuolization, mitosis, apoptosis and percentage of nonviable tissue[25,26]. Addressing specific features of donation after circulatory death, our group developed a similar score evaluating sinusoids dilatation, anoxic vacuoles formation, enlargement of the space of Disse, loss of parenchymal cells and cellular cohesion, and neutrophils infiltration[14,63].

Endothelial compartment

Endothelial injury:

V*ascular resistance*, which can be assessed real-time, increases during ILP in damaged livers[23]. A vascular resistance increase results from disruption of the endothelial cell lining and so-called no flow phenomenon and can therefore be regarded as an indirect marker of IRI[16,23–27,33,35,36,40,47,48].

Hyaluronic acid, a glycosaminoglycan metabolized by sinusoidal endothelial cells[64,65] accumulates in the hepatic microcirculation with ischemic endothelial injury and graft dysfunction[59]. Likewise, increased levels of hyaluronic acid have been observed during ILP and considered a marker of endothelium viability[25,26].

Cholangiocyte compartment

Cholangiocyte injury:

Biliary epithelial injury can be monitored by measuring the biliary concentration of cytoplasmic cholangiocyte enzymes including *gamma-glutamyl transferases* (GGT)*, alkaline phosphatase* (ALP), and LDH[16,29].

14

Biliary concentrations of *thiobarbituric acid reactive substances* as a marker of oxidative stress of cholangiocytes[29] have been also reported.

A composite score assesses the amount of bile duct wall necrosis, peribiliary vascular lesions, intramural bleeding and arteriolonecrosis of the peribiliary vascular plexus[66]. Integrity and proliferation of peribiliary glands were later integrated in this score[67] and used to asses bile duct viability after IRI during ILP[16].

Cholangiocyte function:

Bile production requires energy dependent secretion of bicarbonate by cholangiocytes as a buffer to the potentially detrimental bile acids. Some groups proposed assessment of cholangiocyte function by measuring *biliary concentration of glucose, bicarbonates, and pH*[16,29].

Analysis of the concentration of *bile acids* in bile fluid (along with their clearance in the perfusate)[24], and the *bile salt-to-phospholipid ratio*[68] may provide additional information on hepatic synthesis.

Immune compartment

IRI typically triggers inflammation with recruitment of leukocytes into the liver parenchyma, pro-inflammatory cytokine production, sinusoidal congestion, and edema. An increase in *liver weight* at the end of ILP may be related to the presence and severity of inflammation[16,23–26,32,33,35,47,48].

The appearance of the cytokines *Tumor Necrosis Factor-alfa* (TNF-α)*, Interleukin-8* (IL-8) *and Interleukin-10* (IL-10) in the perfusate directly indicates activation of pro-inflammatory pathways[47].

Oxidative stress during IRI can also be evaluated by quantifying the concentration of *lipid peroxides*[36,40].

15

Inflammation in the liver may lead to hepatocyte necrosis, apoptosis or autophagy: *Beclin 1* and *Caspase 3* may be measured as indicators of hepatocyte autophagy and apoptosis, respectively[29,36].

Discussion.

Our systematic review identified 23 articles in which pig ILP replaced LT to investigate IRI or to explore novel approaches to optimize liver preservation (the majority of which involved dynamic preservation). All the studies carried an unclear risk of bias as they generally underreport different aspects of the experimental environment and outcomes interpretation. Importantly, none of the studies compared ILP to actual liver transplantation in pigs and some of the steps and methodology undertaken by the different groups rely on assumed best practice rather than acquired evidences. Porcine ILP is not a standardized model and the variability in the methodology inhibits any direct comparative analysis between different settings. Indeed, pending uncertainties on circuit design, hemodynamic settings, and perfusate should be addressed in order to facilitate the comparison of results reflecting injury and function of the 4 main liver compartments.

The studies identified reported largely different circuit design and hemodynamic settings equally ensuring adequate perfusion of the liver and mimicking of IRI. However, none of the studies compared diverse ILP settings (ie open vs close system, flow-controlled vs pressure-controlled perfusion, 1 pump vs 2 pumps), hence it is not possible to comment on the superiority of a specific circuit design or hemodynamic to reproduce IRI and mimic LT.

Our knowledge of the nutritional needs of a liver isolated from a metabolically demanding organism is limited, and it is difficult to establish whether the liver displays active metabolism during ILP as, for example, elevated oxygen consumption has been associated to both functioning and failing livers[33,45]. Some groups infused insulin and glucose to support hepatic metabolism

16

during perfusion; however, the glucose transporter 2 (GLUT2) expressed on the surface of hepatocytes is not regulated by insulin[69]. Additionally, insulin does not stimulate glycolysis in the liver, but triggers glycogen synthesis and inhibits gluconeogenesis. Therefore, insulin and glucose infusion might replete the hepatocytes with glycogen rather than fueling the chain of aerobic oxidation to support the physiological needs of the liver.

Heparin is also commonly infused; however, the (anti)coagulative status of the liver during ILP is not well-studied. Some authors reported stable synthesis of coagulative factor V during perfusion[23,25,26,45], whilst others observed prolonged prothrombin time[31]. Currently, data on the effective production of fibrinogen (last effector of the coagulation cascade) and antithrombin (heparin-cofactor) during pig ILP are lacking.

Despite the existing uncertainties, ILP can be used to study events occurring in the early phases of reperfusion. Indeed, parameters of interest and biomarkers released during ILP tend to reflect mainly hepatocellular, endothelial, and -to a lesser extent- cholangiocyte injury, showing a pattern that fairly resembles our current knowledge on the sequence of events occurring in early stages of IRI in both animal experiments and clinical transplantation. Since ILP was never compared to LT, how to interpret parameters and biomarkers released during ILP or how to correlate them to relevant clinical outcomes, including recipient survival, graft function, and posttransplant complications remains unknown.

Obviously, ILP has its advantages and limitations, especially regarding the reproduction and the evaluation of late phases of reperfusion injury. Indeed, at present a maximum of 72 hours, with most studies not extending perfusions over 24 hours, has been reported. Short ILP might not capture all the events occurring during IRI, whilst during extended ILP the absence of hormonal, neural, and metabolic feedback might become more relevant. Although those who described ILP lasting 24 hours did not observe such disturbances, it is yet unclear whether perfusion mimicking

17

the first day after LT would be enough to simulate the most relevant changes occurring at graft reperfusion, as the exact kinetics of IRI are still unknown[70]. Secondly, monocytes and other immune cells are usually mobilized in the late reperfusion phase from primary and secondary lymphoid organs (ie lymph-nodes, spleen, and bone marrow) actively contributing to the pathophysiology of IRI[16], and the lack of this immune interaction might blunt IRI.

Finally, remote injuries related to IRI or long-term drawbacks after LT, such as renal impairment, cannot be evaluated. Nonanastomotic biliary strictures represent a clinically relevant problem, typically occurring within 1 month up to 1 year after transplantation. However, our understanding of the pathogenesis is still limited and reproducible animal models of nonanastomotic strictures are currently missing[71].

The limitations on investigating the reperfusion injury during ILP, might also be related to the lack of reliable biomarkers. Indeed, markers of cholangiocytes injury, function, and regeneration are only reported sporadically and early surrogate of biliary complications have never been described during porcine ILP. Similarly, our capacity to monitor injury and functional recovery of sinusoidal endothelial cells, known to be the least resistant to ischemia and to play a pivotal role in IRI[72], is also very limited.

In summary, porcine ILP can be considered a valuable model to study events of the early reperfusion phase of the ischemia reperfusion cascade that occurs during organ transplantation and a particularly convenient method to explore novel approaches to protect or optimize liver grafts. The advent of dynamic preservation holds potentials to revolutionize the present LT practice. However, a lot of our current knowledge on the effects and benefits of liver dynamic preservation are deduced from ILP models. As all models, ILP has limitations of which researchers need to be aware while interpreting and comparing results. Animal transplantation

18

models should still be considered to further confirm ILP findings, to explore longer-term outcomes, and to evaluate graft and recipient survival.

A standardization of the ILP model is desired and would allow direct comparison of results. The scarce available knowledge on the physiology of an isolated liver (ie metabolism, coagulative status, endothelial and cholangiocyte function) limits progress in both our understanding of hepatic IRI and development of alternative preservation methods by means of dynamic preservation. To advance the field, further studies are needed to compare ILP to LT and to deepen our knowledge of mechanisms by which technical aspects of perfusion might influence IRI.

Figure Legend:

Figure 1. **Schematic illustration of the porcine ILP models identified after systematic literature review.** Wide variation in the design exists among the 11 set-ups considered and the drainage of the Inferior Vena Cava (IVC) constitutes the major difference. Open circuits (from A to H) passively drain the IVC outflow either in the liver receptacle or in a venous reservoir, while in closed circuits (from I to K) the IVC is cannulated and directly connected to the pump.

In all set-ups, the perfusion of the liver is performed via both the Portal Vein (PV) and the Hepatic Artery (HA), except for the model of Amsterdam (A) where only the PV is perfused. The majority of the groups divert the flow generated by a single pump into both PV and HA circulation, with the exception of the model from Guangzhou (C), Groningen (E), and Washington (G) in which 2 distinct circuits separately perfuse PV and HA. In the model proposed by the groups from Oxford (I), Toronto (J), Leicester and Lyon (K), the PV is connected to a reservoir and perfused by gravity only. A dialysis unit was included in the circuits described by the group of Berlin (B), and Washington (G). The concentration of administered oxygen was identical in the PV compared to the HA circulation in most of the circuits, with the exception of the models of Guangzhou (C), Göttingen (D), Groningen (E), and Washington (G), in which the partial oxygen tension was kept lower in the PV.

Note that the model of Pittsburgh[36] could not be included in the figure due to insufficient details on circuit design reported in the original paper.

In the figure - HA: hepatic artery; Heat: heat exchanger; CV: caval vein; O2: oxygenator; P: pump; PV: portal vein.

Table 1 Summary of different approaches to reproduce the steps occurring before graft reperfusion described in porcine ILP set-ups identified after systematic review of the literature.

Research Group	Graft flush	Preservation phase	Anastomoses phase
Amsterdam [30]	5 L cold Ringer's lactate solution	24 h cold storage	30 min rewarming
Berlin [40,41]	5 L cold Euro-collins solution	3 h cold storage	-
Bonn [39]	500 mL cold saline solution	-	30 min at room temperature
Cleveland [19,38,55,56]	1 L saline solution at 21°C	-	-
Essen [44]	2 L new-HTK	18 h cold storage	30 min at room temperature
Göttingen [49]	5 L cold HTK	0.5 – 20 h cold storage	-
Groningen [32]	2 L cold HTK	2 h cold storage, or 2 h cold dynamic preservation	-
Guangzhou [33]	-	10 h cold storage, or 10 h warm dynamic preservation	-
Leicester [42]	3 L cold water	Cold storage	-
Leuven [17]	5 L cold HTK	-	Livers immersed in warm preservation solution progressively rewarmed up to 37°C in 30min
Lyon [35]	500 mL Ringer's lactate solution, or 500 mL Hydroxyethylamidon, or 1 L UW	Cold storage	-
Oxford [26–29]	2 – 3 L cold Euro-collins solution, or 3 L cold hyperosmolar citrate solution	1 – 24 h cold storage, or 20 – 24 warm dynamic preservation	45 – 60 min at room temperature
Padova [67]	2 L cold Celsior	6 h cold storage, or 6 h subnormothermic dynamic preservation	-
Pittsburgh [36]	2 L cold Ringer's lactate solution	24 h cold preservation	-
Toronto [31]	cold UW solution	4 – 12 h cold storage	-
Washington [34]	3 L cold HTK solution	6 h cold storage, or 6 h warm dynamic preservation	-
HTK: histidine tryptophan ketoglutarate solution; UW: university of Wisconsin solution

ALP: alcaline phosphatase; ALT: alanin transferase; AST: aspartate transferase; ATP: adenosine tri-phosphate; GGT: gamma glutamil transferase; H&E: hematoxiline and eosin staining; HSP70: heat shock protein 70; IL: inter-leukin; IRI: ischemia reperfusion injury; LDH: lactate dehydrogenase; TBARS: thiobarbituric acid reactive substances; TNF-α: tumor necrosis factor alpha.

SDC, Methods

Data source, search strategy and eligibility criteria

To investigate whether Isolated Liver Perfusion (ILP) in pigs is a reliable model to study the hepatic Ischemia Reperfusion Injury (IRI) and to which extent it can substitute animal Liver Transplantation (LT), a protocol of a systematic review of animal studies was written in accordance with the guidelines of the Systematic Review Center for Laboratory animal Experimentation (SYRCLE)[1], approved by all authors, registered, and published within the CAMARADES database (available at http://www.dcn.ed.ac.uk/camarades). Then, a search strategy was built according to Leenaars M et al[2] and performed on 18th April 2017.

The Medline (PubMed) database was searched for 'isolated liver perfusion' and ('ischemia reperfusion injury' or 'liver transplantation') and 'pig', including various combination of MeSH terms, phrases, and relevant free-text synonyms (Appendix S1, SDC). To identify potential relevant studies, titles and abstracts were screened by 2 independent reviewers (NG and SL); discrepancies were solved through discussion. Next, the full text of the selected items were screened for eligibility according to the inclusion and exclusion criteria defined upfront in the protocol of the systematic review. Peer-reviewed studies reporting on the use of ILP as a surrogate of LT in pigs of every strain, gender, and age were considered eligible. Exclusion criteria were studies in which ILP was utilized exclusively as dynamic preservation, review article, letter to the editor, and publication with no full-text available or published in languages other than English. Finally, the reference list of every article was searched for relevant titles that could not be identified in the primary search.

Data extraction

Information on the presence of animal transplant model as a control group, circuit design, pressure and flow, type of perfusate, temperature, oxygenation, and duration of perfusion was collected. Outcomes investigated by selected studies were clustered as markers referring to the hepatocytes, sinusoidal endothelial, biliary, and immune compartments.

Quality assessment

The quality of the selected papers was evaluated using SYRCLE's risk of bias tool for animal studies[3], in which the assessment of selection, performance, detection, attrition, and reporting bias is tailored on the specific features of laboratory animal experimentation.

Research Strategy

The following strategy was built according to Leenaars M et al[2], and it was performed on 18th April 2017 to search the Medline (PubMed) database.

<u>Research string 1 (RS1)</u>: isolated liver perfusion (intervention/methodology of interest)

MeSH: "perfusion"[Mesh]

Free-text: "isolated liver perfusion"[tiab] OR "isolated hepatic perfusion"[tiab] OR "ex vivo liver perfusion"[tiab] OR "ex-vivo liver perfusion"[tiab] OR "ex vivo hepatic perfusion"[tiab] OR "ex-vivo hepatic perfusion" OR "ex situ liver perfusion"[tiab] OR "ex-situ liver perfusion"[tiab] OR "ex situ hepatic perfusion"[tiab] OR "ex-situ hepatic perfusion"[tiab] OR "in vitro liver perfusion" OR "in-vitro liver perfusion"[tiab] OR "in vitro hepatic perfusion"[tiab] OR "in-vitro hepatic perfusion"[tiab] OR "isolated liver reperfusion"[tiab] OR "isolated hepatic reperfusion"[tiab] OR "ex vivo liver reperfusion"[tiab] OR "ex-vivo liver reperfusion"[tiab] OR "ex vivo hepatic reperfusion"[tiab] OR "ex-vivo hepatic reperfusion" OR "ex situ liver reperfusion"[tiab] OR "ex-situ liver reperfusion"[tiab] OR "ex situ hepatic reperfusion"[tiab] OR "ex-situ hepatic reperfusion"[tiab] OR "in vitro liver reperfusion" OR "in-vitro liver reperfusion"[tiab] OR "in vitro hepatic reperfusion"[tiab] OR "in-vitro hepatic reperfusion"[tiab]

<u>Research string 2 (RS2)</u>: ischemia reperfusion injury or liver transplantation (disease of interest)

MeSH: "reperfusion injury"[Mesh:NoExp] OR "liver transplantation"[Mesh]

Free-text: "ischemia reperfusion injury"[tiab] OR "ischemia-reperfusion injury"[tiab] "ischemia/reperfusion injury"[tiab] OR "reperfusion injuries"[tiab] OR "reperfusion damage*"[tiab] OR "ischemic injur*"[tiab] OR "ischaemic injur*"[tiab] OR "ischemic damage"[tiab] OR "ischemic damages"[tiab] OR "ischemic damaged"[tiab] OR "ischemic damage*"[tiab] OR "ischemia injur*"[tiab] OR "ischaemia injur*"[tiab] OR "ischemia damage*"[tiab] OR "ischaemia damage*"[tiab] OR "iri"[tiab] OR "i/r"[tiab] OR "IRI"[tiab] OR "I/R"[tiab] OR "liver transplantation"[tiab] OR "liver transplant"[tiab] OR "liver transplantation*"[tiab] OR "liver transplant*"[tiab] OR "LT"[tiab] OR "OLT"[tiab] OR "LT*"[tiab] OR "OLT*"[tiab]

<u>Research string 3 (RS3)</u>: swine (animal of interest)

MeSH: "swine"[Mesh]

Free-text: "pig"[tiab] OR "pigs"[tiab] OR "pig*"[tiab] OR "porcine"[tiab] OR "porcin*"[tiab] OR "swine"[tiab] OR "warthogs"[tiab] OR "wart hogs"[tiab] OR "wart hog"[tiab]

<u>Final research string:</u>

<u>RS1</u> (*MeSH* OR *Free-text*) AND <u>RS2</u> (*MeSH* OR *Free-text*) AND <u>RS3</u> (*MeSH* OR *Free-text*)

("perfusion"[Mesh] OR "isolated liver perfusion"[tiab] OR "isolated hepatic perfusion"[tiab] OR "ex vivo liver perfusion"[tiab] OR "ex-vivo liver perfusion"[tiab] OR "ex vivo hepatic perfusion"[tiab] OR "ex-vivo hepatic perfusion" OR "ex situ liver perfusion"[tiab] OR "ex-situ liver perfusion"[tiab] OR "ex situ hepatic perfusion"[tiab] OR "ex-situ hepatic perfusion"[tiab] OR "in vitro liver perfusion" OR "in-vitro liver perfusion"[tiab] OR "in vitro hepatic perfusion"[tiab] OR "in-vitro hepatic perfusion"[tiab] OR "isolated liver reperfusion"[tiab] OR "isolated hepatic reperfusion"[tiab] OR "ex vivo liver reperfusion"[tiab] OR "ex-vivo liver reperfusion"[tiab] OR "ex vivo hepatic reperfusion"[tiab] OR "ex-vivo hepatic reperfusion" OR "ex situ liver reperfusion"[tiab] OR "ex-situ liver reperfusion"[tiab] OR "ex situ hepatic reperfusion"[tiab] OR "ex-situ hepatic reperfusion"[tiab] OR "in vitro liver reperfusion" OR "in-vitro liver reperfusion"[tiab] OR "in vitro hepatic reperfusion"[tiab] OR "in-vitro hepatic reperfusion"[tiab]) AND ("reperfusion injury"[Mesh:NoExp] OR "liver transplantation"[Mesh] OR "ischemia reperfusion injury"[tiab] OR "ischemia-reperfusion injury"[tiab] "ischemia/reperfusion injury"[tiab] OR "reperfusion injuries"[tiab] OR "reperfusion damage*"[tiab] OR "ischemic injur*"[tiab] OR "ischaemic injur*"[tiab] OR "ischemic damage"[tiab] OR "ischemic damages"[tiab] OR "ischemic damaged"[tiab] OR "ischemic damage*"[tiab] OR "ischemia injur*"[tiab] OR "ischaemia injur*"[tiab] OR "ischemia damage*"[tiab] OR "ischaemia damage*"[tiab] OR "iri"[tiab] OR "i/r"[tiab] OR "IRI"[tiab] OR "I/R"[tiab] OR "liver transplantation"[tiab] OR "liver transplant"[tiab] OR "liver transplantation*"[tiab] OR "liver transplant*"[tiab] OR "LT"[tiab] OR "OLT"[tiab] OR "LT*"[tiab] OR "OLT*"[tiab]) AND ("swine"[Mesh] OR "pig"[tiab] OR "pigs"[tiab] OR "pig*"[tiab] OR "porcine"[tiab] OR "porcin*"[tiab] OR "swine"[tiab] OR "warthogs"[tiab] OR "wart hogs"[tiab] OR "wart hog"[tiab])

40

SDC, Results

Database search

The primary search originated 241 items and additional 16 papers were included after searching the reference lists for relevant titles. A total of 257 abstracts were independently screened by 2 reviewers (NG and SL) identifying 32 potentially eligible publications. After assessment of the full-text articles, a total of 23 items were included in the quality assessment (Figure S1).

Quality assessment

ILP was used as a substitute of LT to test different approaches to prevent or reduce the severity of IRI in all identified papers; however, none of them included animal transplantation as a control group. All the studies considered carried an unclear risk of bias as they generally underreported different aspects of the experimental setting (Table S1). Randomization was performed in 7/23 (30.4%) studies and all were single-blind. The differences in baseline characteristics of animals were considered and results adjusted accordingly in 26% of the papers. Every study reported insufficient details concerning the randomization of animal housing conditions, blindness of caregivers, and selection of animals for measurement of specific outcomes.

Only in 7 studies (30.4%) the measurement of at least 1 outcome was performed by a researcher who was blind for the allocation group of the animal. The reason for animal drop outs were insufficiently described in all 23 articles. All studies were free from reporting bias.

41

Table S1: Quality assessment of the selected publications according to the SYRCLE's risk of bias tool for animal studies[3].

Research group	Article	Year of Publication	Selection bias			Performance bias		Detection bias		Attrition bias	Reporting bias	Other biases
