A cross-sectional association between visual impairment and psychosis exists, but longitudinal evidence from children and young people is limited. We investigated whether childhood visual acuity was associated with subsequent psychotic experiences. Our sample was 6686 individuals from the Avon Longitudinal Study of Parents and Children (ALSPAC). We investigated whether our primary exposures, best corrected visual acuity at ages 7 and 11, were associated with psychotic experiences at ages 17 and 24. We also tested whether the following exposures at ages 7 and 11 were associated with subsequent psychotic experiences: requiring glasses, presence of any visual impairment, and between-eye visual acuity difference; and at age 7: strabismus, measures of binocular vision, history of eye patch, near vision impairment, and abnormal saccadic or pursuit eye movements. Analyses used multilevel models before and after adjusting for confounders. Odds of psychotic experiences increased with each 0.1-point deterioration in visual acuity score at age 11 (adjusted odds ratio [AOR] 1.23; 95% confidence interval [CI] 1.06–1.42), and at age 7 (AOR 1.18; 95% CI 1.00–1.40). Wearing glasses and visual impairment at age 11 were associated with psychotic experiences (AOR 1.63; 95% CI 1.21–2.19; AOR 1.64; 95% CI 1.23–2.19, respectively). There was no evidence of an association with other visual exposures. Visual acuity impairment in childhood is associated with psychotic experiences in late adolescence. Future research should aim to elucidate the nature of this association.

Key words: psychotic experiences/schizophrenia/visual acuity/visual impairment/ALSPAC

Introduction

Psychotic illnesses reduce quality of life and life expectancy.^{1,2} The point prevalence of schizophrenia is

approximately 0.5%,³ whilst symptoms such as delusions and hallucinations affect 5%–6% of nonclinical populations.^{4,5} The peak incidence of both psychotic symptoms and diagnoses occurs in adolescence,^{5–7} which has recently been defined as ages 10–24 based on culturally extended periods of transitioning to adulthood.⁸

Visual impairment, typically defined as reduced visual acuity, has been proposed as a risk factor for psychotic symptoms and illnesses.^{9,10} In younger people the most common cause of reduced visual acuity is myopia,¹¹ when light is focused too far in front of the retina causing blurred distance vision.¹² Myopia affects at least 30% of people in Europe,¹³ but can often be corrected using lenses.¹⁴ Best corrected visual acuity refers to the highest acuity achievable with such aids.

The “Protection against Schizophrenia” (PaSZ) model proposes that aberrant visual input contributes to development of schizophrenia, and that optimal and lifelong absent vision protect against it.⁹ This is based on an absence of reported cases of a congenitally cortically blind person developing schizophrenia, despite shared risk factors.¹⁵ Silverstein et al have observed that compensatory higher-order processes in congenitally blind individuals enhance attention and auditory perceptual abilities in a reverse pattern to typical cognitive impairments seen in schizophrenia, potentially creating a buffering effect.¹⁵ Individuals whose vision deteriorates from normal lack these changes and may be susceptible to psychosis due to reliance on vision for cognitive processing.

Cross-sectional evidence shows that people with visual impairment are more likely to have psychosis than people without,¹⁶ but evidence regarding a temporal association is mixed.^{17–21} Furthermore, most studies focused on adults, although any prevention strategies might be most effective during neurodevelopment and before the peak incidence of first episode psychosis.²² Only 2, relatively

small longitudinal studies were conducted with children. Visual dysfunction at ages 4 and 11–13 was associated with an increased risk of psychotic illness at ages 22 and 31–33, respectively.^{23,24} Both studies used composite exposure measures including squint and eye movement scores combined with acuity. It is therefore unclear which aspects of ocular function drove the association. The studies do not present results adjusted for confounders.

To our knowledge, this is the first large study investigating whether childhood visual impairment is associated with future psychotic experiences. We investigated whether poorer visual acuity at age 7 or 11 was associated with psychotic experiences at ages 17 and 24. We also assessed, as secondary exposures: tests of binocular vision, near vision impairment, and eye movements; in line with other studies.^{23–25}

Methods

We published our advance protocol on *protocols.io*.²⁶

Sample

The Avon Longitudinal Study of Parents and Children (ALSPAC) is an ongoing UK birth cohort designed to further knowledge of determinants of illness and health.^{27,28} All pregnant women in the catchment area with a due date between April 1, 1991 and December 31, 1992 were eligible for invitation at antenatal appointments and through advertisements, and 14 541 were originally recruited.^{27,28} Their children were followed into adulthood. At age 7, 913 additional children were enrolled. In total, 14 901 infants surviving to age 1 were included.²⁹ The ALSPAC Law and Ethics Committee and Local Research Ethics Committees provided ethical approval for the study and participants gave written informed consent. Study data were collected and managed using the REDCap electronic data capture tool hosted at the University of Bristol: a secure, web-based software platform.³⁰

Further details of the cohort profile and a fully searchable data dictionary can be obtained through the study website (<https://www.bristol.ac.uk/alspac/>).

Outcome Variable

The Psychotic-Like Symptoms Screening Interview (PLIKSi) is a semistructured interview based on the Schedule for Clinical Assessment in Neuropsychiatry (SCAN),³¹ designed to assess psychotic experiences in nonclinical populations.³² It includes 11 core questions about psychotic experiences (hallucinations, delusions, and thought interference).³² The PLIKSi has been validated in ALSPAC and was administered by trained interviewers.³² Our primary outcome measures were psychotic experiences at age 17 or 24 as binary variables (suspected or definite psychotic experiences/none). We did not

include symptoms occurring only in partial sleep states or fever, consistent with standard use of the PLIKSi.³³

Exposure Variables

Trained orthoptists performed visual assessments at ages 7 and 11. Visual acuity was measured using the Early Treatment Diabetic Retinopathy Study (ETDRS) chart to give a Logarithm of Minimal Angle of Resolution (LogMAR) score ranging from -0.3 to 1.0 .³⁴ Zero is equivalent to “normal” 6/6 or 20/20 vision, with negative numbers indicating “better than normal” and positive numbers indicating “worse than normal” vision.³⁵ Carers reported whether children wore glasses. Children who had used glasses in the preceding 6 months wore these, and carers supported with matching cards if the child did not know the alphabet. Testing was performed using patches to occlude 1 eye and repeated using a pinhole; a simple device to improve acuity in refractive errors including myopia.³⁵ Best corrected visual acuity was the better measurement; with or without the pinhole.

Additional measures at age 7 included: presence of manifest strabismus (consistent squint)³⁵ on cover/uncover test; abnormal binocular fusion (ability to fuse images from each eye),³⁶ determined by prism cover and Worth Four Dots tests; history of eye patch reported by parent or carer; autorefractometry results; and abnormal pursuit (smooth) and saccadic (rapid) eye movements as observed by the examiner using a picture target and light.³⁷ The autorefractor estimates errors in focusing of light on the retina in Dioptres; a measure of lens strength required for correction, with positive numbers indicating near visual impairment.^{38,39}

Our primary exposure variables were best corrected LogMAR scores at ages 7 and 11 as continuous variables, as the most informative measure of overall visual ability. We tested between-eye visual acuity difference at each age as secondary continuous exposure variables.²⁰ We created a binary variable to compare types of vision: normal vision (LogMAR ≤ 0) without glasses, or visual impairment (reduced vision; or normal vision with glasses). We also analyzed as binary exposure variables: glasses use in past 6 months (yes/no) at ages 7 and 11; and at age 7, presence of manifest strabismus; history of patch (as a proxy for amblyopia or “lazy eye”)³⁵; abnormal prism test; abnormal Worth Four Dots test; near vision impairment ($\geq +2.00$ Dioptres in either eye on autorefractometry); abnormal pursuit movements; and abnormal saccadic eye movements.

Putative Confounding Variables

Confounding variables were selected a priori based on available literature^{5,33,40–49} and included in final models if missing data did not preclude complete case model analyses.

We included sex of child and socioeconomic status of mother, but not ethnicity of parents, owing to small numbers in all ethnic groups except White British (96%).²⁷

Tobacco use and infection in pregnancy were established by questionnaires administered to expectant mothers, and we assessed these as binary variables (present/absent). We included maternal vitamin D consumption estimated from a dietary questionnaire at 32 weeks' gestation as a continuous variable and number of previous pregnancies reported as a discrete variable.

We included Intelligence Quotient (IQ) score at age 8 as a continuous variable, only in analyses when the exposure was measured subsequently (at age 11). We used parental education, a categorical variable for each of mother and mother's partner (CSE/O level/A level/vocational/degree).

The Strength and Difficulties Questionnaire (SDQ) is a measure of childhood adjustment and psychopathology.⁵⁰ Parents completed this when children were aged 6–7, and we included it as a continuous measure of baseline psychopathology. We included maternal Edinburgh Postnatal Depression Scale (EPDS) score when children were 2–3 years old.⁵¹

Analysis

Descriptive Statistics We calculated numbers and percentages for categorical variables. We report mean and standard deviation for continuous variables that appeared normally distributed on visual inspection, and median and interquartile range for skewed variables.

Missing Data Some participants dropped out and others missed assessments intermittently (figure 1). To maximize the sample size and reduce attrition bias, our main analyses used a multiply imputed dataset of participants with a LogMAR score at age 7 and at least 1 of 10 available short Mood and Feelings Questionnaire (sMFQ) scores taken from ages 9 through to 22. The sMFQ is a 13-item self-report measure of depressive symptoms⁵² which is associated with the PLIKSi in the ALSPAC cohort and improves prediction of missing PLIKSi values.⁵³ For example, for the sMFQ score with least missing data (at age 9), the odds of scoring positive on the PLIKSi were increased by 11% for each additional point (odds ratio [OR] 1.11, 95% confidence interval [CI] 1.07–1.16).

We used chained equations through the command *mi impute chained* in STATA version 16.0⁵⁴ to generate the imputed dataset, with 100 imputations, including all exposure, confounder, and outcome variables. This process uses a “burn-in” of 10 cycles for each imputation. We imputed binary variables using logistic regression, ordinal variables using ordered logistic regression, and continuous variables using linear regression. Where continuous variables were nonnormally distributed, we used progressive mean matching via the *pmm* command to impute only observed values, making the distribution of imputed variables consistent with the observed dataset.⁵⁵

Multiple imputation (MI) relies on the assumption that data are Missing At Random (MAR): ie, that missing values are associated with variables observed in the dataset. The latter assumption was made more likely through inclusion of auxiliary variables (variables associated with missing data but not included in our main analyses), such as mother's housing situation, family income, conduct disorder score, and mother's marital status, which are associated with missingness in the ALSPAC data.^{53,56}

Primary Analyses We used multilevel logistic regression (on the multiply imputed dataset) in *Stata version 16.0*.⁵⁴ Imputed data were combined following Rubin's rules,⁵⁵ producing an OR for scoring positive on the PLIKSi at age 17 or 24 for each 0.1-point deterioration in LogMAR score. Our model accounted for within-individual correlation between PLIKSi scores at age 17 or 24 using a random intercept for each individual. We repeated this analysis using each exposure; unadjusted and adjusted for putative confounding variables. We did not use Bonferroni corrections because multiple exposures were testing the same a priori hypothesis, and Bonferroni tests increase the chance of a type II error without significant benefit in this situation.⁵⁷

Sensitivity Analyses We report results from the complete case sample for comparison.

Additionally, visual hallucinations directly secondary to reduced vision in Charles Bonnet syndrome are a well-recognized phenomenon, and generally considered distinct from other psychotic experiences.⁵⁸ We repeated our primary analyses in the complete case sample excluding individuals who reported visual hallucinations except in states of fever, intoxication, or sleep states, to assess whether these drove any association.

Results

Description of the Sample

Characteristics of participants according to visual acuity (“normal” vision [LogMAR ≤0] and reduced vision [LogMAR >0]) are shown in table 1.

Six thousand six hundred and eighty-six individuals provided visual acuity scores aged 7 and at least 1 MFQ score. These individuals comprised the multiply imputed sample in primary analyses. Complete data on the primary exposure at age 7, all confounders, and outcome data at one or both of ages 17 and 24 were available for 3058 individuals. These individuals comprised the complete case sample. Differences between participants with and without missing data (ie, those in the imputed and complete case samples) are shown in supplementary table 1.

From the sample with complete visual acuity data at age 7, 481 (11.5%) individuals with primary exposure data scored positive on the PLIKSi at 1 or more time points; 261 (7.4%) at age 17 and 291 (10.1%) at age 24.

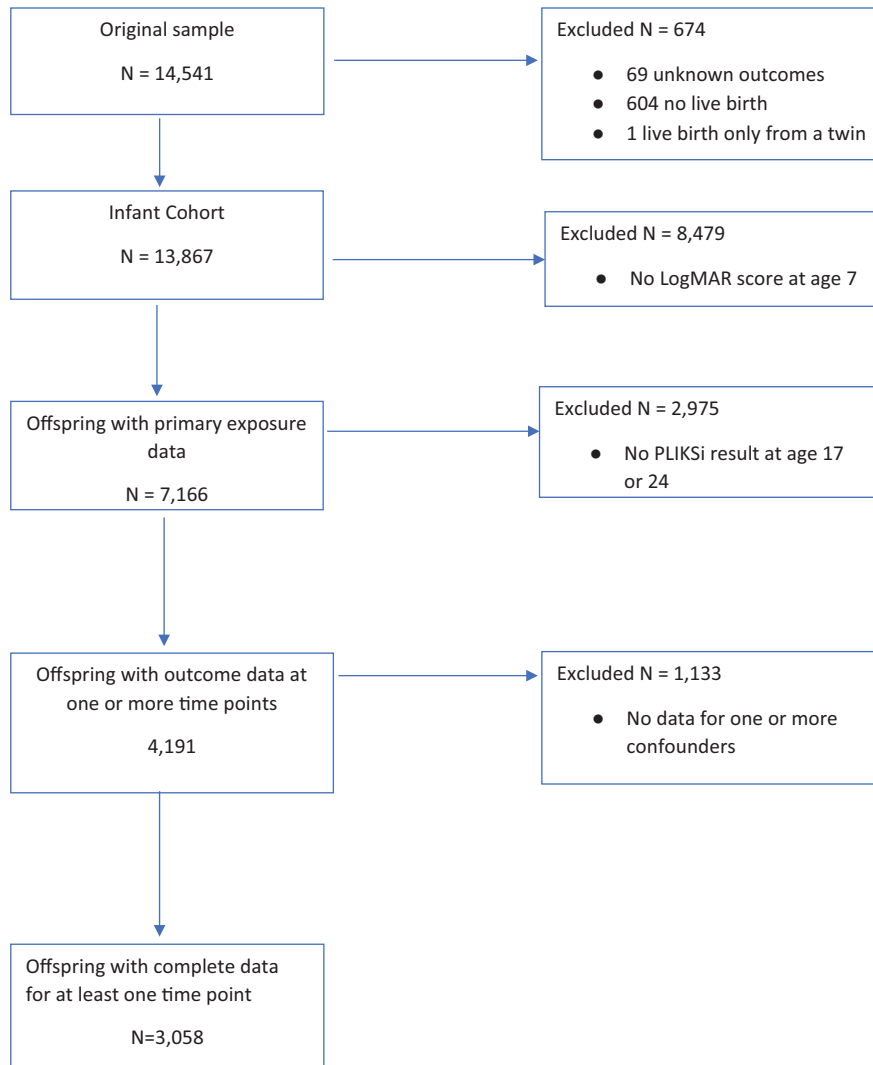

Fig. 1. Missing data flowchart. *Note:* LogMAR, Logarithm of Minimal Angle of Resolution; N, number of participants; PLIKSi, Psychotic-Like Experiences Symptoms Interview.

Potential confounders measured but not included due to a high proportion of missing data (%) included: resuscitation at birth (46), gestational age at birth (44), and polygenic risk score for schizophrenia (28). Bivariable models in the sample with all available data suggested that these were not significant confounders, however.

Primary Results

In the MI analysis, we found evidence that the odds of adolescent psychotic experiences increased with each 0.1-point deterioration in LogMAR score at age 7: OR 1.26 (95% CI 1.06–1.49), and at age 11: OR 1.31 (95% CI 1.13–1.51) (table 2). Evidence of these associations attenuated but remained after adjustments; at age 7: adjusted odds ratio (AOR) 1.18 (95% CI 1.00–1.40), and at age 11: AOR 1.23 (95% CI 1.06–1.42). Visual inspection of histograms suggested that greater variation in the exposure could account for the stronger evidence of association at age 11 relative to age 7.

Secondary Analyses

Following adjustment there was evidence of association between greater odds of adult psychotic experiences and needing glasses (AOR 1.63, 95% CI 1.21–2.19); and any visual impairment (LogMAR >0 or requiring glasses) (AOR 1.64, 95% CI 1.23–2.19), at age 11 (table 2). AORs were also suggestive of a positive association at age 7, but statistical evidence was weaker.

There was no evidence of an association with the outcome for between-eye visual acuity difference at either age, or with manifest strabismus, abnormal prism test, history of eye patch, abnormal Worth Four Dots test, impaired near vision, or abnormal saccadic or pursuit eye movements at age 7, either before or after adjustment.

Complete Case Sample

When we repeated the analyses in the complete case sample, estimates for the association between psychotic

^bRelative to group with normal vision without glasses.

^cAdjusted for sex; mother's socioeconomic status; educational level of mother and mother's partner; maternal smoking during pregnancy; perinatal infection during first trimester; parity of mother during pregnancy; mother's reported vitamin D intake during pregnancy; Strengths and Difficulties Questionnaire (SDQ) score aged 81 months; and maternal Edinburgh Postnatal Depression Scale (EPDS) score in pregnancy.

* $P < .05$.

abnormal pursuit eye movements (AOR 0.47, 95% CI 0.24–0.90) at age 7 and psychotic experiences, that was not seen in MI analyses.

Sensitivity Analysis

Excluding outcome measures from individuals who reported visual hallucinations at each time point did not weaken the evidence of associations in the complete case sample (supplementary table 2).

Discussion

Main Findings

There are 2 plausible explanations for our findings that best corrected visual acuity in childhood; needing glasses; and any visual impairment aged 11 are associated with future psychotic experiences. First, reduced childhood visual acuity may be a risk factor for these experiences. Our findings are consistent with the PaSZ model, and previous work proposing this.^{9,15} We included no known blind participants, so can comment on the first PaSZ model assertion, that visual impairment is associated with an increased risk of psychosis; but not the second, that absent vision is protective. Alternatively, our findings could be explained by early life central nervous system dysfunction predisposing to both visual impairment and psychosis.

Although we found evidence that glasses use and visual impairment at age 11 are associated with psychotic experiences, there was very weak evidence for these exposures at age 7. Best corrected visual acuity improved overall at age 11 compared to age 7 with a slightly broader distribution of values, suggesting that we were predominantly assessing differences within the “normal” range. In our multiply imputed dataset, more children wore glasses at age 11, allowing greater power to detect the association with glasses use. The increase in corrected myopia prevalence is expected since a process of ocular elongation occurs in infants and may continue until adulthood.¹⁴

The finding that eye movement abnormalities and squint were not associated with psychotic experiences seems surprising, given that these are some of the most widely replicated neurological abnormalities in schizophrenia.⁵⁹ This might be because these measures are associated with psychotic illnesses but not other types of psychotic experience, or because they occur closer to the time when psychotic experiences are established, or result from these.

Strengths and Limitations

To our knowledge, this is the first large study to assess the association between reduced childhood visual acuity and psychotic experiences in adolescence. Strengths include the use of a large birth cohort, and the ability to consider

Table 3. Odds of Scoring Positive on Psychotic-Like Symptoms Interview (PLIKSi) According to Eyesight Variables in Complete Case Sample

**P* < .05.

a wide range of potential confounders. The inclusion of children at age 7 is particularly helpful in the context of vision. The resulting age range represents the widest consensus as to when the visual pathway is reaching its final stages of development. Therefore, the development of amblyopia (diminished vision secondary to impaired visual stimulation during this period) would most likely have manifested in this sample of children, and the subsequent measure of reduced visual acuity would have been identified and included in analysis.⁶⁰

Several limitations should be noted. The ALSPAC cohort consists mostly of White British participants,⁶¹ and cannot be considered fully representative of the population of the UK or global community. Although we aimed to include a wide range of confounding variables, residual and unmeasured confounding cannot be eliminated. The proportion of attrition and missing data in ALSPAC is also substantial and could bias findings. In our sample, 57% of participants with complete primary exposure data aged 7 were missing data in the confounders or outcome. The negative association with strabismus and eye movements seen in the complete case sample suggests bias caused by missing data. We have aimed to mitigate this by using MI; simulations in the ALSPAC dataset show that even when outcome data are Missing Not At Random (MNAR), use of MI with appropriate auxiliary variables gives less biased results compared to those from complete case analyses.⁶²

Although visual acuity was measured objectively, full engagement with the process was required, and children's motivation may have influenced test results. Reducing visual acuity to a binary measure reduces its sensitivity, and even small differences within the normal range of vision can lead to significant problems in visual processing. However, we still found associations.⁶³ We could not assess uncorrected acuity, which likely led to an underestimate of the true strength of associations. Conversely, the PLIKSi relies on self-reporting, and it is possible that psychotic experiences were under-detected due to stigma, which might have weakened ability to detect an association.

Although we have shown an association between visual acuity and psychotic experiences, this does not necessarily equate to an association with psychotic illnesses, since these phenomena do not entirely overlap.⁵ Psychotic experiences are associated with a range of psychiatric morbidity,⁵ and so our findings could be driven by an association between visual impairment common mental disorder. Even so, the PaSZ model describes a gradient of risk of psychotic symptomatology as a continuous phenomenon according to degree of visual capacity, and should therefore be generalizable to a broad range of psychotic experiences.⁹

We have not explored possible mediators or effect modifiers of the association in this study. Confounders such as shared genetic mechanisms or risk factors such

as birth trauma could explain the association.⁶⁴ It is also possible that subsequent environmental influences, such as bullying or trauma, might lie on a causal pathway between visual impairment and psychosis.⁶⁵

Comparison With Other Literature

Our findings extend those from 2 small cohort studies of children which found that ocular deficits predicted adulthood diagnosis of schizophrenia.^{23,24} We have demonstrated this association in a large sample, using psychotic experiences rather than diagnoses. We have found that visual acuity impairment specifically, rather than other ocular measures, appears to account for the association. This might be because visual acuity impairments affect more people, leading to greater power. Alternatively, it might be because acuity deficits emerge earlier in the development of central nervous system dysfunction than do other ocular deficits. Our results are consistent with those from a Swedish cohort study, which showed that poorer visual acuity at ages 18–19 was associated with subsequent diagnosis of psychotic illnesses.²⁰ The Swedish study also found that between-eye visual acuity difference was associated with psychotic illness. We did not replicate this finding: perhaps because we measured corrected rather than uncorrected visual acuity, so were less likely to detect between-eye differences; or because this association did not exist in our sample, which was younger; or because we explore psychotic experiences rather than illnesses.²⁰ The Swedish study is one of the 2 largest cohort studies in older adolescents on this topic. The second, Israeli study gave conflicting findings despite reporting on a comparable population of young army conscripts aged 16–17. It reported that refractive errors in late adolescence were negatively associated with subsequent schizophrenia.²¹ It did not describe how refractive error was defined, so perhaps only severe visual impairment was counted as an exposure, which could explain the discrepancy both with our study and the Swedish study.

A 2020 systematic review collated studies that used optical coherence tomography and electroretinography (ERG) to compare ophthalmic structure and function in people with schizophrenia and people without.⁶⁶ Across studies, there is evidence of retinal thinning and altered retinal waveforms in schizophrenia, which are conceptualized as biomarkers representing an underlying neuropathological process.⁶⁶ The timing of the development of these alterations is unknown, but rates of ERG abnormalities are also elevated in children at high risk of psychotic illness.⁶⁷ Reduced visual acuity could therefore result from this process in some children in our study and share an underlying neuropathology or genetic predisposition with psychosis.

Conclusions

Our findings support a temporal association whereby childhood visual acuity impairment is associated with

late adolescent psychotic experiences. Future research should aim to elucidate the underlying mechanisms behind this association, to further our understanding of the development of psychotic illnesses and symptoms and how they relate to vision.

Funding

This work was funded by National Institute of Health Research (NIHR) fellowship NIHRDH-NIHR300703 and supported by the University College London Hospitals NIHR Biomedical Research Centre. The views expressed are the authors' and not necessarily those of the NIHR or the Department of Health and Social Care. J.F.H. is additionally supported by Wellcome (211085/Z/18/Z) and the NIHR North Thames Applied Research Collaboration. The UK Medical Research Council, Wellcome (Grant ref: 217065/Z/19/Z), and University of Bristol provide core support for ALSPAC. This publication is the authors' work and NS will serve as guarantor for its contents. *A comprehensive list of grants funding is available on the ALSPAC website. This research was specifically funded by Medical Research Council (MRC) G0701503/85179, National Institute of Health Research (NIHR) CDF/2009/02/35, and Wellcome Trust and MRC (Core) 076467/Z/05/Z.*

Acknowledgments

We are extremely grateful to the families who took part in ALSPAC, the midwives who helped in recruiting them, and the whole ALSPAC team, including interviewers, computer and laboratory technicians, clerical workers, research scientists, volunteers, managers, receptionists, and nurses. Thank you to Ian White for helpful advice on multiple imputation. Any errors remaining are ours. Thank you to our PPI advisors including Katherine Barrett and Sarah Markham who commented on a draft. The authors have declared that there are no conflicts of interest in relation to the subject of this study.
