ABSTRACT

The most luminous quasars at high-redshift harbour the fastest growing and most massive black holes in the early Universe. They are exceedingly rare and hard to find. Here, we present our search for the most luminous quasars in the redshift range from $z = 4.5$ to 5 using data from SkyMapper, *Gaia*, and *WISE*. We use colours to select likely high-redshift quasars and reduce the stellar contamination of the candidate set with parallax and proper motion data. In $\sim 12\,500\text{ deg}^2$ of Southern sky, we find 92 candidates brighter than $R_p = 18.2$. Spectroscopic follow-up has revealed 21 quasars at $z \geq 4$ (16 of which are within $z = [4.5, 5]$), as well as several red quasars, Broad-Absorption-Line (BAL) quasars and objects with unusual spectra, which we tentatively label OFeLoBALQSOs at redshifts of $z \approx 1$ to 2. This work lifts the number of known bright $z \geq 4.5$ quasars in the Southern hemisphere from 10 to 26 and brings the total number of quasars known at $R_p < 18.2$ and $z \geq 4.5$ to 42.

Key words: galaxies: active – quasars: general – early Universe.

1 INTRODUCTION

Quasars at high-redshift point to the most extreme supermassive black holes (SMBHs) in the early Universe. They are centres of early galaxy and star formation and provide the first evidence for heavy chemical elements not created by Big Bang nucleosynthesis. They are interesting objects in their own right as they showcase the existence of extreme black holes, whose formation we struggle to understand (Bromm & Loeb 2003; Volonteri & Bellovary 2012; Pacucci, Volonteri & Ferrara 2015). They are beacons of high luminosity that shine through assemblies of matter, which are otherwise virtually impossible to detect, let alone characterize; through that they support studies of the build-up of chemical elements and early structure in the universe (e.g. Ryan-Weber et al. 2009; Simcoe et al. 2011; Díaz et al. 2014).

Traditionally, high-redshift quasars have been hard to find, as they are very rare. Unsurprisingly, the field was propelled from an aspirational undertaking into a mainstream science by the advent of the first truly wide-area deep multiband survey, the Sloan Digital Sky Survey (SDSS; York et al. 2000), as evidenced by

a series of works from Fan et al. (2001) to Jiang et al. (2016). One frontier of this work is to push searches to higher redshifts (Mortlock et al. 2011; Bañados et al. 2018), while the other is to push to the highest and rarest luminosities (Wu et al. 2015; Wolf et al. 2018b).

High-redshift quasars are proverbial needles in the haystack, even more so as we look for the rarest, most luminous specimens. Quasars at high redshift appear star-like and their colours are to some extent similar to those of cool stars in the Milky Way. True quasars are vastly outnumbered by cool stars, and as we move towards the highest and most interesting potential luminosities, the fraction of true quasars in any candidate sample reaches zero.

Searches for luminous high-redshift quasars have identified samples of them in parts of colour space, where contamination by stars is modest. E.g. Wang et al. (2016) used SDSS, which covers a large fraction of the Northern sky, in combination with data from the all-sky Widefield Infrared Survey Explorer (*WISE*; Wright et al. 2010) and found 72 new quasars at redshifts $z > 4.5$, bringing their total number known at the time to 795.

Further work has ventured into the regions in redshift where contamination by stars is a serious problem, finding a smaller number of objects despite strong efforts (Wang et al. 2017; Yang et al. 2017). Many searches have also added near-infrared data from the UKIRT Deep Infrared Sky Survey (UKIDSS; Warren et al.

* E-mail: christian.wolf@anu.edu.au (CW); christopher.onken@anu.edu.au (CAO)

2007), the UKIRT Hemisphere Survey (UHS; Dye et al. 2018), and the VISTA Hemisphere Survey (VHS; McMahon et al. 2013) to improve the selection at various redshifts (Schindler et al. 2018, 2019a,b; Yang et al. 2019a,b).

At all redshifts the luminosity function of quasars is known to be very steep such that quasars of very high luminosity are extremely rare. E.g. among 1054 quasars at redshift $z \geq 4.5$ listed in the MILLIQUAS catalogue (version 6.2 from 2019 May, Flesch 2015), only 18 are brighter than $R_p = 18$ mag as measured by the *Gaia* mission (Gaia Collaboration 2018) of the European Space Agency (ESA). By now, the *Gaia* mission has provided a true all-sky survey with homogeneous calibration in the optical wavelength regime. Among the very brightest objects, where every candidate is a priori expected to be a star, there are still hidden surprises such as the ultra-luminous quasar J0010+2802, which harbours a black hole of 12 billion solar masses (Wu et al. 2015).

The Southern sky has only recently seen the publication of a hemispheric digital survey, i.e. the SkyMapper Southern Survey (Wolf et al. 2018a; Onken et al. 2019). By combining SkyMapper with *WISE*, a similar search for high-redshift quasars has become possible across the whole Southern sky. This search has also revealed a surprise, in the form of the intrinsically most luminous quasar found so far (J2157–3602; Wolf et al. 2018b). As the object appears not to be gravitationally lensed, it is expected to harbour the fastest growing black hole we currently know.

This paper presents our first stage of searching for high- z quasars in the Southern sky. Besides SkyMapper and *WISE*, we use data from the *Gaia* satellite, which measures parallaxes and proper motions for the more nearby stars in our Milky Way and thus identifies by far most of the common cool dwarf stars that may look similar to high-redshift quasars. Our search here aims at the most luminous quasars we can find, where the previously staggering contamination by stars made spectroscopic confirmation unaffordable. Owing to the release of *Gaia* DR2 (Gaia Collaboration 2018), this section of parameter space can now be tackled with confidence.

In Section 2, we describe data and methods used to select our candidate sample and in Section 3 our spectroscopic results, before we close with a summary. We adopt a flat Lambda cold dark matter cosmology with $\Omega_\Lambda = 0.7$ and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$. We use Vega magnitudes for *Gaia* and infrared data and AB magnitudes for SkyMapper passbands (where $i_{AB} - i_{\text{Vega}} = 0.40$ and $z_{AB} - z_{\text{Vega}} = 0.52$).

2 DATA

In this section, we describe how we select candidates for high-redshift quasars in the Southern hemisphere from survey catalogues using information on spectral energy distributions (SEDs) and on apparent motions that can be seen for nearby stars. Quasars at high redshift are characterized by three features in their SEDs that help differentiate them from other objects:

- (i) At wavelengths shorter than the Ly α emission line the intrinsic quasar light is strongly attenuated by intergalactic absorption, creating a red colour between passbands located on either side of the line (e.g. at $z \approx 4.8$ the Ly α line appears at 700 nm).
- (ii) At wavelengths just longer than the Ly α emission line the typical quasar continuum is bluer than most other objects.
- (iii) Relative to stars, the optical-minus-mid-infrared colours of high-redshift quasars are redder. Colours such as $z - W1$ capture mostly the blue Rayleigh–Jeans tail in the spectra of cool stars, while

the accretion disc continuum in quasar SEDs comprises blackbody contributions across a range in temperature, and given the high redshift we do not see their tails.

Following the example of Wang et al. (2016), we use optical as well as mid-infrared photometry to select quasar candidates. Mid-infrared photometry from *WISE* has been immensely helpful for selecting quasars with high completeness across the whole range of redshifts from $z \approx 0$ to beyond $z \approx 4$ (e.g. Wu et al. 2012; Pâris et al. 2018). It is just at redshifts $z > 4$ that the contamination by cool stars has traditionally been a challenge, which is here addressed with data from *Gaia*. There is now also the work by Calderone et al. (2019), which focuses on the most luminous QSOs at lower redshifts using *Gaia*, *WISE*, and SkyMapper DR1.

2.1 Parallax and proper motion information from *Gaia*

The Data Release 2 (DR2) of the *Gaia* mission (Gaia Collaboration 2018) is the first and currently only release with parallax and proper motion measurements for objects as faint as we are targeting in this work. The release also contains photometry in two very broad passbands that cover roughly the wavelength range from 330 to 660 nm (B_p) and 630 to 1000 nm (R_p), respectively.

How useful parallaxes are for differentiating Galactic and extragalactic sources depends on the colours of the selected sources, hence it is not useful to consider a random subsample of *Gaia* sources. Instead we consult the sample of 795 quasars at $z > 4.5$ collated by Wang et al. (2016) to learn what range of *Gaia/WISE* colours they occupy and to quantify how much *Gaia* helps to reduce the contamination of candidate samples for high- z quasars specifically. The vast majority of known quasars at $z > 4.5$ are fainter than 19 mag in SDSS i/z bands. Some are too faint to be detected by *Gaia*, and at the highest redshifts we expect that their dominant flux is redshifted beyond the R_p passband. However, the 111 brightest objects in the Wang et al. (2016) compilation, with either $i_{AB} < 19.2$ or $z_{AB} < 18.8$, all have a counterpart in *Gaia* DR2. Six of those 111 have G band but no B_p and R_p photometry, while only one of them is bright enough to be missing from our later selection due to this issue.

At this point, we use only simple colour selections, as the *Gaia* argument does not depend on details. The detailed colour selection for this first candidate list among our works on high-redshift quasars will only be finalized in Section 2.4. Wang et al. (2016) show that $z > 4.5$ quasars cover the interval $W1 - W2 = [0, 2]$, although their own search is constrained to $W1 - W2 > 0.5$ to avoid the dramatic stellar contamination below this threshold; this argument is based both on empirically found quasars as well as on the colour tracks of simulated quasars. They use further cuts, such as red colours in $z_{\text{SDSS}} - W1$, for their candidates, and here we like to replace the SDSS filters with *Gaia* photometry as the latter is available for the whole sky. Using dereddened colours (see Section 2.4 for details), we find that the selection $(B_p - R_p)_0 > 1.8$, $(R_p - W1)_0 > 2$, $W1 - W2 > 0$ retains all of their $z > 4.5$ quasars at $R_p < 19$ except for one at $R_p = 18.99$. We further select objects at galactic latitude $|b| > 20^\circ$ to avoid the denser star fields of the Galaxy, leaving a sky area of $\sim 26\,000 \text{ deg}^2$. In Fig. 1, we show the number counts of *Gaia* objects satisfying these criteria: the solid line represents the whole sample of objects satisfying the simple colour cuts above. At $R_p < 18$, the full object sample contains ~ 11 million objects. The symbols represent quasars from MILLIQUAS v6.2 (Flesch 2015), which at $R_p < 18$ contains only 18 objects. Down to $R_p < 19$, the numbers are 135 known quasars out of ~ 20 million objects in total.

Figure 1. Differential number counts of objects with red *Gaia*/*WISE* colours in the range covered by $z > 4.5$ quasars. Solid line: all objects satisfying criteria specified in Section 2.1. Dotted line: sample after removing objects with parallaxes or proper motions identifying them as Milky Way stars. Dashed line: the sample after removing objects without parallax and proper motion measurements. Symbols: known high-redshift quasars before (black) and after (grey) removing those excluded by the dashed-line rule.

We then remove objects with parallaxes or proper motions suggestive of Milky Way stars from this sample. At $R_p \lesssim 18$, *Gaia* measures parallaxes with an error of ~ 0.35 mas per year and proper motions with ~ 0.5 mas per year in each coordinate axis. We thus choose to remove objects with a parallax of > 1 mas per year and those with a proper motion of $\sqrt{pm_{ra}^2 + pm_{dec}^2} > \sqrt{2}$ mas per year. At $R_p < 18$ this leaves $\sim 300\,000$ objects, whose number counts are shown as the dotted line. Hence, 97.3 per cent of the initial sample have been removed based on positive evidence of star-like motions.

An optional, more stringent, step is to remove objects for which *Gaia* does not provide any parallax and proper motion measurements in DR2. This will produce a purer candidate list at the risk of introducing incompleteness. Adding this criterion shrinks the sample to only 21 923 objects at $R_p < 18$ or 1 part in ~ 500 of the original sample (dashed line in Fig. 1).

Using MILLIQUAS, we estimate the incompleteness caused by applying cuts based on *Gaia*'s motion data, which is appropriate since the previously known quasars were found before *Gaia* data had become available, and used only colour criteria. At $R_p < 18$ all 18 known quasars pass the motion cuts, but incompleteness sets in when going fainter, mostly because the errors on *Gaia*'s proper motion measurements increase significantly. Fig. 1 shows the known quasars passing the stringent motion-based cuts as grey symbols. At $R_p = [18, 18.5]$ and $R_p = [18.5, 19]$, the cuts lose ~ 20 per cent and ~ 33 per cent of the quasars, respectively. Of course, a more complete and efficient selection function could take motion errors into account on a per-object basis, which will be advisable when exploring fainter magnitudes, but as this is beyond the scope of this paper, we continue with the selection motivated above.

We summarize here that, before further colour selections are made, we reduced a list of ~ 11 million objects at $R_p = [15, 18]$ to $\sim 22\,000$ objects based on *Gaia*'s motion data. This list covers $26\,000$ deg² of sky, in which 18 high-redshift quasars had been listed in MILLIQUAS, although not the whole area had been searched systematically before SkyMapper data became available.

2.2 The SkyMapper Southern Survey

SkyMapper is a 1.3-m-telescope at Siding Spring Observatory near Coonabarabran in New South Wales, Australia (Keller et al. 2007). It started a digital survey of the whole Southern hemisphere in 2014. The survey provides photometric data in six optical passbands. The only two SkyMapper bands we use in this work are the *i* and *z* bands, which have transmission curves that are similar to those of the eponymous SDSS filters. Differences in width and central wavelength are below 30 nm, and the SkyMapper passbands can be approximated by $(\lambda_{\text{cen}}/\text{fwhm})$ of (779/140) and (916/84) for *i* and *z*, respectively.

When the first release of the SkyMapper Southern Survey (DR1; Wolf et al. 2018a) became available in 2017, we started our search for high-redshift quasars, finding two of the objects reported here. When *Gaia* DR2 was released in 2018 April, we accelerated our efforts, which led within a couple of days to the discovery of the quasar with the highest UV–optical luminosity known to date (Wolf et al. 2018b) and further objects.

Recently, the second release (DR2) became available to Australian astronomers (Onken et al. 2019). It mostly supersedes the first in sky coverage, depth, and calibration quality, but also drops some of the older images by applying stricter quality limits. While DR1 was complete to $i \approx 18.2$, DR2 goes to $i \approx 19.5$ mag on nearly 90 per cent of the Southern hemisphere. DR2 includes many more images, but its production was more selective in terms of image quality. As a result, 1 per cent of the sky area in DR1 has no *i* or *z* photometry in DR2. We note that two of the quasars we found before DR2 are in this lost area. One lacks photometry in the *z* band, and the other is not in the DR2 catalogue at all.

Although our work was started with DR1, we choose to report our results based on data from the superior DR2. For the two objects without *z*-band photometry in DR2, we borrow their photometry from DR1 for the purpose of estimating their luminosity. Calibration differences between the two releases are small enough, such that if their *i/z* magnitudes had been available in DR2, they would still have been selected as candidates. We expect the next release from SkyMapper to contain twice as many Main-Survey images and include those two objects again.

2.3 Sample selection and quality flags

The master table in the SkyMapper data release is cross-matched to *Gaia* and AllWISE. We consider SkyMapper objects that have a *Gaia* match within 2 arcsec (to accommodate centroid shifts when SkyMapper blends sources that are close together) as well as a *WISE* match within 4 arcsec distance. We also require photometric errors in *WISE* of $W1\text{sigmpro} < 0.1$ and $W2\text{sigmpro} < 0.2$, while we make no such requirements for *Gaia* and SkyMapper since cuts in these bands are less critical when $R_p \lesssim 18$. We find that ~ 50 per cent of *Gaia* sources at $|b| > 20$ deg and $R_p < 18$ have SkyMapper counterparts, driven by the survey footprint: SkyMapper covers nearly exactly the Southern hemisphere while *Gaia* is all-sky. Requiring a counterpart from the AllWISE all-sky table reduces the sample by ~ 5 per cent; the lost objects are most likely stars,

which have bluer optical/mid-infrared colours than high-redshift quasars and thus the latter would be bright enough to be all retained by this rule.

We exclude two regions centred on the two Magellanic Clouds with an area of $\sim 190 \text{ deg}^2$, which leaves an effective search area of approx. $12\,500 \text{ deg}^2$. Finally, we remove 0.05 per cent of objects, whose SkyMapper DR2 flags indicate that their photometry is not reliable (flags > 3). SkyMapper flags up to value 255 come from Source Extractor (Bertin & Arnouts 1996), but we also use bespoke flags with higher values to indicate sources that are likely affected by either scattered light from nearby bright stars (with $i < 6 \text{ mag}$ or $z < 5 \text{ mag}$), or possibly by uncorrected cosmic rays as indicated by higher light concentration than is allowed for a point source (for details see Onken et al. 2019).

2.4 Colour selection

We explore colour criteria for selecting high-redshift candidates using *Gaia* B_p and R_p , SkyMapper i and z , and *WISE* $W1$ and $W2$ bands. We start with a sample of objects that is expected to contain nearly all $z = [4.5, 5.2]$ quasars with typical SEDs, using dereddened colour cuts of $(B_p - R_p)_0 > 1.8$, $(R_p - W1)_0 > 2$, and $W1 - W2 > 0$, as already motivated and chosen in Section 2.1.

We corrected SkyMapper and *Gaia* magnitudes for interstellar extinction using the reddening maps by Schlegel, Finkbeiner & Davis (1998, hereafter SFD), while leaving *WISE* data unchanged given the long wavelength. We adopt reddening coefficients from Wolf et al. (2018a), whose $R_i = 1.582$ and $R_z = 1.2$ are used with $A = R \times E(B - V)_{\text{SFD}}$, and for *Gaia* from Casagrande & Vandenberg (2018), whose $R_{B_p} = 3.374$ and $R_{R_p} = 2.035$ are used with $A = R \times 0.86E(B - V)_{\text{SFD}}$.

We search a magnitude range of $R_p = [15, 18.2]$, given that the brightest known objects at $z > 4$ have $R_p \approx 17$, and that we are interested in the brightest possible quasars in this first step of our work (in future work, we will reach deeper magnitudes as more telescope time for follow-up becomes available). Finally, we apply the stringent motion cuts from Section 2.1. The resulting 13 362 objects are shown in colour–colour diagrams in Fig. 2.

The black round symbols mark 12 high- z quasars in our sample that were already known when we started this work. Four of these are at $z \approx 4.4$, just outside the notional redshift interval we are aiming for, but equally relevant. Three further objects with known spectra are carbon stars, marked by the asterisk symbols. The latter can have extremely red optical/mid-infrared colours, and some are known at $(z - W1)_0 = [5, 8]$, beyond our diagrams.

In the next step, we deselect the dense clump of Milky Way stars and define a candidate list for spectroscopic follow-up using further and tighter colour cuts. We aim for discovering our first batch of ultra-luminous high-redshift quasars and would not yet apply Bayesian selection approaches, but use conservative cuts aimed for purity; the spectroscopic follow-up of this candidate list is done with observations of one candidate at a time. In the near future, we will be able to follow up vastly larger candidate lists as ancillary science targets embedded in the Taipan Survey (da Cunha et al. 2017); then we will aim for a complete sample by penetrating the stellar locus. For now, however, we define candidates using the following criteria:

$$(B_p - R_p)_0 > 1.9, \quad W1 - W2 > 0.25, \quad (i - z)_0 < 0.4 \quad (1)$$

$$\text{and } W1 - W2 > 0.25 + 0.4 \times (3 - (z - W1)_0). \quad (2)$$

These criteria selected 92 candidates with $R_p < 18.2$ (see sky chart in Fig. 3) for spectroscopic follow-up. None of the known

Figure 2. Colour–colour diagrams of objects with red *Gaia*/*WISE* colours and magnitude $R_p = [15, 18.2]$ after applying motion cuts. The small grey symbols are all objects, the round black symbols are known $z \gtrsim 4.5$ quasars, and the asterisks are known carbon stars. The lines indicate the selection cuts.

$z > 4.5$ quasars would be missed by these criteria, even if we pushed as faint as $R_p = 18.8$, except for the object without R_p data. Only at $R_p > 18.8$ would we miss objects, presumably due to colour scatter from higher photometric errors. Results are discussed in Table 1 and Section 3. Without the motion cuts another 3478 candidates would have been selected, so the *Gaia* data allowed us to compress the candidate list by a factor of ~ 40 even in this part of colour space that is away from the main stellar locus.

2.5 Spectroscopy at the ANU 2.3m-telescope

We took spectra of the candidates with the Wide Field Spectrograph (WiFeS; Dopita et al. 2010) on the ANU 2.3m-telescope at Siding Spring Observatory. We used 18 nights, most of which were useful (2018 April 29, 2018 September 16–18, 2018 December 4 and 5; 2019 March 11–13 and 30, 2019 April 1, 2019 June 30, 2019 July 1–5, 2019 August 29). Two quasars were identified already with earlier observations on 2017 December 21 during a pilot search that had not yet benefited from *Gaia* data.

We used the WiFeS B3000 and R3000 gratings in the blue and red arm, which between them cover the wavelength range from 3600 to 9800 Å at a resolution of $R = 3000$. Exposure times ranged from 600 to 1800 s, and observing conditions varied significantly in terms of cloud cover and seeing.

The data were reduced using the PYTHON-based pipeline PyWiFeS (Childress et al. 2014). PyWiFeS calibrates the raw data with bias, arc, wire, internal-flat, and sky-flat frames, and performs flux calibration and telluric correction with standard star spectra. Flux densities were calibrated using several standard stars throughout the year, which are usually observed on the same night. We then extract spectra from the calibrated 3D cube using a bespoke algorithm for fitting and subtracting the sky background after masking sources in a white-light stack of the 3D cube.

Figure 3. Sky map of objects with red *Gaia*/*WISE* colours in the magnitude range $R_p = [15, 18.2]$ after applying motion cuts. The small grey symbols are all 13 362 objects from $\sim 12\,500$ deg² of effective search area, and large black symbols show our 92 final candidates selected by the cuts illustrated in Fig. 2.

Table 1. High-redshift quasars in our candidate sample. Four of the sources are radio loud and detected in the radio survey NVSS; one of them (J052506.17–334305.6) is also detected in SUMSS. Errors on R_p , z_{PSF} , and $W1$ range from 0.01 to 0.03 mag, well below the intrinsic variability of quasars. The average error on $W1 - W2$ is 0.05 mag, but ranges from 0.04 to 0.09 mag. We only quote errors for the H band, which are less homogenous.

We obtained spectra for all candidates except the objects reported in the literature. Reduced spectra were visualized with the MARZ software (Hinton et al. 2016) and quasar templates were overplotted to aid the redshift determination. We estimate redshifts from broad Si IV and C IV lines where available, and consider the blue edge of the Ly α line when necessary. We estimate that redshift uncertainties range from 0.01 to ~ 0.05 for the weak-lined objects. Despite good signal, four of the 92 candidates from our sample remain currently unclassified. Their spectra are unlike anything we have seen before, and we deem them unlikely to be high-redshift quasars.

3 RESULTS

3.1 High-redshift quasars among the candidates

The spectroscopy revealed 21 ultra-luminous quasars at $z \geq 4$ (see Fig. 4), of which 17 are newly identified. The most luminous object among the new 18 was already reported in Wolf et al. (2018b). Four more objects in our sample were independently observed by other teams and published in the literature only after our observations were done: Yang et al. (2019b) revealed a $z = 4.8$ quasar, Calderone et al. (2019) one at $z = 4.52$, and Schindler et al. (2019a) found two more quasars at $z = 4.45$. Three of the newly identified objects are at slightly lower redshifts of $z = 4$, $z = 4.25$, and $z = 4.34$, while the others are at $z \geq 4.5$ as expected.

In the bottom part of Table 1, we list 13 further high-redshift quasars in our sample, and one outside our sample, that were known already when our observations commenced: 10 of them are in the target redshift window of $z = [4.5, 5.2]$ and four more at slightly lower redshifts. Altogether then, 34 objects out of 92 candidates with good spectra are quasars at high redshifts of $z \geq 4$.

As a result of this work, we have lifted the number of known bright ($R_p < 18.2$) $z \geq 4.5$ quasars in the Southern hemisphere from 10 objects prior to our observations to 26 now.

We derive luminosities in two restframe bands, M_{145} centred at 145 nm and M_{300} at 300 nm, and show the impact of our work on the luminosity-redshift space of known quasars in Fig. 5. For previously discovered quasars, authors most often listed M_{145} as it is constrained by the i and z passbands in which the optical discovery is made, and usually also covered in the spectrum, so it can be determined while avoiding influence from the broad emission lines. Also, M_{145} is the best available proxy for the ionizing flux from the quasar. Measuring M_{300} , in contrast, requires HK photometry, which has previously been available only for the most extreme objects that were bright enough to be detected by the 2 Micron All-Sky Survey (2MASS; Skrutskie et al. 2006). M_{300} is a better predictor of the bolometric luminosity of quasars as it is closer to the peak in their SED. Now, the much deeper VHS and the VIKING survey (Edge et al. 2013) are available, at least in the Southern hemisphere, and provide very precise photometry for most quasars in our sample.

We estimate M_{145} first for all objects in Table 1 with a simple linear interpolation of the SkyMapper i - and z -band photometry. For the subset of objects with spectra from the 2.3m-telescope, we also measure M_{145} from the spectra after normalizing them to the photometry. As we find no differences larger than ± 0.05 mag, we report the simpler measure of M_{145} that is available for all objects consistently. We do not report errors as they are smaller than the intrinsic long-term stochastic variability of quasars.

We measure M_{300} in the best case from H , K_s photometry in the VHS; these objects have H -band errors up to 0.03. For a few objects, VHS currently has J , K_s photometry but no H band, and for these we estimate H magnitudes from J , K_s photometry. For

most objects, we have all three near-infrared magnitudes, J , H , K_s , and for those we find that $(H - K_s)/(J - K_s) = 0.41 \pm 0.028$. We apply this tight relation to derive $H(J, K_s)$ and combine the measurement and relation errors; the resulting H -band errors range from 0.03 to 0.07. Six objects have no VHS coverage but we find three of them in VIKING (J032444–291821, J221111–330245, and J230429–313426), one in UKIDSS (J090527+044342), and for the final two (J013539–212628, and J035504–381142) we resort to 2MASS photometry, which has larger H -band errors of 0.1 to 0.15 mag. However, we stress that all these errors are smaller than the intrinsic long-term variability of quasars.

3.2 Radio detections

None of the listed objects is detected in the 1.4 GHz VLA survey ‘Faint Images of the Radio Sky at Twenty-Centimeters’ (FIRST; Becker et al. 1995), mostly due to its mostly Northern sky coverage. The 1.4 GHz NRAO-VLA Sky Survey (NVSS; Condon et al. 1998) covers the sky at $\delta > -40^\circ$ with a flux limit of 2.5 mJy; it contains four of the quasars; one of these, J052506.17–334305.6, is also detected by the 843 MHz Sydney University Molonglo Southern Survey (SUMSS; Bock et al. 1999), which covers the polar half of the Southern hemisphere at $\delta < -30^\circ$ with a limit of 5 mJy. Its fluxes of 183.8 ± 5.9 at 843 MHz and 188.3 ± 5.7 at 1.4 GHz suggest that it is a flat-spectrum radio quasar (FSRQ; Urry & Padovani 1995).

We use the radio-to-optical ratio $R = f_{\nu, 6\text{cm}}/f_{\nu, B}$ defined by Kellermann et al. (1989) to label objects as radio loud ($R > 10$) or radio quiet ($R < 1$); in that work the ratio is based on the flux density at 6 cm and 440 nm wavelength for a sample with average redshift of ~ 0.5 , but for our objects these bands are redshifted on average ($z = 4.75$) to ~ 23 cm, which is approximately the NVSS wavelength, and 1700 nm, which is in the NIR H band. A sensitivity limit of $f < 2.5$ mJy in the NVSS corresponds to $R < 10$ for $H = 16.6$, the typical magnitude of the faintest sources in this work, and $R < 2$ for the $H = 14.8$ of the brightest source.

The four sources detected by NVSS and SUMSS range from $R \approx 40$ to $R \approx 300$ and are thus clearly radio loud. Of these four, one is newly discovered and three have been known as quasars before. This is consistent with the fact that the fraction of radio-loud quasars is generally small, while known quasars in the Southern hemisphere have previously often been discovered by optical follow-up of radio source catalogues. All except one of the newly discovered quasars are thus radio quiet

3.3 Gravitationally lensed quasars?

Gravitationally lensed quasars are intrinsically very rare, but their fraction is higher among quasars of brighter apparent magnitude, as their brightness is boosted by the lensing. When quasars are lensed, they show multiple magnified images and hence their luminosity is overestimated. We thus look for signs of multiplicity among the objects in the *Gaia* catalogue, which is known to be incomplete at separations of < 2 arcsec. We find just one object that has a *Gaia* neighbour within 5 arcsec, J090527.39+044342.3. There, we actually see two objects in the SkyMapper image coincident with two *Gaia* sources separated by 4 arcsec. The catalogued SkyMapper source is a blend of the two objects, with the centroid location close to the brighter of the two. The SDSS DR14¹ has separate photometry for the two sources and shows the fainter source to have colours that

¹<https://skyserver.sdss.org/dr14/>

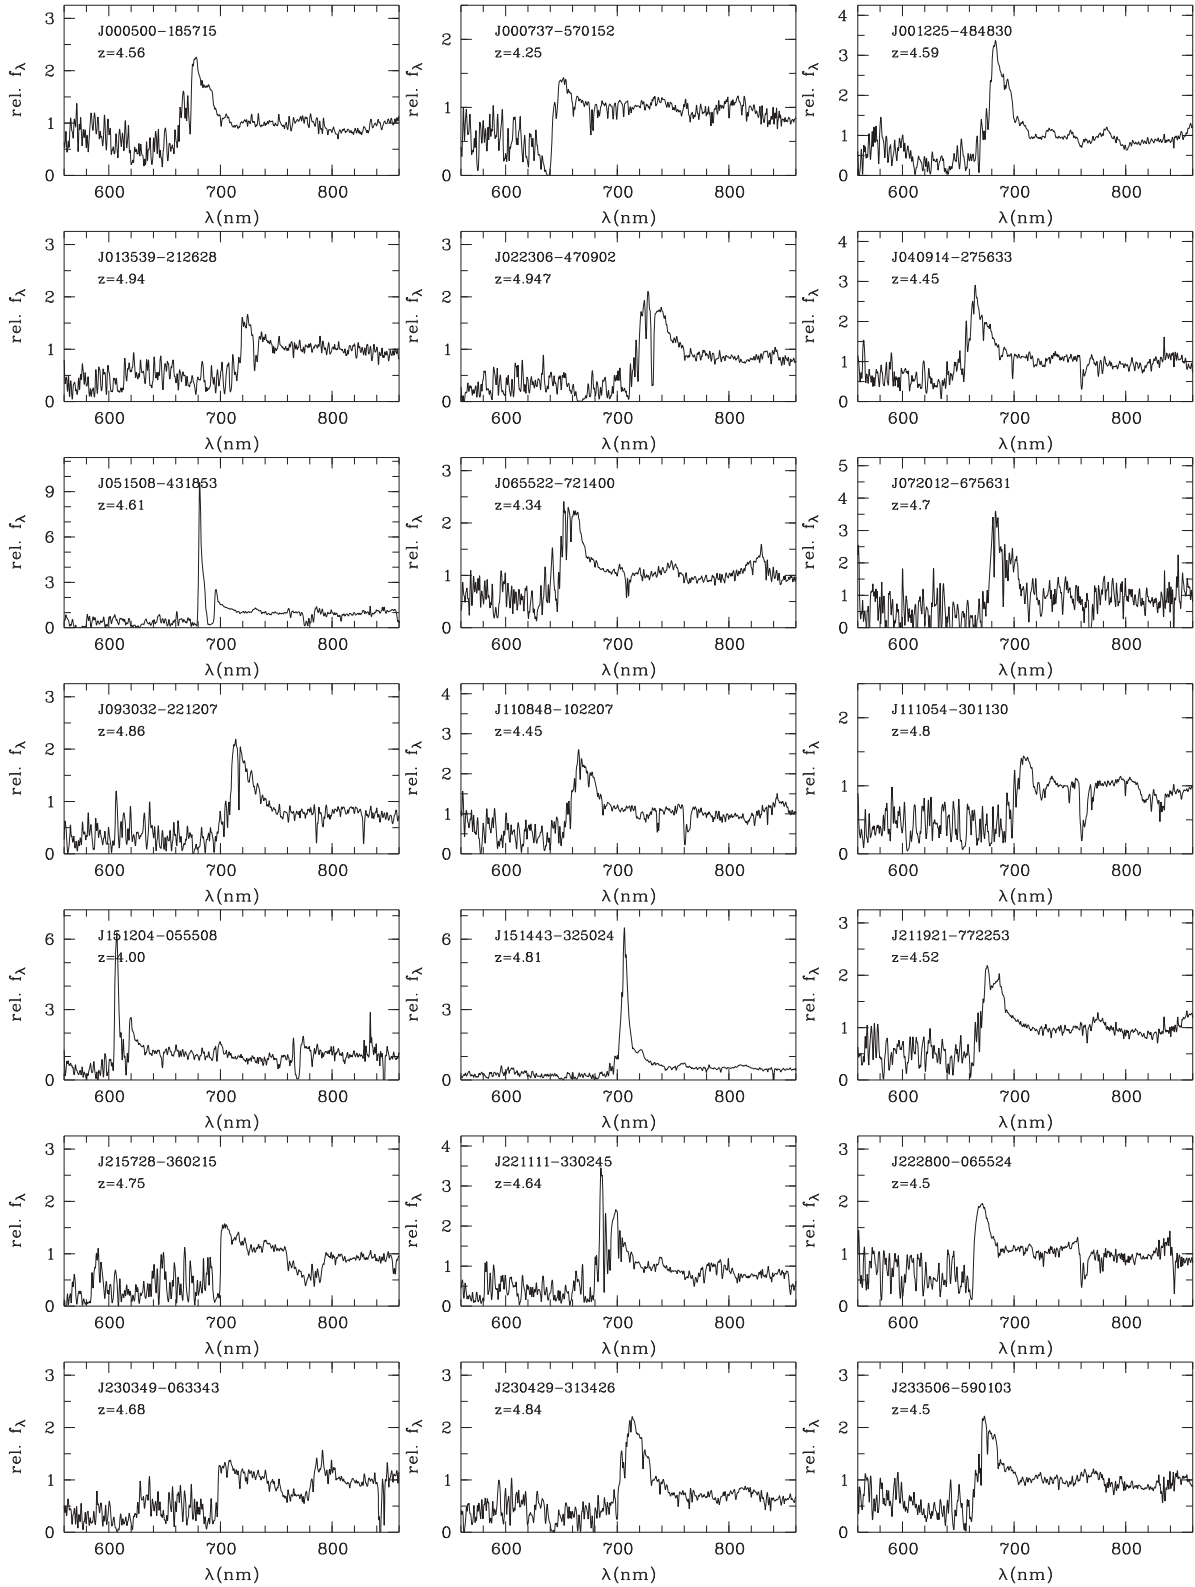

Figure 4. Gallery of 21 quasar spectra with $z \geq 4$ observed by us. The two quasars with weak emission lines have clearly visible Lyman forests in the 2D spectra. Example spectra from the 24 red or unusual quasars at lower redshift are shown in Fig. 6.

Figure 5. Ultra-luminous high-redshift quasars with $R_p < 18.2$, known before this work (grey) and identified in this work (black, see Table 1). Our sample improves especially in the regime of high bolometric luminosity, for which M_{300} is a useful proxy.

are different from the first and typical for a star. Hence, these are not expected to be two images of one object. The SkyMapper PSF magnitudes are 0.2 mag fainter than the SDSS measurements of the (brighter) quasar source; this is either a consequence of long-term variability, or the blending causes the SkyMapper PSF magnitude and the luminosity to be underestimated here.

3.4 Contaminants in candidate sample

Most contaminants in our candidate sample turn out to be cool stars and include a few carbon stars and long-period variables. But we also identify 24 quasars at lower redshift. Typical quasars at those lower redshifts are firmly excluded by our selection cuts, and the spectra reveal that these quasars are unusual. They fall into three categories (see Fig. 6 for example spectra):

- (i) Five quasars at $z = 0.5$ to $z = 2$ have atypically red continua; Richards et al. (2003) found that 6 per cent of quasars in a large SDSS sample fall into this category, which would be missed by surveys for quasars with typical, blue, colours.
- (ii) Three quasars at $z \approx 2.6$ to 3.3 have strong broad absorption lines (BALQSOs; Weymann et al. 1991; Scaringi et al. 2009), which render the emission lines nearly invisible. They are not easily separated from the other objects without resorting to spectra. Richards et al. (2003) also find that BALs are more common among red quasars.
- (iii) 16 objects have extremely wide absorption troughs at nearly full depth, such that it is very challenging to determine any redshift at all. Objects with qualitatively similar spectra have been found in the past and typed as OFeLoBALQSOs (Overlapping Iron Low-Ionization Broad-Absorption line QSOs) by Hall et al. (2002) and Zhang et al. (2015). Their spectra are believed to be nearly fully absorbed bluewards of the Mg II line, which suggest a rough redshift based on the assumption that the unabsorbed continuum starts around 280 nm wavelength. If this is true, the objects we found would all reside at redshift $z \approx 1$ to 2 . This category of objects will be discussed in a separate publication.

The number of lower z quasars with unusual SEDs is roughly as large as the number of true high- z quasars and may come as a surprise when compared to earlier surveys. They also reach ~ 1 mag brighter in R_p than the $z > 4.5$ quasars. It seems clear, how the lower z OFeLoBALQSOs are confused with $z > 4.5$ quasars: the strong suppression bluewards of the Mg II line simply mimics the effect of Lyman forest. But why are they more common than in previous searches? We believe, this is because we target high- z quasars of

such high and rare luminosity that we run out of objects, while the interlopers appear still with their natural abundance. Also, the $B_p - R_p$ colour selection selects objects that are nearly B_p -dropouts, either due to the Lyman forest at $z \gtrsim 4$, or due to extreme OFeLoBAL absorption at $z \lesssim 2$.

We note that nearly all the $z < 2.5$ quasars, whether those with generally red continua or the OFeLoBALQSOs with extreme absorption bluewards of the Mg II line, have *WISE* colours of $W1 - W2 \approx [1, 1.5]$, which are typical for quasars at $z < 2$ (see Fig. 7). In contrast, all of the high-redshift ($z \geq 4$) quasars in this work have $W1 - W2 = [0.3, 0.75]$ (see Fig. 7), with a mean colour of 0.52; the RMS scatter of 0.11 appears to be mostly intrinsic, as the average error on the $W1 - W2$ colour is 0.053. The conclusion is, however, that we could distinguish low-redshift interlopers from high-redshift objects using appropriate ranges in $W1 - W2$ colour. We note that the high-redshift quasars reported in Wang et al. (2016) include objects with $W1 - W2$ colours as red as ~ 1.7 despite moderate errors on the *WISE* photometry, although these are all fainter than our search regime. Either the errors of their *WISE* photometry is underestimated or high-redshift quasars with red mid-infrared colours are intrinsically rare at the highest luminosity studied here, so that none show up in our sample.

4 SUMMARY

We used data from SkyMapper DR1 and DR2, from *Gaia* DR2, and from AllWISE to search for quasar candidates at $z > 4.5$ in the Southern hemisphere. We focus on the bright end of the quasar distribution, where true quasars are outnumbered by cool stars to the most extreme degree possible.

The role of *Gaia* DR2 is primarily to remove the vast majority of objects in the search space, which are cool stars in our own Milky Way that show noticeable parallax or proper motion. The *Gaia* data allow us to reduce the target density by a factor of ~ 40 now and several hundred in the future.

In this paper, we focus on very likely quasars and suppress stellar contamination further with a colour-based selection. In an area of $\sim 12\,500$ deg², we find 92 high-redshift candidates with a brightness of $R_p < 18.2$, among which were 13 already known high-redshift quasars. We take spectra of the others and identify 21 more quasars, some of which have been identified and published independently since our observations.

This new sample increases the number of Southern $z \geq 4.5$ quasars at $R_p < 18.2$ from 10 to 26, and takes the number in the whole sky to 42. The new quasars are mostly in the luminosity range of $M_{145} \approx [-29, -28]$. At this point we refrain from investigating luminosity functions, because our search for more quasars will continue into more challenging parts of search space; those have been avoided in the past due to the abundance of cool stars that appear with similar colour to quasars and dramatically inflate the candidate samples. However, this area of search space is critical for assembling complete samples of quasars and will soon become accessible, owing to *Gaia* DR2 and because spectroscopic follow-up of many thousand targets at low sky density is becoming affordable with projects such as the Taipan Survey.

We also find among our candidates 24 lower redshift quasars with unusual red spectra, most of which appear to be OFeLoBALQSOs. These are particularly prevalent in our sample relative to $z > 4.5$ quasars, because we target a magnitude range where high-redshift quasars are truly rare, shifting the balance in favour of unusual low- z objects. However, they can easily be distinguished using mid-

Figure 6. Gallery of three lower-redshift quasar spectra. Left: a generally red continuum. Centre: a BALQSO. Right: an OFeLoBAL QSO.

Figure 7. Confirmed quasars in our selected sample: at $z = [4, 5]$ they have $W1 - W2 = [0.3, 0.75]$, while lower redshift quasars are redder. They are in our sample because of red continua, strong BAL features, or extreme absorption bluewards of the Mg II line as in the case of OFeLoBAL QSOs.

infrared colours: while the rule $W1 - W2 < 0.75$ retains all our high-redshift objects, it removes most low-redshift interlopers.

In the future, we will venture into the stellar locus with massive spectroscopic follow-up, and revisit also part of the Northern sky with this approach, taking advantage of the *Gaia* motion measurements. We will also go deeper and to redshifts $z > 5$. Finally, we will pursue measurements of black hole masses for our sample.

ACKNOWLEDGEMENTS

This research was conducted by the Australian Research Council Centre of Excellence for All-sky Astrophysics (CAASTRO), through project number CE110001020. It has made use of data from the European Space Agency (ESA) mission *Gaia* (<https://www.cosmos.esa.int/gaia>), processed by the *Gaia* Data Processing and Analysis Consortium (DPAC, <https://www.cosmos.esa.int/web/gaia/dpac/consortium>). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the *Gaia* Multilateral Agreement. The national facility capability for SkyMapper has been funded through ARC LIEF grant LE130100104 from the Australian Research Council, awarded to the University of Sydney, the Australian National University, Swinburne University of Technology, the University of Queensland, the University of Western Australia, the University of Melbourne, Curtin University of Technology, Monash University, and the Australian Astronomical Observatory. SkyMapper is owned and operated by The Australian National University's Research School of Astronomy and Astrophysics. The survey data were processed and provided by the SkyMapper Team at ANU. The SkyMapper node of the All-Sky Virtual Observatory (ASVO) is hosted at the National Computational Infrastructure (NCI). Development and

support the SkyMapper node of the ASVO has been funded in part by Astronomy Australia Limited (AAL) and the Australian Government through the Commonwealth's Education Investment Fund (EIF) and National Collaborative Research Infrastructure Strategy (NCRIS), particularly the National eResearch Collaboration Tools and Resources (NeCTAR) and the Australian National Data Service Projects (ANDS). This work uses data products from the Wide-field Infrared Survey Explorer, which is a joint project of the University of California, Los Angeles, and the Jet Propulsion Laboratory/California Institute of Technology, funded by the National Aeronautics and Space Administration. It uses data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation. This paper uses data from the VISTA Hemisphere Survey ESO programme ID: 179.A-2010 (PI. McMahon). This publication has made use of data from the VIKING survey from VISTA at the ESO Paranal Observatory, programme ID 179.A-2004. Data processing has been contributed by the VISTA Data Flow System at CASU, Cambridge and WFAU, Edinburgh. Support for this work was provided by NASA grant NN12AR55G. We thank Francis Zhong (University of Melbourne) for his contribution and ideas behind the final step of the script for extracting the spectrum from the 3D cube. We thank Ian McGreer for pointing out the SDSS photometry of J090527.39+044342.3 to us. Finally, we thank the anonymous referee for comments that improved the manuscript.
