3 January 2023

4 **Key Findings**

- 5 • Road Accidents during the vacation periods are similar to those on ordi-
6 nary weekends
- 7 • Accidents follow clear temporal patterns during a day and during a week
- 8 • There are temporal patterns for accidents occurring under the influence
- 9 • Intoxicated driving is shifting to weekdays

10 **Abstract**

11 This study investigates how the road safety in New Zealand is in-
12 fluenced by recreational factors, such as holiday weekends, alcohol and
13 time/spatial patterns. The results of our analysis show that the num-
14 ber of accidents during holiday periods are similar to those on normal
15 weekends. There are clear patterns of accidents during commuting times
16 and accidents occurring under the influence on weekends. In recent years,
17 accidents that occur with intoxicated drivers also occurs more frequently
18 during the work week.

19 **Keywords:** accidents; new zealand; holidays; intoxication; alcohol

20 1 Introduction

21 Road traffic accidents are a major source of damages to property and people.
22 Their impact on the economy and the livelihood of people is substantial. In New
23 Zealand, hundreds of people loose their lives on the road and many more are
24 injured every year. According to the OECD 71.6 people per 1 million inhabitants
25 died in 2019 on New Zealand’s roads, which is considerably higher compared to
26 Australia (47.1) Germany (36.6) and the UK (27.6 in 2018) (OECD, 2021).

27 The Ministry of Transport in New Zealand estimated in 2017 that the the
28 average social cost is NZD 4.916 million per fatal crash, NZD 923,000 per re-
29 ported serious crash, and NZD 104,000 per reported minor crash. The total
30 social cost of motor vehicle injury crashes in 2016 is estimated at approximately
31 NZD 4.17 billion (of Transport, 2017).

32 There is an inherent risk in participating in road traffic, may it be as a mo-
33 torist, cyclist or pedestrian. While many use the roads for commercial purposes,
34 such as to transport goods or to commute to work, there is also a considerable
35 traffic due to recreational objectives, such as to attend social gatherings or to
36 go on vacations, although this type of traffic has been impacted by the Covid-19
37 crisis in the past year. In this study we focus on road accidents that are related
38 to recreational activities in New Zealand from the years 2000-2019.

39 1.1 Holidays

40 The Ministry for Transport is operating a holiday road toll statistics¹ that counts
41 the number of deaths and injuries during four special vacation periods in New
42 Zealand:

43 • Easter holiday

44 – The Easter period ranges from the Friday before Easter Sunday to
45 the Monday following Easter Sunday. Easter Sunday is calculated
46 using the “Computus”². This results in a moving holiday that is
47 typically on the first Sunday following the full Moon that occurs on
48 or just after the spring equinox.

49 – The official Easter holiday period begins at 4pm on the Thursday
50 before Good Friday and ends at 6am on the Tuesday after Easter
51 Monday.

52 • Queen’s Birthday

53 – 1st Monday in June

54 – The official Queens birthday weekend holiday period begins at 4pm
55 on the Friday before the weekend and ends at 6am on the Tuesday
56 after Queens Birthday.

¹<https://www.transport.govt.nz/statistics-and-insights/safety-road-deaths/holiday-periods/>

²<https://en.wikipedia.org/wiki/Computus>

- 57 • **Labour Day**
- 58 – 4th Monday in October
- 59 – The official Labour day weekend holiday period begins at 4pm on
- 60 the Friday before the weekend and ends at 6am on the Tuesday after
- 61 Labour Day.
- 62 • **Christmas & New Year**
- 63 – When Christmas Eve and New Year’s Eve falls on a week day the
- 64 holiday starts at 4.00 pm on 24 December
- 65 – If the holiday begins on a Monday or a Tuesday it ends at 6am on 3
- 66 January (9.6 days)
- 67 – If the holiday begins between Wednesday and Friday it ends at 6am
- 68 on 5 January (11.6 days)
- 69 – When Christmas Eve and New Year’s Eve falls on a Saturday the
- 70 holiday starts at 4pm on Friday 23 December and ends at 6am on
- 71 Wednesday 4 January (11.6 days)
- 72 – When Christmas Eve and New Year’s Eve fall on a Sunday the holi-
- 73 day starts at 4.00pm on Friday 22 December and ends at 6.00 am on
- 74 Wednesday 3 January (11.6 days)

75 The published statistics are accompanied by safety advertising campaigns³
76 that are widely broadcast in the New Zealand media. During the vacation
77 period, radio stations continuously report on the vacation road toll. Tay (2001)
78 showed that the publicity campaign helped reducing accidents while van Lamoen
79 (2014) showed that the “Safer Summer” campaign helped to reduce speeding
80 offences. We were, however, unable to find rigorous statistical evidence about
81 the road toll during vacation periods in New Zealand. We are interested if
82 driving during these special holiday periods is more dangerous than during other
83 weekends in the year.

84 1.2 Intoxication

85 It is perceived that traveling during these holiday periods is more dangerous and
86 Anowar et al. (2013) showed that traffic accidents in Alberta, Canada during
87 festive periods (2004-2008) are over represented despite publicity road safety
88 campaigns. They identified risk factors, such as driver intoxication, speeding
89 and restraint use. While non-use of restraint is more prevalent during these hol-
90 idays in Alberta, driver intoxication and speeding are less prevalent. Such road
91 safety models can be used to help allocating police resources to specific time
92 periods and places (Guria and Mara, 2000). Keall et al. (2005) showed that in
93 New Zealand alcohol contributes almost half of the risk for young male drivers

³<https://www.nzta.govt.nz/safety/what-waka-kotahi-is-doing/our-advertising/road-safety-advertising-calendar/>

94 on open roads during night times but contributes little to the overall risk on
95 busy roads. This indicates that drunken drivers have a tendency to use lower
96 volume roads to avoid police. Scuffham and Langley (2002) created a model
97 for traffic accidents in New Zealand for the period of 1970-1994 that showed
98 the connection between the number of crashes and other economic indicators,
99 such as gross domestic product per capita, unemployment rate and alcohol con-
100 sumption. They showed that change in alcohol consumption per capita is an
101 important factor in traffic crashes.

102 **1.3 Research Questions**

103 This study investigates the following research questions:

- 104 1. Do more accidents occur during Easter, Queens Birthday and Labour
105 Weekend compared to ordinary weekends?
- 106 2. Has the proportion of accidents on open roads increased over time?
- 107 3. Has the severity of accidents on open roads and urban roads changed over
108 time?
- 109 4. What is the influence of intoxication?
- 110 5. How are accidents spread across the week/time?
- 111 6. How are accidents associated with intoxication spread across weekday/time?

112 **2 Data**

113 The data for this study was acquired from the New Zealand Transportation
114 Agency's Crash Analysis System (CAS)⁴. It includes a wide spectrum of infor-
115 mation related to all crashes that have been recorded by the New Zealand police.
116 All of the data used in this study is also publicly available through their Open
117 Data platform and hence no Human Ethics application at the *** removed for
118 anonymity *** was necessary. We included CAS data from the years 2000-2019,
119 which contains the details of 36,890 recorded accidents. The variables included
120 in this study are:

- 121 • Time and date of the accident
- 122 • Road type (open or rural road)
- 123 • Severity of the accident defined by the worst recorded injury:
 - 124 – No injuries
 - 125 – Minor injuries

⁴<https://cas.nzta.govt.nz>

- 126 – Serious injuries
- 127 – Fatal injuries
- 128 • Intoxication – driving under the influence of either alcohol or drugs (DUI).

129 In addition, we included some social-economic indicators for New Zealand
 130 that are publicly available from the Ministry of Business, Innovation & Employ-
 131 ment and from Statistics New Zealand.

- 132 • Petrol prices
- 133 • Vehicle Kilometers Driven (VKT)
- 134 • Population

135 Due to the high variability and extended length of the Christmas & New
 136 Year vacation period we decided to exclude it from the analysis. While the
 137 long weekend holidays can be compared to other weekends, it would have been
 138 difficult to identify a period of time to which the Christmas & New Year period
 139 could have been compared.

140 3 Methods

141 To answer the research questions posed above, we have used Bayesian frame-
 142 work, which is often considered more flexible and intuitive than the classical
 143 methods. Bayesian inference combines the information available about the pa-
 144 rameters before the study, the prior, with the data-generating mechanism, the
 145 likelihood, to produce the posterior distribution for the parameters of interest.
 146 If no prior information is available, a non-informative prior can be used and
 147 the results will usually be numerically similar to those of the classical maxi-
 148 mum likelihood estimation. The posterior means and the 95% credible intervals
 149 (CIs), derived from the posterior distribution, usually provide the point and the
 150 uncertainty estimates respectively. Instead of the classical p-values, posterior
 151 probabilities that a specific statement is true given the data (sometimes called
 152 Bayesian P-values) and the modeling assumptions can be evaluated. For the
 153 comparison of weekend tolls, we have fitted a Poisson generalised linear model
 154 (GLM):

$$x_{y,wtype,i} \sim Poisson(\lambda_{y,wtype}),$$

155 where $x_{y,wtype,i}$ is the number of accidents recorded in year y on a week-
 156 end of type $wtype$. Note, that there will be only one observation per year
 157 for a non-BAU (Business As Usual) weekend. We assumed a non-informative
 158 $\Gamma(0.01, 0.01)$ prior for the intensity parameters $\lambda_{y,wtype}$. We then used
 159 simulations to evaluate the posterior probabilities that the toll for a specific
 160 weekend type was higher than that for BAU, $Pr(\lambda_{y,wtype} > \lambda_{y,BAU})$, for each
 161 year y . As well as for all the years: $Pr(\cap_y(\lambda_{y,wtype} > \lambda_{y,BAU}))$.

162 To model the annual proportion of accidents on urban roads, we have fitted
163 a binomial logistic regression with linear trend in years. The model was im-
164 plemented in WinBUGS Lunn et al. (2000) and the R2WinBUGS Sturtz et al.
165 (2005) was used to interface it with the R-software.

166 To investigate possible differences in factors contributing to accidents during
167 business-as-usual weekends and holiday weekends respectively, we have generally
168 followed the methodology of Anowar et al. (2013), and fitted a binary logistic
169 regression within the Bayesian framework.

170 In order to test, whether the distribution of crash severity frequencies has
171 changed over years, we have implemented a multinomial model (for the four
172 response categories: Fatal crash, Serious crash, Minor crash, and Non-injury
173 crash) with Dirichlet prior for the category-specific probabilities. Two models
174 were fitted (with and without the above probabilities depending on the year)
175 and compared using the Deviance Information Criterion (DIC) Spiegelhalter
176 et al. (2002) to check for the statistical effect of year. DICs are used for Bayesian
177 model comparison in a manner similar to the use of AICs in classical model com-
178 parison. Smaller DICs correspond to statistically better models, and a difference
179 of at least 3 is considered sufficient to infer difference. A similar comparison
180 was done for the models with and without the urban/rural division respectively,
181 to see whether the distribution of frequencies of various types of crashes was
182 different for the urban and the rural roads.

183 Finally, we have taken a look at the distribution of the recorded time of
184 accidents within a calendar week. Only business-as-usual days were included
185 (Easter, Labour Weekend, Queen’s Birthday, Christmas and New Year holidays
186 were excluded). We have postulated that the observed distribution of times of
187 accidents t_i consists of a mixture of normal components with unknown param-
188 eters, and, furthermore, that the number of components itself is unknown. Such
189 Bayesian cluster analysis is described in detail in Richardson and Green (1997),
190 and has been implemented in R via mixAK package Komárek and Komárková
191 (2014). We have applied it to all accidents and DUI accidents only for each year
192 to identify the likeliest number of normal components and their parameters.
193 Although the results of cluster analysis are often not directly interpretable, in
194 this case they might have corresponded to different traffic surges (such as morn-
195 ing commute to work, evening commute from work, early Saturday morning
196 commute from a party etc.)

197 4 Results

198 There are three societal factors that could play a role and that are at a level
199 of magnitude that they could influence accidents in a major way. This would
200 be the population fluctuation, the vehicle kilometers driven, and the fuel prices
201 in New Zealand. Best and Burke (2019) showed that the number of crashes on
202 New Zealand’s roads is correlated to the fuel prices. This could be based on
203 the fact that petrol prices and vehicle kilometer driven are correlated (Kennedy
204 and Wallis, 2007).

205 The trends in petrol prices, population, vehicle kilometers driven, the total
 206 number of crashes as well as the number of victims involved in them are shown
 207 in Figure 1. Note the high negative correlation between the petrol prices and
 208 the total number of crashes: -0.37 for the entire study period of 2000-2019,
 209 -0.70 for the last ten years.

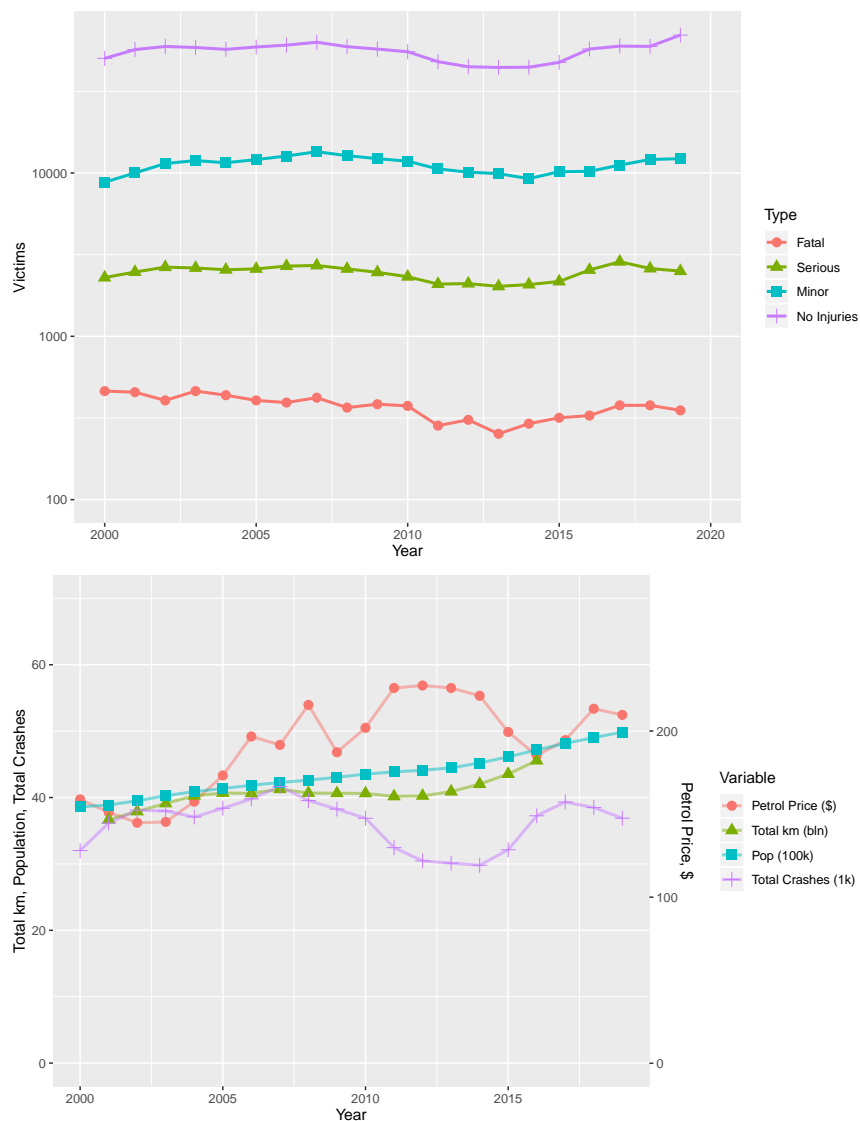

Figure 1: Trends in Petrol Prices, Total km driven, population, total number of crashes, and the number of victims involved. Note the logarithmic scale on the upper graph.

210 Our results confirm the work done by Best and Burke (2019) for the period
211 of 1989-2017, although their work focused on fatalities only. While any loss of
212 life is a traumatic event, the total social costs of accidents are much heavier
213 influenced by taking into account all casualties and property damages. Fatal
214 accidents are thankfully rare. Hence our correlation between the number of
215 crashes and the petrol prices seem to be more meaningful than the correlation
216 between fatal injuries and fuel prices as proposed by Best and Burke (2019).
217 Still, finding a similar but not identical correlation validates our model.

218 The observed dip in the number of crashes in the years 2013 to 2017 could
219 be related to a variety of factors. Walton et al. (2020) showed that the increase
220 in crashes after 2013 can be attributed to alcohol, learner license holders and
221 regional effects for Auckland.

222 4.1 Large Scale Temporal Trends

223 We compared holiday periods (Easter, Queen’s Birthday, Labour Day) to Business-
224 as-Usual (BAU) weekends. The later are defined as all non holiday weekends.
225 In addition, we compared the holiday periods to the weekends before and after
226 the holiday periods.

227 4.1.1 Number of accidents

228 The results of accident incidence modeling for the Easter Weekend are shown in
229 Figure 2. The posterior estimated mean ratio of Easter Weekend accidents to
230 Business-as-Usual Weekend ranged from 0.85% in 2006 to 1.10% in 2003. There
231 did not appear to be a consistent trend in the ratio. Overall, across the years,
232 the posterior estimated mean for the ratio was 0.96 with the 95% CI of 0.77 to
233 1.18.

234 2003 was the only year for which the posterior estimated probability of the
235 Easter Weekend number of fatal injuries being higher than BAU weekend num-
236 ber of fatal injuries was above 95% . We repeated the analysis comparing the
237 number of fatal injuries at Easter with the previous weekend with the same
238 result. However, the probability of the number of fatal injuries at Easter be-
239 ing higher than during the following weekend was above 95% for the years
240 2000,2003,2005,and 2014.

241 The results of accident incidence modeling for the Queen’s Birthday and
242 Labour Weekend are shown in Figure 3. The posterior estimated mean ratio
243 of Queen’s Birthday accident incidence to that for BAU ranged from 0.88% in
244 2003 to 1.15% in 2019. Across the years, the posterior estimated mean ratio
245 was 1.02 with the 95% CI 0.79 to 1.27.

246 The posterior estimated mean ratio of Labour Weekend number of accidents
247 to BAU number of accidents ranged from 0.73% in 2011 to 1.20% in 2006. Across
248 the years, the posterior estimated mean ratio was 0.93 with the 95% CI 0.69 to
249 1.23.

250 The posterior estimated probability of the Queen’s Birthday weekend num-
251 ber of accidents being higher than that of BAU number of accidents was above

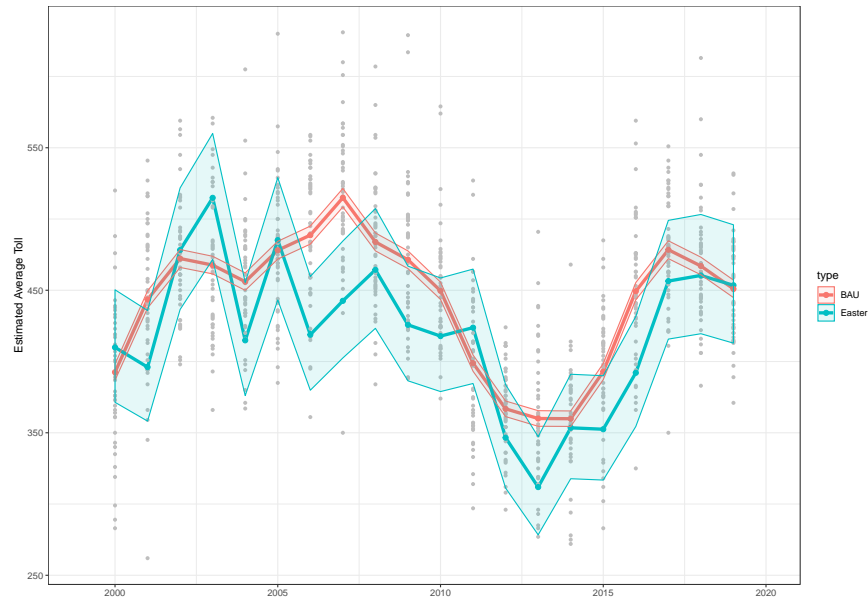

Figure 2: Easter Weekend accidents vs. Business-as-Usual Weekend accidents. The The graph shows the posterior means estimated by the model, and the 95% credible envelopes. The only year for which $P(\lambda_{Easter} > \lambda_{BAU} | data) > .95$ was the year 2003. The gray points are the observed weekend-specific accidents.

252 95% for the years 2000, 2001, 2008, 2009, and 2019 whereas the number of acci-
 253 dents for the Labour Weekend was only certainly higher than BAU for the year
 254 2006.

255 4.1.2 Road type

256 The proportion of accidents on urban roads has been steadily going down (see
 257 Figure 4). The odds of having an accident on the urban rather than open road
 258 have been found to decrease at an average of 1.40% per year with the 95% CI
 259 of 1.31% to 1.49%.

260 4.2 Crash Severity

261 The distribution of crash severity for the open and urban roads is shown in
 262 Table 1, and the temporal dynamics is illustrated in Figures 5 and 6. Our
 263 modeling showed no substantial difference in distribution of crash severity over
 264 years ($\delta DIC = 342981.5$), but substantial difference in distribution of crash
 265 severity for the open vs. urban roads ($\delta DIC = -14158.54$). The proportion of
 266 non-injury crashes on urban roads is much higher compared to open roads and
 267 the proportion of fatal and serious crashes much lower.

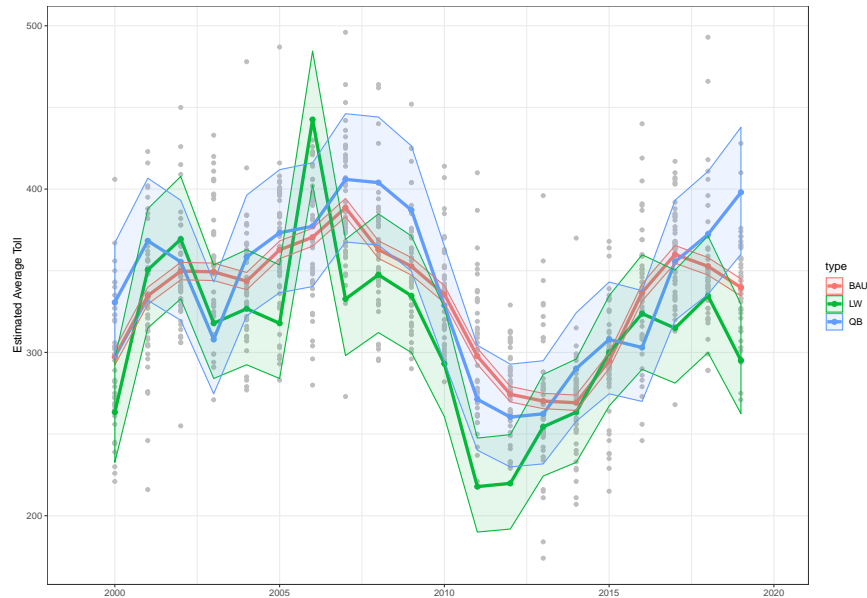

Figure 3: Labour Weekend and Queen’s Birthday Weekend Toll vs. Business-as-Usual Weekend number of accidents. The The graph shows the posterior means estimated by the model, and the 95% credible envelopes. The gray points are the observed weekend-specific number of fatal injuries.

	Fatal Crash	Minor Crash	Non-Injury Crash	Serious Crash
Open	4774 (2.1%)	61015 (26.2%)	147180 (63.3%)	19512 (8.4%)
Urban	1799 (0.4%)	101781 (20.8%)	366074 (74.7%)	20597 (4.2%)
Total	6573 (0.9%)	162796 (22.5%)	513254 (71.0%)	40109 (5.5%)

Table 1: Crash Severity for Open and Rural Roads, 2000-2019.

268 We fitted a logistic generalised linear model to see whether certain types
 269 of crashes were likelier to happen on a holiday weekend (defined, in this case,
 270 as Saturday or Sunday occurring during either of the following: Christmas,
 271 New Year, Queen’s Birthday, Labour Weekend or Easter) as compared to the
 272 non-special Saturday or Sunday.

273 The resulting posterior mean estimated odds ratios, accompanied by 95%
 274 credible intervals and Bayesian P-values, i.e., the posterior probabilities of the
 275 of the odds ratios being above 1, are shown in Table 2. Note, that if the 95%
 276 CI includes 1.0, there is no evidence that crashes of a particular type are more
 277 relatively prevalent during the holiday periods than the non-holiday ones.

278 The results show that the crashes on urban roads and crashes at night time
 279 (defined as 12am-6am) were significantly less prevalent on the holiday peri-
 280 ods. On the other hand, crashes while driving under the influence (DUI) were,

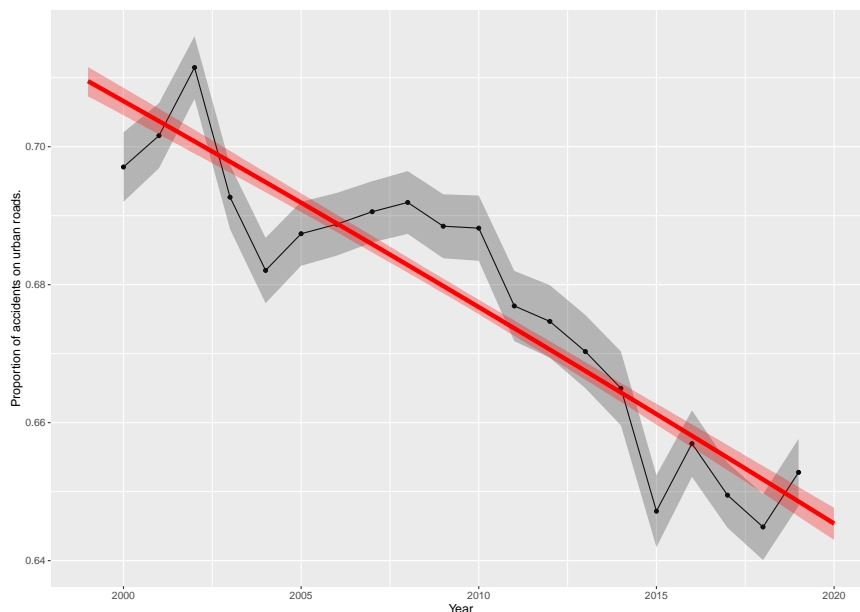

Figure 4: Proportion of accidents on urban roads out of the total. The gray ribbon corresponds to the year-specific estimates, while the red line illustrates the linear fit.

Factor	post. mean OR	95% CI	$Pr(OR > 1.0)$
Severity (Ref: No Unjury)			
Minor Crash	0.9817	(0.9427, 1.0262)	0.196
Serious Crash	0.9806	(0.9253, 1.0413)	0.235
Fatal Crash	1.1244	(0.9744, 1.3014)	0.938
Zone (Ref: Open Road)			
Urban Road	0.8551	(0.8244, 0.8862)	< 0.001
Time (Ref: 6am - 12pm)			
Night, 12am-6am	0.8181	(0.7721, 0.8586)	< 0.001
Afternoon, 12pm - 6pm	0.9583	(0.9157, 1.0035)	0.028
Late Evening, 6pm - 12am	1.0079	(0.9604, 1.0532)	0.635
DUI (Ref: No)			
Yes	1.0512	(1.0092, 1.0985)	0.995

Table 2: Comparison of crash factors during holidays and BAU weekends. Results of a Bayesian logistic regression model: posterior estimated odds ratios (ORs), 95% credible intervals and the posterior probabilities of the odds being greater than 1.

281 perhaps unsurprisingly, more prevalent during the holiday periods. The DUI
 282 accidents were defined as those where either alcohol or drugs were recorded as
 283 factors in the CAS data.

284 **4.3 Small Scale Temporal Trends: Weekly Patterns.**

285 We investigated the weekly dynamics in all and DUI accidents. An example for
 286 half-hourly counts over week for the year 2015 are shown in Figure 8 (for all
 287 accidents) and Figure 7 (for DUI).

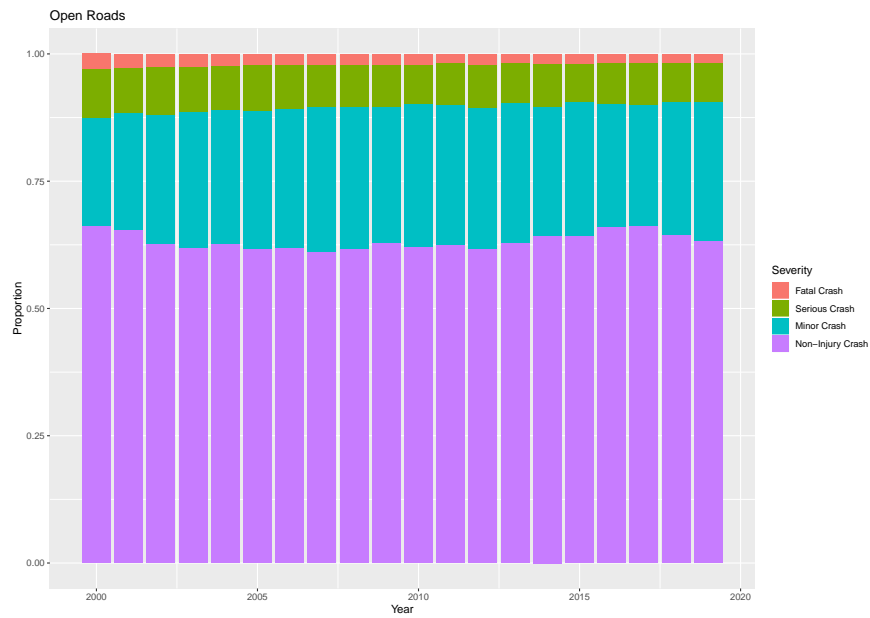

Figure 5: Annual Crash Severity Counts on the Open roads.

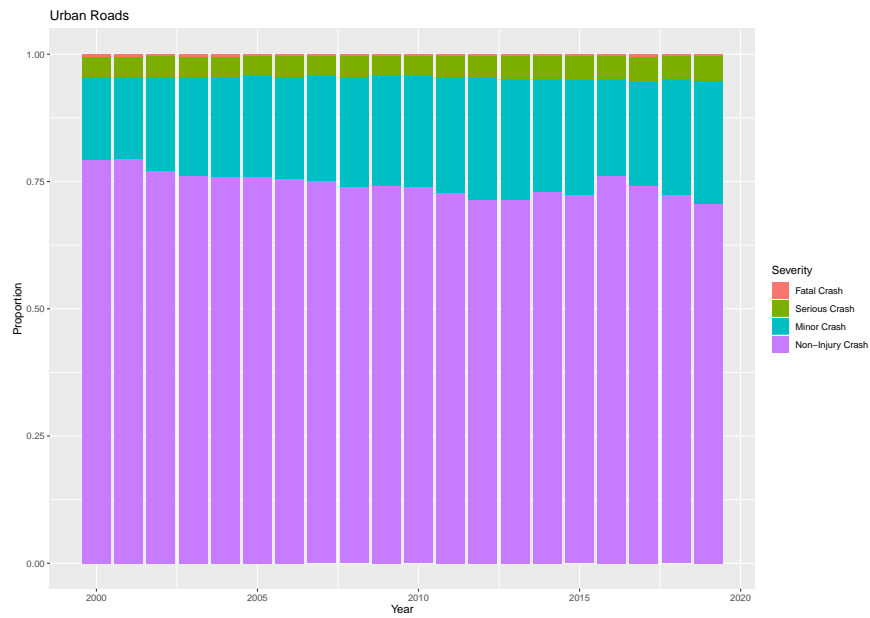

Figure 6: Annual Crash Severity Counts on the Urban roads.

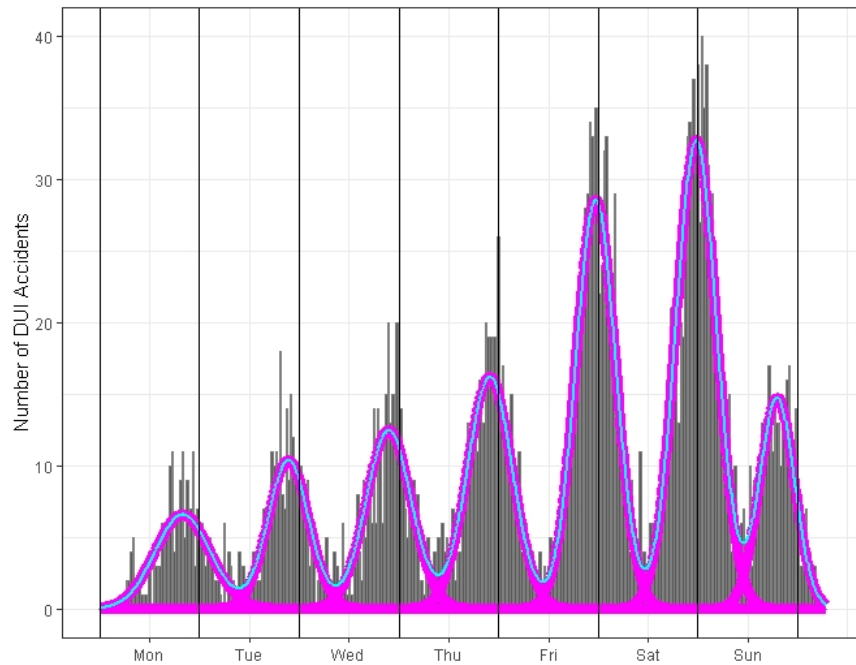

Figure 7: Weekly dynamics in DUI accidents, 2015. The gray histogram reflects the recorded counts. The magenta curves corresponds to individual normal components, whereas the blue curve is the resulting marginal distribution.

288 For consistency reasons, only non-holiday days were included. The gray
 289 histogram reflects the recorded counts. The magenta curves corresponds to
 290 individual normal components, whereas the blue curve is the resulting marginal
 291 distribution. The DUI counts exhibited seven clear peaks, corresponding to
 292 the nights. The probability mass associated with each peak was higher for the
 293 Friday and Saturday nights.

294 The dynamics for all the accidents was less clear-cut as is demonstrated
 295 for some spurious small individual components. However the fitted marginal
 296 distribution has two clear peaks for every weekday and one for Saturday and
 297 Sunday each.

298 The fitted marginal distributions for the weekly dynamics over the study
 299 period 2000-2019 is shown in Figures 10 for all accidents and 9 for the DUI
 300 accidents respectively. They show that the pattern appears to have remained
 301 the same for all accidents, but has shifted over years for the DUI.

302 The posterior probability distribution for the possible number of components
 303 is shown in Figures 9 for all and 10 for DUI accidents respectively. The most
 304 likely number of components for the DUI accidents was 7, although it has shifted
 305 to more in 2017-2019. The most likely number of components for all accidents

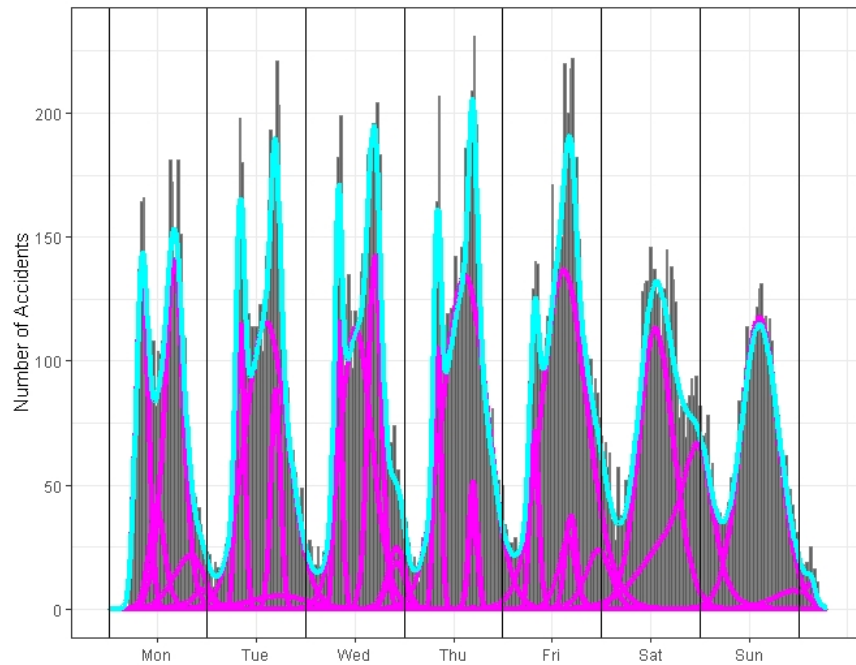

Figure 8: Weekly dynamics in all accidents, 2015. The gray histogram reflects the recorded counts. The magenta curves corresponds to individual normal components, whereas the blue curve is the resulting marginal distribution.

306 was 19, although there was a lot of variability.

307 5 Conclusion

308 The number of accidents during the holiday weekends was not consistently
 309 higher than that of BAU weekends, nor that of weekends before and after.
 310 This indicates that probability to die on the road during holiday periods was
 311 similar to that of other weekends in New Zealand. Further analysis indicates
 312 that there was no difference in the severity of the crashes either. The frequency
 313 of crashes on urban roads and during the night time were even decreased dur-
 314 ing the holiday periods. The only factor of concern is the increased number of
 315 accidents that involve intoxication during the holiday periods.

316 The total number of crashes on urban roads will naturally be higher than
 317 those on open roads due to the different population density. Still, the the
 318 proportion of accidents that occur on urban roads have decreased over time
 319 with an average of 1.4% per year. This is counter intuitive, since there is a
 320 general urbanisation trend. It is assumed that the number of people living

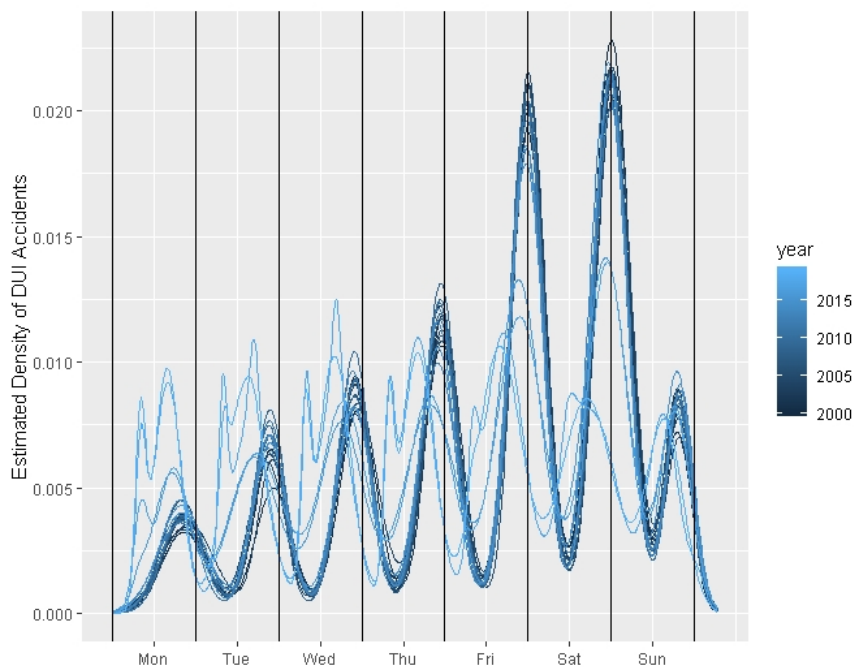

Figure 9: Fitted marginal distributions for the weekly dynamics in DUI accidents, 2000-2019.

321 in urban areas is slowly but steadily increasing (Grimes et al., 2016). Hence
 322 the proportion of accidents should follow this pattern. We are uncertain on
 323 why we observed the opposite trend. One possible explanation could be that
 324 people living in urban areas travel more on open roads. This could be caused
 325 by Auckland’s housing market, which might force many to commute to work
 326 using the open road from the satellite cities surrounding Auckland.

327 Accidents on the open road tend to be substantially more serious compared
 328 to those on urban roads. This could be explained by the general corresponding
 329 speed limits, which are 50 km/h on urban roads and 100 km/h on open roads.
 330 Travelling at higher speeds almost automatically increase the accident severity
 331 due to the increase in kinetic energy and the decrease in available reaction times
 332 of the drivers.

333 When we have a more fine grained look at the distribution of accidents
 334 across weekdays for the exemplary year 2015 we notice that accidents that
 335 involve intoxication clearly increases during Friday and Saturday nights. This
 336 pattern is to be expected due to the recreational behaviour patterns of New
 337 Zealanders. When expanding the analysis to all accidents, we notice a clear
 338 commuter peak at around 9am and 5pm during weekdays which confirms earlier
 339 work by Kingham et al. (2011). The number of accidents during the weekends

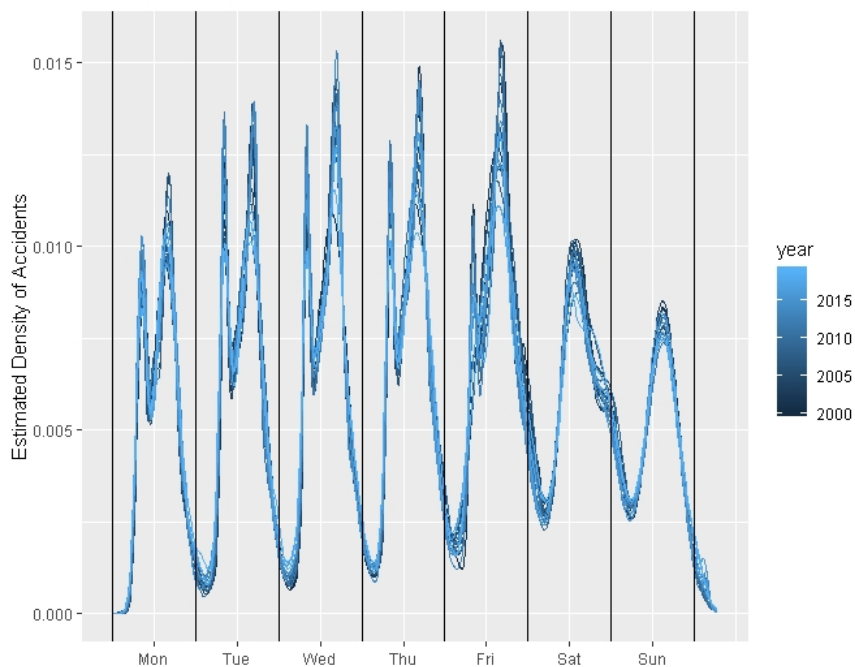

Figure 10: Fitted marginal distributions for the weekly dynamics in all accidents, 2000-2019.

340 is usually lower than that during the week, although the accidents are shifted
 341 to the later hours of the day. This is likely a direct result of the absence of
 342 commuting traffic. Still, a small extra peak is visible during Saturday night even
 343 when considering all accidents, which is likely due to recreational activities.

344 When considering all the years we notice that accidents that involve driving
 345 under the influence has in recent years become less focused on the weekends.
 346 More accidents involving an intoxicated driver are now taking places even during
 347 Mondays to Wednesday and they have shifted slightly from night time events
 348 due to a pattern that more resembles all accidents. This could hint at that more
 349 intoxicated driving is taking place during normal working hours. We have no
 350 information available as to what exact drug has been involved.

351 6 Limitations and future work

352 The CAS data is an extremely rich data source and number of potential rela-
 353 tionships between the factors recorded are very high. A complete analysis for
 354 all the factors is not only very labour intensive, but also impractical for just one
 355 research publication. Books could be published about the possible statistical

356 analyses. We had no choice but to focus on a few research questions that we
357 considered important while acknowledging that the data and analysis presented
358 is certainly incomplete.

359 We have no access to vehicle kilometer driven on a per day basis and hence
360 we could not calculate traffic densities for the holiday periods or BAU weekends.
361 We can therefore only establish a relationship between the accidents and amount
362 of road traffic on an annual basis.

363 It could be argued that due to the holidays less people commute and hence
364 the traffic and the associated accidents might have decreased. One could also ar-
365 gue that many New Zealanders take the opportunity of having a holiday to travel
366 around the country and thereby increase the potential for accidents. These two
367 factors could even cancel each other out. The road safety during the holiday
368 periods could also be influenced by the safe roads publicity campaigns. Again,
369 we can only speculate about the relationships between these factors.

370 This study did not consider the changes to the transportation law, such as
371 the lowering of the legal limit of alcohol for driving in 2014. We can also not
372 take into account any changes in the policing policies, such as potentially more
373 routine intoxication checks or the availability of easy to use on the spot test
374 for a variety of drugs. We can therefore not exclude the possibility that the
375 temporal changes observed in Figure 9 are based on these changes.

376 For future work we would like to consider the influence of the weather on
377 accidents. Many open roads in New Zealand are highly exposed to the harsh
378 weather conditions and some holiday periods might be more affected by them
379 than others. Furthermore, it would be interesting to investigate the relationship
380 between risk taking behaviour, such as speeding and intoxication, and the age
381 of the drivers. Along the same lines it would be worthwhile to consider the
382 relationship between the intoxication and the crash severity.
